One of the key components of CLOS in inheritance. The CLOS Browser provides functionality for displaying this structure and for extending it. It also provides functions for displaying and changing the class definitions and method definitions which make up a system written in CLOS.

Creating a Browser

A browser can be created in two ways:

- Via a menu option from the Background Menu
- By calling the function CLOS-BROWSER:BROWSE-CLASS on a class

Creating a browser via the Background Menu

When the CLOS-BROWSER module is loaded, an entry is added to the Background Menu, as shown below:

```
BrowseClass
  Idle
  SaveVM
  Snup
  Hardcopy
  EXEC
  PSW
```

Selecting the menu item BrowseClass brings up a window, with a prompt for the name of the class to use as the root of the browser as shown below.

```
Class> ^

CLOS-browser
```

Type in the name of the class you wish to browse at the flashing cursor, and the class graph will be drawn in the window.
Creating a browser programmatically

Browsers can also be created by calling the function BROWSE-CLASS:

\[
\text{(BROWSE-CLASS &OPTIONAL CLASS-NAME-OR-LIST &KEY :WINDOW-OR-TITLE :GOOD-CLASSES :POSITION)} \]

This function brings up a browser on the class named or the list of classes named. If a window is supplied for the :WINDOW-OR-TITLE argument, then the browser is created in that window, else an appropriately sized window is created. The window is positioned at the :POSITION argument or, if not supplied, then the position is set via the mouse. If a text string is supplied for the :WINDOW-OR-TITLE argument, then that string is used for the window title, else the string “CLOS-browse” is used. If :GOOD-CLASSES is supplied, then only those classes in the list are displayed.

Using the Class browser

Instances of CLOS-BROWSER are operated on through a mouse-based interface.

Buttoning on the browser will cause one of the following menus to be popped up:

- One menu appears when the left or middle button is pressed while the mouse is in the title bar. This menu has operations that apply to the browser itself.
- The other menu appears when the middle button is pressed when the mouse is on one of the nodes in the browser.

If the left button is pressed when the mouse is on a node, that node is boxed. This marks the node for some operations.

Options in the title bar menu

The following menu appears when you left- or middle-button in the title bar.

Recompute and it’s suboptions

Selecting the Recompute option and dragging the mouse to the right causes the following submenu to appear:
Most of these items change the appearance of the browser, not the contents.

Recompute  Recomputes the browser from the starting objects. It does not recompute the labels for each node if those labels are cached in the Label-Cache slot of the browser.

Recompute Labels  Recompute the browser from the starting objects, including the labels.

Recompute inPlace  Recompute the browser without affecting the scrolled location of the lattice within the window.

Clear caches  Clear the caches of the nodes.

Browser looks and it’s suboptions

Selecting the Browser looks menu item and sliding to the right causes the following submenu to appear:

- Shape to hold: Make the window for the browser just large enough to contain the browser.
- Change font size: Causes a menu of alternative font sizes to pop up. Selecting one of these causes the browser to be redrawn with the nodes at that font size.
- Change format: Causes the following menu to appear:
  - Horizontal/Lattice: Lays out the grapher as an horizontal lattice.
  - Vertical/Lattice: Lays out the grapher as a vertical lattice.
  - Horizontal/Tree: Lays out the grapher as a horizontal tree.
  - Vertical/Tree: Lays out the grapher as a vertical tree.

Options in the Middle-button menu
The following menu appears when you middle-button over a node in the graph:

<table>
<thead>
<tr>
<th>Edit</th>
<th>Edit</th>
</tr>
</thead>
<tbody>
<tr>
<td>Add method</td>
<td>Edit</td>
</tr>
<tr>
<td>Browse</td>
<td>Edit</td>
</tr>
<tr>
<td>Print</td>
<td>Inspect</td>
</tr>
<tr>
<td>Specialize</td>
<td>slots</td>
</tr>
<tr>
<td>slots</td>
<td>methods</td>
</tr>
</tbody>
</table>

**Edit and it’s suboptions**

Selecting *Edit* causes an editor on the class definition to be brought up. Sliding the mouse to the right causes the following menu to appear:

- **Edit**: Edits the class named by the node
- **Inspect**: Inspects the class object named by the node.

**Add Method**

Selecting the *Add Method* option brings up an editor window with a template for a method to be added to that class. When the editor is done the method is installed for that class and the menu updated.

**Browse**

Selecting the *Browse* option causes a browser to be created starting with that class as the root.

**Print and it’s suboptions**

Selecting *Print* prints out the class definition. Sliding the mouse to the right causes the following menu to appear:
Print

Print's the class definition

Describe

Describes the class, listing its metaclass, its superclass, its subclasses, its CPL, and the number of methods specialized to it.

Documentation

Print's the documentation string for the class

**Specialize**

Selecting the Specialize option brings up an editor window with a template for a subclass to be added to that class. When the editor is done the class is installed and the browser updated.

**Slots**

Selecting the Slots option is the same as selecting the Edit option, it brings up an editor on the class definition.

**Methods**

The Methods option allows you to edit one of the methods defined for that class. Selecting it and sliding to the right brings up the following sub-menu:

Local

Bring up a menu of the local methods, i.e., methods directly defined for this class

Inherited

Bring up a menu of the methods this class inherits from its superclasses.

All

Bring up a menu of all the methods defined for this class, both local and inherited.
Selecting an item with the left button from the resulting menu brings up an editor on that method. If there are multiple methods that apply, a gray triangle appears in the right edge of the menu next to that item. Sliding to the right brings up a menu of method specializers to select the appropriate method.

Atom Hash Table | 1/2 seg | 24,0 | 1 seg | 7,0 |  |  
Pname Chars *** | 8 seg | 30,0 | 6 seg | 72,0 |  |  

* Collision table occupies 1 segment, all preallocated, for no particularly good reason. It wants to be big, because once it fills up, you have to disable gc. I have seen the table get as large as a quarter segment. Current algorithms prevent it from being larger than one segment, but it would be easy to make it 2 segments long.

** GC Overflow table is actually just a few words. Current microcode relies on it being in the same segment as GC Hash, but this is not very important.

*** Pname char space is currently far too large for 32K litatoms; it might be about right for 64K, but we plan to dispose of it when pnames are hunked (taken as allocblocks), leaving just enough to get thru MAKEINIT.

**** Want to allow a little extra space for DTD in case we expand number of datatypes. This layout allows us to expand from 256 datatypes (8 bits) to 1536 datatypes (11 bits) before bumping into the LockedPageTable.

Further notes, June 1986 (post-Koto):

Pname char space now gone—all pnames are allocated from hunks.

Atom Hash Table address range used also for cml Character type (an immediate). With packages, atom hash table will go away eventually.
problem type: Performance
Subject: Want faster GETPROP

From: VanLehn.PA
Subject: HELPFLG bug
To: Lispbug^PA
cc: VanLehn
Reply-To: VanLehn

LISPX seems to be rebinding HELPFLG so that SETQ’s at top level have no effect. I can’t force errors to break by setting it to BREAK!, which makes debugging under errorsets damn near impossible.
In the macro for CONSTANT, I propose that the evaluation of the form be done under ERRORSET protection, with an error causing the thing to be treated as a DEFERRCONSTANT, just as is done when the value fails to pass the CONSTANTOK test.

neil

Subject: SEPRCASE/GETBRK bug
To: LispCore
If a character X is defined as a macro in readtable Y, then (SYNTAXP X 'BREAK Y) is NIL, but X is not in (GETBRK Y). I don’t know whether this is a bug or a feature, but in any case it means that SEPRCASE treats such a char as an alphabetic, and FINDCALLERS and friends will miss when the target atom is preceded by the macro character.

The manual on page 18.21 states "Whenever bcompl or brecompile encounter a block declaration they rebind retfns, specvars ... to their top level value". This is NOT true as far as SPECVARS are concerned. The reason is the function LOCALVARS in COMP seeing that LOCALVARS are T sets SPECVARS to SYSSPECVARS without checking what the current value of SPECVARS is. This bug has been around since Sept 1976! These two functions with the cons show off the bug:

(FOO (LAMBDA NIL (PROG (X) (FUM)
(FUM (LAMBDA NIL (NILL X))
(SETQ BUGCOMS '((FNS FOO FUM)
(specvars X)
(BLOCK (FOOBLOCK FOO FUM (ENTRIES FOO)

I noticed that DECLARE: don’t get compiled away (the function DECLARE: always get called), but DECLARE does get compiled away. This problem has been around awhile. Also that the example on the end of page 23.16:

(FOR X IN Y (DECLARE: (LOCALVARS X)) -- )

doesn’t work.

I defined a skeleton for the \TAKEINTERRUPT macro on AINTERRUPT.
It has dummy calls to 2 primitives, one for checking whether \INTERRUPTABLE is T everywhere above its lowest binding (which is predictably NIL by the client of \TAKEINTERRUPT). I can simulate this with a stack search using a constant stack pointer, but this probably should be done at a lower level.

The other is a function for calling INTERRUPTED (I called it \CALLINTERRUPT). I don’t think this can be the same as \CAUSEINTERRUPT. Maybe it is sufficient simply to branch to the keyboard context here.

I noticed that there are 2 global variables used mark that an interrupt is pending, \InterruptChar (used in the keyboard handler) and \INTCHAR, used in INTERRUPTED. \CAUSEINTERRUPT clears \InterruptChar and sets \INTCHAR. I don’t quite understand this—is it temporary cause we haven’t committed to WIND?

Subject: Bug in BCOMPL/BRECOPILE
To: MASINTER

I noticed that BRECOMPILE and BCOMPL setup LOCALVARS slightly differently.

BCOMPL initializes it to SYSLOCALVARS. BRECOMPILE does that only if LOCALVARS is T. If it is not T, it sets it to (UNION SYSLOCALVARS LOCALVARS).

Do you understand this? Which is correct, or are both correct?

If the UNION makes sense, should it also happen for SPECVARS?

Date: 23 Jun 1982 1332-EDT
From: DISRAEL at BBNG
To: masinter at PARC-MAXC

(1) YY2 is the Interlisp version of the standard fixed point
(recursion) operator in the lambda calculus. As written in lambda calculus form, it looks like this: LAMBDA P. (LAMBDA X. P (X X)) (LAMBDA X. P (X X)). You apply it to a functional - a function that returns a function as value - and then apply the result to, say a number. So if you give YY2 the factorial functional - everyone’s favorite example: LAMBDA FUN. (LAMBDA N. IF N = 0, 1, ELSE TIMES N (FUN N-1)) - you get something which when applied to 3 yields 6. It does this bit of magic by unwinding an internal lambda expression 4 times (in this case). So it simulates recursion by as much iteration as you need. Note: the definition of FACTFUN is not syntactically recursive, and if one defines FACT as (YY2 ‘FACTFUN), then FACT is also not recursively defined.

One can actually think of YY2 (never mind why it’s called that and not Y) as the limit (the least fixed point) of an infinite series, starting with Y-0 (which see) and getting on by applying Yn to G to get Yn+1. (Moreover Yn = (G ‘Yn) - so every Y is a fixed point of G).

Z is another, slightly unstandard recursion operator - written in lambda calculus form as follows: LAMBDA P. ((LAMBDA X. F (LAMBDA Z. (X X) Z)) (LAMBDA X. F (LAMBDA Z. (X X) Z)). Again Z of FACTFUN is a non-recursively defined FACTORIAL applicable to numbers.

(3) As for COMBOY - it’s the Y-type recursion operator written out purely in terms of the two (so-called) primitive combinators. K (LAMBDA X. (LAMBDA Y. X)) and S (LAMBDA X. (LAMBDA Y. (LAMBDA Z. ((X Z) (Y Z))))). But there is a bug in the code: as it stands, it is not applicable to numbers - only to functions; e.g. not to 3 but to LAMBDA.() 3 - and of course TIMES, SUB1, etc. barf at these.

(4) Speaking of combinators; BB is functional composition (in disguise), SKIAPPLY is function application and SKIAPPLY2 is "APPLY" - again in disguise. It takes a function and an arg as arguments; SKIAPPLY takes a function and returns a function which is the argument function to SKIAPPLY primed for application. (Baroque, eh??). WW takes a function and produces a function which when applied to an argument, produces a version of a two-placed function whose two arguments are identified. (So SQUARE is WW applied to TIMES.)

(5) F and J are weird functionals of purely theoretical interest (unlike the others which are, as you’ll surely allow, of immense practical import). J is a function provably equal to I (LAMBDA X. X); but which is, unlike I, provably non-normalizable. I, moreover, is provably the only fixed point of F. (I think J, like COMBOY, may require functions as arguments all the way down.)

To TEST:

(APPLY* (YY2 ‘FACTFUN) 3) will do nicely to compute (factorial 3). (The same goes for (APPLY* (Z ‘FACTFUN) 3).) You can go (APPLY* (FACTFUN ‘FACTORIAL) 3) - where FACTORIAL is the regular recursively defined factorial function. And, since YY2 (or Z) are fixed point operators (so F = YF) you can go (APPLY* (APPLY* ‘FACTFUN (YY2 ‘FACTFUN)) 3). ETC...

The bad news

My view is that Interlisp is sinking of its own weight, and the move onto a personal computer has shown the hulk in alarming vividness. This section presents a brief justification of this view and offers possibilities for remedies. The problem can be fixed, but it may be costly.

The problem, as I see it, is that Interlisp has never had a clean internal structure of the system (as separate from the language): features and packages have accreted, wired into the existing maze to create a tighter maze. It’s now so bad that a good programmer who encounters an Interlisp system is at a loss for what to do for a good long time. Few if any of the “interfaces” in Interlisp correspond to things he recognizes from other environments. He has to seek out facilities one by one; his intuition for where to look is often wrong; and he remains worried about deep interactions among various parts of the system.

This problem has been made worse by the move onto a personal computer. I think to a great extent, new facilities are added to Interlisp using the same rather low standards of interface definition that have characterized Interlisp so far. For example, while I think the facilities provided by the Interlisp-D stuff for graphics are mostly OK, the interfaces can be substantially improved.

I feel the "system" part of Interlisp needs a thorough overhaul. I favor the "open system" approach in which a very few low-level primitives are built in, and the rest is done with packages that can be separated and that have well-defined interfaces.

I realize that an undertaking such as this is a big one. However, I believe that a great deal of the detailed functionality of Interlisp can be retained (even much of the code can be retained), but the interfaces need to be redesigned in light of the tremendous evolution of the system. It’s remarkable that they’ve remained useful as long as they have, but they need overhaul. I see two hopeful signs:

1. To the extent possible, new work should be done in the form of LISPUSERS packages. I’m delighted, for example, to see the new editor done in this way. (But I suspect the interface between it and the rest of the system could be improved if the system were improved.) I think it’s important that some (perhaps all) of these packages be distributed in source-file form so that users can actually understand what they do.

2. The new Common Lisp effort is an opportunity to redesign
many of these functions. Perhaps a long-range plan might be
to put Common Lisp up on the Dolphin. Should the Xerox group
be contributing to the design of Common Lisp, especially in
those areas where it has the most expertise (e.g., user I/O)?

Another approach is to invest some effort in restructuring
Interlisp. I think it might be worth a few days' effort to estimate
the difficulty of this problem and the improvements that could be
reasonably expected.

(long paragraph)

To summarize, I'd like a complete, consistent "graphics
package" at the low level. Some of the pieces are there
(bitblt, line, etc.), but I don't see the structure. It
appears to be a complex set of stuff with complex
inter-relations. There is no clear description of what a
bitmap is, or what a display stream is, or what a window is.
This needs to be cleaned up.

More to the present point, however, is that I find the
manual almost completely lacking is discussion of concepts.
To pick an example from the current manual, consider the
file package. What is a "file" from the point of view of
Lisp? What is its purpose? What does it contain? What is the
distinction between what is remembered inside the Lisp
virtual memory and what is retained on the disk? And so on
and on . . . While the file package might have once started
out so simple that none of these questions arose, it's long
past that point now.

The new graphics stuff definitely needs a good deal such
concept documentation. In the manual, old and new, there's
too much emphasis on functions and not enough on structure
and concepts.

The best manual would result from a system restructuring
The Interlisp language should form a distinct part of the
manual -- some sections
of the current manual are salvageable in this respect. If
the interface between the language and the packages were
cleaned up, this section would describe the interface. I,
for one, would benefit enormously from a self-contained
section that describes the language without reference to any
of the system stuff.

Date: 8 July 1982 8:25 am PDT (Thursday)
From: VanLehn.PA
Subject: main data space overflow
....
I've tried to find the storage leaks using COUNTDOWN, MAPATOMS and
so forth. So far, the only circularities I've come across are on
LISPXHISTORY. I need better leak-finding tools. One would be to do the mark
& sweep part of garbage collection, including the freelist as "accessible"
during the mark. The list that the sweep delivers is therefore all the cons
cells that got leaked. By looking through the ones with atomic cars and cdrs,
I could probably figure out from the pnames where the leaks came from.

4. Of course, having found all the lost storage, it could be put back on
the freelist, saving me a reload (but probably still taking 20 minutes).
Since there is plenty of array space around, the mark & sweep could be written
simply, using its own array to hold the mark bits. I don’t see any reason to
do the "copy" part of a "stop & copy" since swapping doesn’t seem to be a
problem on the Dorado (according to temporal intuition and control T).

5. If the mark’s bit array is the screen bitmap, one could probably learn
alot about the storage use and maybe the chronology of the leaks by seeing not
only where in vmem the leaks are, but watching the mark propagate out from
specific atoms. A quick calculation has it that marking the current Mds,
assuming it’s mostly cons cells (95% in my program), would take a 900 by 900
bitmap.

I’d be willing to help code such a tool, or any other.

Any tools or diagnostic ideas would be welcomed with extreme enthusiasm.

Date: 8 JUL 1982 1155-PDT
From: ROACH.PA
Subject: DEFINEQ and MACROs
To: LISPSUPPORT
cc: ROACH

Dear Interlisp Support,

I think MACROs, DEFINEQ, and the Interlisp compiler interact
incorrectly. I would like to define macros such as DEFFEXPR, DEFFEXPR,
etc. that can appear in files and will expand out into DEFINEQ forms
which go on to be compiled like other DEFINEQ forms. I’ve been told
by Ronald Kaplan that this won’t work, and in fact, it doesn’t. What
is Interlisp’s problem? I might point out that Maclisp does allow you
to do this sort of thing. This is a pretty serious deficiency on
Interlisp’s part.

Secondly, instead of compiling expressions in the order in which
they occur, the Interlisp compiler gathers functions definitions into a
separate group from all other expressions. This is also a bug. (Again
Maclisp does the right thing.) Compiled forms ought to load in the
same order in which the uncompiled forms loaded.

I am hopeful that action will be taken on these problems.

Date: 27 JUL 1982 0935-PDT
From: KAPLAN.PA

. . .

We probably also ought to implement a device info interface that could,
for example, tell how many pages are left on the disk, in an ifs directory,
or in the ifs as a whole.

We need to have an inbound CHAT server so you can CHAT to a machine from a remote terminal over the PUP and NS Ethernet.

We need to handle UNIX filenames better
We need device synonyms and pseudo-devices
We need to be able to delete 1100 {DSK} files without building the whole map

We need to document the facilities for doing Binary i/o for bitmaps, integers, floats. AOUT/AIN.

Compiler: [14 NOV 1981 1815-PST] (FUNCTION (LAMBDA --)) expression used as a value to be stored into a record slot. The compiler did produce a suitable subfunction, but then compiled as the value of the (FUNCTION --) expression the free varaible NEWVALUE.

We need to fix Sandbarring
Storage management:
We need to fix the GC so that it collects items which are only held as keys of hash-tables. (CLISPARRAY in particular).

We need unwindprotect

many system functions have Names which can conflicts with user fns

We need to unify the handling of meta, blank keys

we need to clean up GLOBALVARS situation

We need more diagnostics and system tests

We need to fix it so that expanding macros doesn’t take so long

* FUNARG doesn’t work
* MASTERSCOPE:
  WHO USES FILE FREE causes funny error messages

Date: 16 SEP 1982 1802-PDT
From: BURTON.PA
Subject: compiler bug

The bind merge optimization gets carried away with the function DSPDESTINATION on <LISPCORE>WIND>LLDISPLAY and binds the variable \INTERRUPTABLE with the variable DS. The effect is that the \DTEST is called in a context that is uninterruptable leading to a call to RAID when DSPDESTINATION is given a bad argument such as (DSPDESTINATION 123 (DSPCREATE)).

Subject: Re: Problem with open leaf files -- and patch
In-reply-to: BOBROW’s message of 21 SEP 1982 1517-PDT
To: LISPSUPPORT
cc: Bobrow, Stefik

Danny’s patch to FINDOPENFILE seems to get around the immediate problem, but some more permanent fixes are needed. Ron and I talked about these problems for a while; I thought I would send out some notes on our conversation and some additional thoughts.

There are currently three separate problem areas in the current system:

a) READ/PRINT given file names which are not fully qualified scans the directory every time, which is TERRIBLY SLOW
b) for LEAF files, the file CANNOT BE FOUND by INFFILEP/OUTFILEP/FINDFILE if it is already open
c) There are a number of inconsistencies having to do with the use of
DIRECTORIES and the error mechanism to implement search paths.

Proposals:
a) files which are presented to READ/PRINT (i.e., in a context where an OPEN file is required) will ONLY scan against the set of files which are open with appropriate access.

This is a change from Interlisp-10 semantics, where if you do an INFILE(FOO), and then create a NEW VERSION of FOO, and then do READ(FOO), you will get a FILE NOT OPEN error.

b) we should implement the notion of a "search path" device, e.g. {LISPUSERS} and {SOURCES}. The system will support assigning search paths to a device (new function), so that one can say {SOURCES} = {PHYLUM}<LISPCORE>WIND>, {PHYLUM}<LISPCORE>SOURCES>

Doing an INFILEP on {SOURCES}xxxx will return a full filename of {PHYLUM}<LISPCORE>WIND>xxxx, i.e., the name returned will be fully qualified. OUTFILE on {SOURCES} will write on the FIRST directory on the search path.

The general idea here is to take what is currently done via the error mechanism and DIRECTORIES and FINDFILE and instead build it in in at a lower level. This will allow some more rational implementations of the facilities.

It will also make more logical the link between the "connected" directory and the search path; that is, one can either connect to {SOURCES} or to {WIND} or to {LISPUSERS}. It will remove the distinction between FINDFILE and INFILEP in the non-spelling-correction case.

Finally, all of this is relatively easily implemented in Interlisp-10! Interlisp-10 already supports a (undocumented) feature where if you PUTPROP(LISPUSERS DIRECTORIES (<LISPUSERS> <LISP>)) and attempt to FINDFILE(LISPUSERS:filename), it will in fact search those directories.

renamefile on {DSK} doesn't work. If you have a file A 100 pages long and a file B 200 pages long and (RENAMEFILE A B), you end up with a file B 200 pages long, its first 100 being the old A and the last 200 being garbage from the old B. You have to
(DEFILE B) before the renamefile. This despite what the manual says.

From: JONL.PA
Subject: PUNTing a broken compilation

To: lispbug^ 

1) There needs to be an advertised way to do a BCOMPL which ignores errors which occur during the compilation of a single function, so that a single call to BCOMPL will proceed thru the whole file, finding perhaps other errors before ending.

2) I tried the unadvertised function (PUNT) after one of my macros caused a BREAK during compilation, and it appeared as though the then-current break window became the normal TTY display stream.

-----------------------------
Date: 30 SEP 1982 1119-PDT
From: SHEIL.PA
Subject: two comments on the RESETFORM macro

Currently, the RESETFORM macro evaluates the resetform (a) outside of errorset protection and (b) some time (during which an interrupt can occur) before the resetlst entry for undoing it is made. This could be disastrous if one is resetting, for example, a display stream clipping region and the user bombed you out. [(a) may or may not be a bug or non-feature, depending on how one reads the manual; (b) is nasty to fix and probably requires interrupt protection]

Also, the RESETFORM macro doesn't do a very good job if one passes it a LAMBDA expression as the reset function (two copies wind up in the compiled code). [The motivation for this is for two arg fns like DSPCLIPPINGREGION, as (RESETFORM ((LAMBDA (X) (DSPCLIPPINGREGION X window)) NEWREG) forms) is much more elegant than (RESETLST (RESETSAVE NIL (LIST 'DSPCLIPPINGREGION (DSCLIPPINGREGION NEWREG window) window)) forms)

In fact, since I just realized that, it might be worth noting this trick in the manual for other slow thinkers.]

*** I really want to shift to this notation in DEDIT, so this patch would be greatly appreciated ***

Beau

PS: From a slightly broader point of view, it would be nice to have a wizard scrutinize these macros as (a) this is not the first non-feature report for them (b) they don't look to be as good code as they could be. Last time I raised this, the discussion quickly expanded to include respecifying the
whole error handling machinery (and thus nothing happened). Perhaps a useful
intermediate step would be to define a few more useful abstractions, such
as CATCH and THROW, which we could start using in our code to replace the
convoluted RESETLIST constructions that tend to generate these discussions in
the first place.

Subject: Re: Interlisp-D planning

Larry and Bill, -

The Lisp features (desired by Mark et al.) were

(1) Ability to have functions without naming them.
(2) Ability to hash on strings (or unintered atoms?) for our LOOPS uids.
(3) Access to an efficient (say B-tree) database (perhaps cedar?).

Of more immediate importance will be some participation by your guys in design reviews of LOOPS, and consulting on performance tuning. Mark

1) Must function call always go through an atom? Perhaps the name slot on the stack could be made in the "naked" case to point to the fn data object. Inspect macros might allow at least finding out about arguments expected. One might even have a string in such an object to name it (this would work for our methods).

2) The current atom hash table code made available as string hashing would do quite nicely at this stage for us, I think. More than 2^16 atoms would be nice, but is not right, since we want separate name spaces with overlapping names, and I don’t think we need anything but string hashing.

3) Eventually we might want to use file based indexes for knowledge bases (e.g. BTrees) when they get too large. The current Alpine project is NOT planning to provide a BTree index interface at the moment (I checked with Mark Brown). Most of the indexing stuff is done now on the clients side of the Cedar database.

Stats runs show that our GetValue and PutValue are remarkably slow (about 250 microseconds on a Dorado) and take most of the time, as we expected. Help on redesign on that would be most welcome.
If you edit a macro, MasterScope will correctly tell you that certain functions depend upon it; but when calling UNSAVEFNS, it always prints the message "Loading FooFunction", regardless of whether it is really loading it, or merely UNSAVEDEFing it.

* Compiler: [14 NOV 1981 1815-PST] (FUNCTION (LAMBDA --)) expression used as a value to be stored into a record slot. The compiler did produce a suitable subfunction, but then compiled as the value of the (FUNCTION --) expression the free variable NEWVALUE.
* Name conflicts with system fns

document VRAID package; I think as a LispUsers package.

we should provide PLOUT and READ/WRITEBINARYBITMAP for fast i/o of floatps
and bitmaps.

Schoen has a VAXPRINT package (possibly similar to VanBuers) which causes the vax to hardcopy screen bitmaps. He doesn’t know what the Versatec they use is exactly, but it has 2112 dots across, he says.

Date: 8 OCT 1982 1620-PDT
From: SHEIL.PA
Subject: Lisp task list
To: MASINTER
cc: lispcore^

I just spent 15 mins reading it. Very comprehensive; fine job; don’t envy you the task of prioritizing it! A couple of additional points:

ERRORSET compilation
Possibility of marking the stack rather than introducing new function call. If not, the making compiler suppress or rename forced new specvars.

Error handling
Proposal to make ^D work by ^E (incompatible but worth it?) Some improvement over current mess. Failing that, debugging optimization of RESETLST/SAVE/FORM

Global vars
If RESETVARSLST is known not to be declared global, lets fix it rather than documenting it! Mike Sannella needs some help to get new manual to indicate which system params are global - maybe he could propose a list derived from the manual and we could dispose of this one.

Garbage collection
Compiled code blocks (pointers therefrom)
Hash arrays [urgent; current incompatibility + perf problem]

File package
Hasdef problems
Fixing EDIT interfaces to use same.

Yet another (perhaps the same) request for (RAISE T) for files...

-------------------------------
Mail-from: Arpanet host SU-SCORE rcvd at 11-OCT-82 1414-PDT
Date: 11 Oct 1982 1402-PDT
From: David E. Smith <CSD.SMITH at SU-SCORE>
Subject: lower case
To: vanmelle at PARC-MAXC
Stanford Phone: (415)497-1809

I need a way of forcing interlisp to be case independent for file input as well as terminal input. Read macros won’t do it because I don’t want the lower case letters to be break characters and "ALWAYS" forces this. Advising or rewriting READC presumably wouldn’t work either because strings and characters prefaced by "%" would then get upcased.

How do I do this? Am I forced to rewrite LOAD and all of its accomplices? Crufty and/or release dependent solutions will not be sneezed at. Help!

-- de2
If you do (FONTSET 'STANDARD) to turn off fonts (e.g., to make a fontfree file), subsequent calls to the inspector die in a `DTEST of FONTDESCRIPTOR because DEFAULTFONT is NIL.

I wonder how many other places make such assumptions.

Incidentally, herewith a reminder that `DTESTFAIL desperately needs to produce a better error message, at least incorporating its second arg (the intended type).

Bill

Subject: Re: Schlumberger URGENT
In-reply-to: Raim.EOS’s message of 14 Oct. 1982 10:24 am PDT (Thursday)

Eric (and users in general) should avoid doing (APPLY 'IMAX LST) and instead write (for X in LST maximum X).

The limit of number of arguments to a function is indeed 80; it is possible that we could bump it, but there still would be a fixed limit.

Larry

Date: 15-Oct-82 15:05:36 PDT (Friday)
From: vanMelle.PA
Subject: LARGEST/SMALLEST
To: LispCore^

It has been pointed out that these names are confusing, due to the ambiguity of what you might want the iterative to return. I propose that LARGEST be called MAXIMIZING, SMALLEST be MINIMIZING, and that there also me oprs MAXIMUM and MINIMUM. Since FIND is a synonym of FOR, we could thus have:

(find X in L maximizing (FOO X))
returns the X for which FOO is largest, and
(for X in L maximum (FOO X))
returns the largest value of FOO over L.

Bill
I spent some time finding out who uses hiloc/loloc and what they use them for. The following is a summary:

**10MBDECLS:**

- D0ETHERIOCB
- DLETHERIOCB

All iocb’s are in the lowest addresses, so 10MBdecls takes advantage and only puts in the piece of the pointer necessary (loloc)

**10MBDRIVER:**

- \RELEASE.IOCB: change the "next iocb" field of the given iocb to a null value.
- \INIT.ETHER.BUFFER.POOL: change the "next iocb" fields to null.
- \QUEUE.INPUT.IOCB: next iocb ptr of last iocb = this iocb, or make this the first one.
- \QUEUE.OUTPUT.IOCB: rearranging the queue of iocb’s

**ABASIC:**

- EQUAL: uses loloc as an optimization on fixp vs smallp comparisons.

**ACODE:**

- CHANGECCODE: uses hiloc, loloc during refcount operations
- CODEBLOCKP: uses hiloc to determine what segment of storage the piece being looked at is in.

**ADARITH:**

- MACRO: .XUNBOX.

**APRINT:**

- \PRINTADDR: tries to print a lisp address nicely. Uses both HILOC and LOLOC.

**ASTACK:**

- SETSTKNAME: ? (HILOC)

**CMLARRAY-SUPPORT:**

- MACRO: %SMALLFIXP-SMALLPOSP: converts smallfixp to a number. (LOLOC)

**CMLCHARACTER:**

- ACCESSFNS: CHARACTER: how to create and access a common lisp character. (loloc)
- CL:CHAR-CODE: change a character into a #(Loloc)
- DEFOPTIMIZER: CL:CHAR-CODE: fast changing of char into code. (loloc)
- CL:CODE-CHAR: fast checking for smallposp (hiloc)
- DEFOPTIMIZER: CL:CODE-CHAR: fast checking for smallposp (hiloc)

**CMLEVAL:**
DEFSTRUCT CLOSURE :print-function to print the ptr (hiloc,loloc)
DEFSTRUCT ENVIRONMENT :print-function to print the ptr (hiloc,loloc)

set-symbol checks if environment is the stackhi

CMLSTRING

%%STRING-BASE-COMPARE-EQUAL get the character code from a string of CL:CHARS (loloc)

COMPILEDREPLACEFIELD figure out what to do with an X pointer.

Note:: Both DLION and DOVE disk code also uses LOLOC and HILOC...
—End of message—
INTRODUCTION

The Action Request data base is the primary vehicle through which the state of Xerox Lisp, including outstanding problems, requested features, and the like, is tracked. Since ARs are the primary channel of communication between the user, customer support, marketing, and development, it is important that the maximum amount of correct information be compressed into each AR. This allows technical information to get to development, and just as importantly, get back out. This process can be facilitated by correct use of the fields of the AR.

THE AR FORM - THE FIELDS AND WHAT THEY MEAN

The basic component of the AR data base is the individual AR. An AR is the melding of a blank AR form with the data specifying a need. The AR form provides 31 areas, or fields, for the input of information giving a concise summary of the need. A need can be either a problem with the Xerox Lisp system that must be corrected, or a request for a feature that would improve the system if implemented. Since the structure of the AR form must be standardized to allow entry of a wide variety of needs, the data detailing the needs becomes an important component of the AR system. Correct use of the various fields comprising an AR facilitates the exchange of information between the submitter of the AR and the developer who will act upon the AR.

The FillInDefaults option of the left button menu associated with the AR Bug Report Editor title bar will fill in the Submitter:, Source:, Status:, Machine:, Microcode Version: and Memory Size: fields, and will place MAKESYSNAME as well as MAKESYSDATE in the Lisp Version: field. Please fill in the Lisp Version: field when submitting an AR, either by typing it in or by using FillInDefaults from the pop-up menu. The version of software the bug is being found in is important data.

Number: Generated by the AR data base, every AR has a unique number. AR numbers are never recycled. ARs are never deleted. The AR number cannot be changed by the user.

Date: The date the AR was originally submitted. This is filled in by the system.

Submitter: The login name of the person who submitted this AR. This is filled in by the system.

Source: The name of the person reporting the problem being documented in the AR. The name or names appearing in this field must give enough information to enable contact if needed, i.e., Doe.PASA or Doe@Berkeley.edu.

Subject: A terse summary of the problem, providing both enough information to identify it uniquely and enough keywords for querying. "FOO doesn’t work" or "Floppy problem" is not good enough. Think of yourself as a newspaper headline writer: "Attempt to write file when floppy door is open causes awful noise." Implementors may change the Subject: field as more details about the true nature of the problem become apparent.
As much as possible, relevant keywords should be included in the Subject: to facilitate querying on the database. If the problem relates to a specific package, that package name should be mentioned in the Subject:. File names, commands, functions, error messages, etc., are good examples of relevant keywords. For example, rather than "Floppy breaks when using mailfile", a better subject would be "Loading mail file from floppy causes break in FLOPPY.OPEN with error ILLEGAL ARG: 42."

Assigned To: The name of the person or persons who took some action based on the AR.

Attn: The name of the person or persons responsible for fixing the AR.

Status: This field shows the status of the AR. This changes as action is taken on the AR.

New All ARs are generated with a default Status of New when submitted. New ARs have not been reviewed.

Open This reviewed AR describes an outstanding problem with released software.

Open/Unreleased This reviewed AR describes a problem with unreleased software.

Fixed Problem has been fixed in an Internal loadup. Developers marking ARs as Fixed should mark the In/By: field according to the release into which the fix is being incorporated. At this time, the developer should also fill in the Release Note: field.

Closed System with fix in it has been tested, documented, & released.

Declined ARs can be declined for any of a variety of reasons. Perhaps it’s a request for feature that is officially "never" going to be implemented (e.g., we think it’s a bad idea). Perhaps the bug report is considered spurious (development doesn’t think it is a bug). The reason for the AR being declined should be included in the Description: field. Declined ARs will be reviewed periodically so that old ARs may be re-opened.

Superseded Another AR already includes the problem described in this one. The In/By: field of the superseded AR should include the AR number of the one that supersedes it (ex., 7064), and the beginning of the Subject: field should be edited to include a notation such as: "Superseded by AR #7064". The superseding AR should contain the information contained in the AR it supersedes, with a notation in the Description: such as: "[Supersedes AR #7911.]."

Obsolete The problem reported is no longer a problem, e.g. the module containing the reported problem is no longer supported.

Incomplete The information submitted is not enough to take action, i.e., there is not enough information to identify the bug, or the feature request doesn’t give enough detail about what is wanted. This is different from Declined in that the request is considered valid, but the AR remains open awaiting more detail.
<table>
<thead>
<tr>
<th>Internal</th>
<th>This status is used to report problems with internal software.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Wish</td>
<td>This status is usually used to request new features, change of</td>
</tr>
<tr>
<td></td>
<td>features, Design-Impl or Design-UI.</td>
</tr>
</tbody>
</table>

**Problem Type:** Defines the type of problem described in the AR. Possibilities for the **Problem Type:** field follow:

- **Bug**
  The system does not work as documented.

- **Design-Impl**
  The system works, but the internal implementation is wrong. (This type is generally submitted by other developers.)

- **Feature**
  Used to indicate a feature request.

- **Design-UI**
  The design of the user interface is wrong. This includes problems in the way in which things display, as well as program callable structures.

- **Documentation**
  The system works, but the documentation is wrong, unclear, or incomplete. The **System:** and **Subsystem:** fields should reflect the area in which there is a problem with the documentation. The **System:** should not be **Documentation** unless there is a specific problem with the documentation, apart from the system, e.g. "need better index".

- **Performance**
  The system works, but it is too slow doing the described operation.

**Difficulty:** A rough estimate of the difficulty of the problem. This field is to be filled in by developer only. Categories within **Difficulty:** follow:

- **Easy**
  < 1 week to fix

- **Moderate**
  < 1 month to fix

- **Hard**
  < 6 months to fix

- **Very Hard**
  > 6 months to fix

- **Impossible**
  can’t be fixed

**In/By:** Used to specify the release for which an AR is/will be fixed or to indicate the number of a superseding AR.

**Impact:** How seriously does it affect your ability to get work done, value of Xerox Lisp, etc. The items apply to bug reports, but feature requests should be rated along analogous lines. The categories within **Impact:** follow:

- **Fatal**
  Causes the system to crash, causes a loss of work, etc. Problem resolution is a requirement for project completion.

- **Serious**
  The problem can be worked around but it seriously interferes with work. This type of problem usually requires substantial reimplementations.
**Moderate**
The problem is tolerable, but clearly a problem, and the responsibility of Interlisp development.

**Annoying**
The problem is annoying, a minor request for a new feature that "would be nice".

**Minor**
May be some dispute about whether it is even a bug, or a very minor feature request.

**Frequency:**
How reproducible is the problem? If it is not known or is irrelevant to the AR, leave it blank. This is generally only relevant for bug reports. **Frequency:** can be one of:

- **Everytime**
  Reproducible every time.

- **Intermittent**
  Doesn’t always happen.

- **Once**
  Saw it happen once.

**Priority:**
The perceived priority of this problem relative to the next release. A submitter may fill in their desired priority when submitting the AR. **However, priorities are approved/changed only by the Change Control Board.** Four different priorities are possible:

- **Absolutely**
  A showstopper. The pending release will be held if this AR is not completed. Requirements for this rating are: 1) Work lost with no workaround; 2) Highly embarassing to Xerox; or 3) Marked Hopefully for previous release.

- **Hopefully**
  Preferable to be in the pending release, otherwise will be in next release.

- **Perhaps**
  Will get implemented if other revisions in same area are completed.

- **Unlikely**
  Unlikely to be included in the next release.

**System:** **Subsystem:**
The category and sub-category of the Xerox Lisp system that is pertinent to this AR. **System:** and **Subsystem:** categories are:

- **Communications**
  - NS Protocols
  - NS Filing
  - NS Printing
  - PUP Protocols
  - PUP FTP

Machine: Disk:
The value of these fields should be the type of Xerox hardware that is pertinent to this AR, i.e., the machine and disk on which the problem is happening. Machine: and Disk: categories are:

1108
SA1000 (10 MB)
SA4000 (29 MB)
Q2040 (43 MB)
Q2080 (80 MB)
T80 (80 MB)
T300 (300 MB)
Other

1132
T80 (80 MB)
Century315
Other

1186
ST212 (10 MB)
TM703 (20 MB)
TM702 (20 MB)
ST4026 (20 MB)
Q530 (20 MB)
Q540 (40 MB)
Micropolis 1303 (40 MB)
Micropolis 1325 (80 MB)

Lisp Version:
This field should identify the Xerox Lisp sysout in which the problem occurs (or the feature doesn't occur). The sysout should be identified by the name associated with the release (Koto, Lyric, Medley, etc.,) and/or MAKESYSDATE.
Microcode Version:
This information may be found by typing (MICROCODEVERSION) in an Interlisp Exec or (il:microcodeversion) in a Common Lisp Exec.

File Server:
What type of file server, if any, is involved with this problem. The menu contains the following items:

8037
IFS
NS
VAX/VMS - 3 MB
VAX/VMS - 10 MB
VAX/UNIX
Micro VAX/VMS
Other

Source Files:
The source files pertinent to the problem being reported in this AR.

Memory Size:
This value is the amount of "real memory", or RAM, in pages. This information may be found by typing (REALMEMORYSIZE) in an Interlisp Exec or (il:realmemorysize) in a Common Lisp Exec.

Server Software Version:
The version of software running on the server.

Disposition:
The record of who has changed which fields of this AR and when it was done. This is filled in by the system.

Release Note:
This field should contain the information to be included in the Release Notes for a given release. It should be release specific, such as: "Medley: In the debugger, the frame inspector window . . ." If a release note isn't required, that should also be explicitly mentioned, example: "Lyric LOOPS: None needed."

Description:
This field should contain a complete description of the problem or request, including any subsequent discussion after the AR submission. If the bug report came via electronic mail, the entire report should be added into this field. In cases where there are a number of electronic mail messages discussing this problem, all messages should be appended into this field.

Workaround:
This field should contain a known procedure to work around the problem until it is fixed. This would generally be a short recipe.

Test Case:
This field should contain a list of the files needed to recreate the problem. Please note that any Common Lisp or Interlisp recipes for reproducing the problem should be in the Description: field, not in the Test Case: field. When the problem is Fixed the Test Case: field should include any appropriate information that can be used to confirm the fix (or a note that a Test Case is not applicable, ex. "N/A").

Edit-By:
The login name of the last person to edit the AR. This is filled in by the system.

Edit-Date:
The date of the last change made to the AR. This is filled in by the system.

WHAT HAPPENS TO AN AR AFTER IT IS SUBMITTED?
Change Control Boards have been established for each XAIS product to bring AR priorities more in line with customer needs. The membership of each Change Control Board consists of the Product Development Project Leader, a member of Customer Support, and a member of Release Management. Incoming ARs are reviewed weekly by the appropriate board. At this meeting priorities are assigned for each AR, and other pertinent information, such as who will deal with the AR, is gathered. This information is input to the AR data base and summaries of ARs are generated for each responsible developer.

When a problem is resolved, the Status: field of the associated AR is changed to Fixed. At this point, the software is incorporated into the Development environment, which is the precursor for the next release. The Fixed AR is sent to the Documentation group for incorporation into the appropriate part(s) of the product documentation. When a release of software to customers occurs, all Fixed ARs that have been incorporated into that release, software and documentation, are marked Closed.
\COUNTREALPAGES \LOCKED\) is what you want. Other interesting arguments to \COUNTREALPAGES include \DIRTY, \REF (pages that have been referenced since the last sweep of the real page table) and \OCCUPIED (pages inhabited by Lisp vmem pages, as opposed to things like the Alto emulator (Dorado), the real page table and low-level system buffers, thus less than \REALMEMORY\SIZE)).

Bill
Subject: A proposed design for big bitmaps (for Maiko Color (aka Kaleidoscope))
From: shih:mv:envos

Here’s a proposed design for big bitmaps (for Maiko Color). This message is also filed as BigBitmaps.TEdit, under {Pogo:MV:envos}<DSUNLISP>Documents>Development>Color>, and {Eris}<lispcore>internal>doc>.

There are basically two alternatives, either change allocblock to allow blocks bigger than 65K, or to change bitblt (and perhaps many other functions) to allow a new datatype, BIGBM.

The following describes the second BIGBM alternative.

------

DESIGN MOTIVATION

The color code currently uses ALLOCPAGEBLOCK to create a non-GC’able large bitmap for the color screen. Windows on that screen, I believe point to that screen bitmap, but Window "backing bitmaps" (the thing that holds what is behind an open window, and what is inside a closed window), is a separate bitmap.

The problem is that the backing bitmap currently cannot be as big as the window would like it to be.

The BIGBM design would keep the noncollectible color screen bitmap, but would allow windows to have BIGBM backing bitmaps. In addition, this design is more likely to be portable backwards (e.g. into Medley1.0 or Medley1.1) since no existing system datatypes need to be changed (unlike the plan to change ALLOCBLOCK).

Since XAIE does not (I believe) allow (currently) DIG operations on closed windows, then there are no DIG operations (except BITBLT) which need to occur on BIGBM backing bitmaps.

Therefore, a BIGBM need merely be a GC’able datatype which supports BITBLT between itself and all other legal datatypes (principally windows and bitmaps, but possible streams (e.g. Interpress), and possible other datatypes).

Longer term, having a generalized BITBLT will be useful, for the following reasons:

Color - 8 bpp bitmaps will begin to push Medley’s 32Mb address limitation, and 24 bpp bitmaps certainly will (the screen alone will take up 3Mb = 10% of the address space!).

Remote Bitmaps - there may be applications which need bitmaps outside of the address space (color above for example). Nick Briggs’ Maple color processor for the 1186 had a generalized remote bitblt, which "did the right thing" when source and destination bitmaps were both remte (e.g. remote bitblt).

XWindow Medley- might require remote bitmaps.

NonSun Medley - might require remote bitmaps, especially because it is doubtful the SunOS system call MMAP exists elsewhere. When not, the screen itself will need to be remote.

------

BIGBM DESIGN
A straightforward design would be to have a BIGBM simply be a collection of ordinary bitmaps ("slices of the big bitmap"), and then generalize BITBLT to handle the collection (by repeated bitblts).

More elaborate designs would allow BIGBMs to be a collection of any BitBlt’able objects (streams, windows, bitmaps, bigbitmaps), or perhaps collections of raw blocks (to save some of the BITBLT initialization overhead).

Probably at least one dimension of the slices should be a multiple of the LCD (least common denominator) of any TEXTURE (currently 16), so that textures do not show seams across the slices.

Probably also the slices should be "short and fat" (e.g. the BIGBM is made up of several rows of bitmaps), since the ucode inner loop runs in the X direction, but this partially depends on the application.

For example, font bitmaps are short and *very* wide. If large color fonts need a BIGBM font bitmap, then each character would cut across several slices, slowing down each character. For fonts, column slices might be better. Note that each character is also more "coherent" in memory this way, which might improve paging behaviour.

Having BIGBMs be composite objects (rather than a large coherent allocblock) might also improve GC behaviour, because a BIGBM can be allocated out fragmented free space. There may not be enough coherent free space to allocate a large allocblock, due to fragmentation.

Another design elaboration would be to provide full Imagestream capabilities onto BIGBMs, to that (DSPCREATE dest) will work on BIGBMs.

------

BIGBM IMPLEMENTATION

There is currently a draft implementation of BIGBMs on {Eris}<lispcore>internal>library>BIGBM. It has several limitations:

0. It is intended to be a subfunction of BITBLT (which explains the limits 1 & 2 below)
1. It doesn’t handle clipping (I’m not sure, but clipping might be handled generically in BITBLT by changing the srcex, srcey, destx, desty, width, & height args).
2. It doesn't handle default arguments (BitBlt does this).
3. It currently only makes the slices 16 bits tall (it should make the slices as big as possible).
4. It's not very efficient. It only walks the slices linearly (the first relevent slice could be found by algebra), and it doesn’t stop when the last relevent slice is bltted.
5. Because of 3 & 4, for large bitmaps its roughly 2x slower than normal bitmap blts. For small bitmaps, it may be much worse. This may be OK though for backing color windows, because color windows are large.

Mostly, this code needs to be folded into BITBLT & BLTSHADE, at the appropriate spots, and optimized if necessary.
For Internal Use Only

Raison d’Etre

The purpose of this document is to help immigrants adapt to the local computing community. "The local community" primarily means Interlisp-D users within PARC’s Intelligent Systems Laboratory and the development group of Xerox Artificial Intelligence Systems. Immigrants to other computing communities within Xerox may also find this document of interest no guarantees are made. I shall assume herein that said immigrants know quite a bit about computers in general. Hence, I shall concentrate upon discussing the idiosyncratic characteristics of the local hardware environment, software environment, social environment, linguistic environment, and the like. This document was "ripped off" from a similar one written for the Computer Sciences Laboratory of PARC, whose members primarily use another environment -- Cedar, in the great PARC tradition of developing many different programming environments.

There is a great deal of useful information available on-line at Xerox in the form of documents and source programs. Reading them is often very helpful, but finding them can be a nuisance. Throughout this document, references to on-line material are indicated by <reference>, where n is a citation reference in the bibliography at the end of this document. Standard citations to the open literature appear as [reference].

Reading a document from front to back can be mighty boring. Fortunately, this document is so disorganized that it is not at all clear that it really has a front and a back in any normal sense. You might as well just browse through and read the parts that look interesting. To help out the browsers in my reading community, I have more or less abandoned the custom of being careful to define my terms before I use them. Instead, all the relevant terms, acronyms, and the like have been collected in a separate Glossary. Some information is contained only in the Glossary, so you may want to skim through it later (or now, for that matter). While writing the Glossary, I assumed that you have a basic knowledge of computer science, and a modicum of common sense: don’t expect to find terms like “computer” and "network" in the Glossary.

Naming Things

At the outset, you should know something about the names of the creatures that you will find here. The prevailing local philosophy about naming systems is perhaps somewhat different from the trend elsewhere. We do have our share of alphabet soup, that is, systems and languages that are named by acronyms of varying degrees of cuteness and artificiality; consider, for example: PARC, FTP, IFS. But we are trying to avoid making this situation any worse. To this worthy end, names for hardware and software systems are frequently taken from the Harvard Concise Dictionary of Music, or the Sunset Western Garden Book [sunset]; Grapevine servers are named after wines; Dorados are named after hotels, spices, philosphers or ships (depending on who owns them); XDE releases are named after California rivers. This convention about names does not meet with universal approval.

Local Hardware

Most of the offices and some of the alcoves around have personal computers in them of one flavor or another. The first of these was the Alto. There are more than a thousand Altos in existence now, spread throughout Xerox, the four universities in the "old" University Grant program (U. of Rochester, CMU, MIT, and Stanford), and other places. (There’s a "new" University Grant program in progress.) In recent years, most of the local Altos have been replaced by various flavors of D-machines: Dorados, Dolphins, and Dandelions. Both D-machines and Altos come equipped with bitmap displays, mice, and Ethernet interfaces. Let’s discuss these components first, and then turn our attention to the various personal computers that contain them.

Bitmap Displays

First, let’s talk about displays. Different displays use different representations of images. A character display represents its image as a sequence of character codes. This is a very compact representation, but not a very flexible one: text is all you can get, and probably in only a limited selection of fonts. A vector display represents its image as a list of vector coordinates. This works very well for certain varieties of line drawings, but not so well for filled areas or text. A bitmap display, on the other hand, produces an image by taking a large matrix of zeros and ones, and putting white where the zeros are and black where the ones are (or vice versa). The great advantage of bitmap displays are their flexibility: you can specify a tremendous number of images by giving even a relatively small array of bits. Cursors and icons are two large classes of prominent examples. Of course, you do have to supply enough memory to hold all those bits. Altos and D-machines store their bitmaps in main storage. An alternative would be to provide a special chunk of memory on the side where the display’s image sits; such a memory is often called a frame buffer.

The primary display of the Alto is a bitmap that is 608 pixels wide by 808 pixels high. Such a display is almost
large enough to do a reasonable job of rendering a single 8.5" by 11" page of text. The CRT on a D-machine has the long axis horizontal instead of vertical, giving a bitmap display that is 1024 pixels wide by 808 high. It had to be 808 high so that D-machines could emulate Altos, of course. The extra space allows you to have something else on the screen as well as the somewhat scrunched page of text that you are editing.

Were I leave you with a mistaken impression, let me note in passing that bitmap displays are not the final solution to all of the world’s problems. Raster displays that can produce various levels of gray as well as black and white can depict images free of the “jaggies” and other artifacts that are inherent in bitmap displays [grayscale]. And, for some purposes, color is well worth its substantial expense.

Mice
But now on to mice. A mouse has two obvious properties—it rolls and it clicks. Inside the machine, the mouse position and the display cursor position are completely unrelated; but most software arranges for the cursor to "track" the mouse’s movements. Some mice have two buttons, others three. The three mouse buttons go by various names; "left", "middle", and "right" is one set of names. The mouse buttons have at some point also been called "red", "yellow", and "blue" respectively, even though physically they are nearly always black. These colorful names were proposed at an earlier time when some of the mice had their buttons running horizontally instead of vertically. Using colors (even imaginary ones!) worked better than switching back and forth between the nomenclatures "top-middle-bottom" and "left-middle-right".

Mice also come in two basic flavors: mechanical and optical. Our current mechanical mice roll on three balls: two small ones, and one large one. Motion of the large ball is sensed by two little wipers inside the mouse, one sensing side to side rolling while the other senses forward and backward rolling. The motion of each wiper drives a commutator, and little feelers slide along the commutator, producing the electrical signals that the listening computer can decode. Building one of these little gadgets is not quite as hard as building a Swiss watch, but it’s in the same league. The optical mice are a more recent innovation. An optical mouse lives on a special pad, covered with little white dots on a black background. A lens in the mouse images a portion of the pad onto the surface of a custom integrated circuit. This IC has sixteen light-sensitive regions, some of which notice that they are being shined on by the image of a white dot on the pad. As the mouse slides along the pad on its Teflon-coated underbelly, the images of the white dots move across the IC; it is subtly constructed so as to observe this phenomenon, and take appropriate electrical action. For more details on this interesting application of a custom chip, you might enjoy checking out the blue-and-white report on the subject [opticalmouse].

The Ethernet
Two’s company, three’s a network. A collection of machines within reasonable proximity is hooked together by an Ethernet; if that doesn’t sound familiar, I know of some blue-and-whites that you might like to browse [ethernet]. Ethernets are connected to each other by Gateways and phone lines, which for most purposes allow us to ignore the topology of the resulting network. The resulting network as a whole is called an Internet. Occasionally, it’s nice to know where things really are, and that’s when a map <netmap> is helpful.

Ethernets come in two flavors: old and new. The old one runs at 3 Mbits/sec, and should now be referred to as the t“Experimental Ethernet”. The unqualified name "Ethernet" should be reserved for the new one, the standardized version used in OSD products; it runs at 10 Mbits/sec.

We all know how uncommunicative computers can be when left to their own devices. That’s why we invent careful protocols for them to use in talking to each other. There are two entirely worlds of protocols that are spoken on our various Ethernets as well: old and new. The old ones are called PUP-based (PARC Universal Packet) [PUP]. The new ones are known by the acronym NS (Network Systems) [NS]. I’m sure that the NS protocols must be documented, but I don’t know where; sorry. Each protocol world includes a hierarchy of protocols for various purposes such as transporting files, or sending and receiving mail.

In addition to connecting up all of the personal computers, the network also includes a number of machines generally called servers. Normally, servers have special purpose, expensive hardware attached to them, such as large-capacity disks, or printers. Their purpose in life is to make that hardware available to the local community. We tend to identify servers by function, so we talk about print servers, file servers, name lookup servers, mailbox servers, tape servers, and so on. Many of the protocols for use of the Ethernet were developed precisely so that personal computers could communicate effectively with servers.

The Alto
The innards of the Alto are wonderfully described in a clear and informative blue-and-white report [ALTO]. For our purposes, suffice it to say that the Alto is a 16-bit minicomputer whose primary claim to fame is that it comes equipped with a bitmap display, a mouse, and an Ethernet interface.

D-Machines
The D-machines are a family of personal computers, each member of which has a name starting with the letter "D". As long as you don’t look too closely, D-machines look a lot alike. In particular, they are all 16-bit computers with a microprogrammed processor that handles most of the I/O as well running the user’s programs. And they all generally come equipped with a hard disk, a bitmap display, a keyboard, a mouse, and an Ethernet interface. There are differences of course: in size, in speed, and in flexibility.
The Dolphin (formerly called the D0)

The Dolphin was one of the early D-machines, and there are still some of them around. Dolphins are housed in the same sized chassis as Altos. You can tell that they aren’t Altos because they have wide screen terminals, and because they don’t have a slot on top for a removable disk pack. Instead, they use a 28MByte Winchester disk drive made by Shugart. Dolphins can talk to both 3 MBit and 10 MBit Ethernets. It was sold by Xerox AI systems as the Xerox 1100 with Interlisp-D and Smalltalk.

The Dandelion

The Dandelion is the D-machine processor that is used in the Star products and the Xerox 1108. It comes in a box about half the width of an Alto chassis, and roughly the same height and depth. Dandelions are both faster and much cheaper than Dolphins. Dandelions talk only to 10 MBit Ethernets. Recently a number of hardware enhancements have been developed for Dandelions, including the ability to add a lot more memory (up to 4MByte) and hardware floating point, IBM PC Bus controller, etc.

The Dorado

The Dorado was (and probably still is) the most powerful personal computer around. The Computer Science Lab built the Dorado as the current high-performance model in the D-machine line. The processor, the instruction fetch unit, and the memory system of the Dorado have been written up in papers for your enjoyment [DORADO]. Dorados came equipped with a 315 MByte Winchester drive; older models have an 80 MByte removable-pack disk drive at present. Dorados talk only to 3 MBit Ethernets at present.

A Dorado is roughly three to five times faster than an Alto when emulating an Alto, that is, running BCPL. Dorados are generally 3-5 times faster than DLions running Interlisp, except for some notable exceptions (Dorados have an incredible memory bandwidth, and so can move the bits around the screen *really* fast; the DLions have special hardware for floating point which makes them faster than the (microcoded) Dorados.). One primary difficulty about Dorados is that they’re a lot more expensive than DLions, and don’t fit in your office. As a result, while some people have personal Dorados, there are also *pool* machines. When you borrow a Dorado, you generally also want to borrow at least some of the space on that Dorado’s local disk. In order for this sharing to work out well, certain social taboos and customs concerning the use of such local disks have emerged, under the general rubric of "living cleanly". More on this topic anon.

In a return to the ways of the past, the Dorado processors are rack mounted in a remote, heavily air-conditioned machine room. It was initially intended that the Dorado, like the Alto, would live in your office. To prevent its noise output from driving you crazy, a very massive case was designed, complete with many pounds of sound-deadening material. (This case was known as the APC, or Armored Personnel Carrier, which it resembled.). But experience indicated that Dorados ran too hot when inside of these cabinets, and the concept of having Dorado processors in offices was abandoned. With progress in general and VLSI in particular, there is hope that the *next* high-performance contender will come out again and live in your office.

The Dicentra

The Dicentra is another D-machine of which there aren’t a lot around. Essentially, it consists of the processor of the Dandelion with the tasking stuff striped out squeezed onto one Multibus card. It communicates with its memory and with I/O devices over the Multibus. Dicentras will talk to any Ethernet, or any I/O device for that matter, for which you can supply a Multibus interface card: that’s one of the Dicentra’s strengths. The initial application of the Dicentra is as a processor for low cost Internet gateways. The Dicentra and the Dandelion are named after wildflowers partially because they are outgrowths of an initial design called the Wildflower.

The Dragon

The Dragon is a high-performance processor based on custom integrated circuits that is being designed in CSL; confusingly enough, though, the Dragon is not really a D-machine. For example, the Dragon word size is 32 bits rather than 16. The underpinnings of Cedar will be adjusted as necessary so that Cedar will run on a Dragon; but this will take some doing.

Other D-machines

There may well be other D machines brewing in laboratories and development groups. This document won’t talk about them, as they are more closely tied with some product plans that should not be widely circulated.

A few comments about Booting

All of the local processors come equipped with a hidden button called the "boot button" that is used to reinitialize the processor’s state. The Alto had just one boot button, hidden behind the keyboard; pushing it booted the Alto. On Dolphins, the situation is only slightly more complex: there are two boot buttons, one at the back of the keyboard, and the other on the processor chassis itself. They perform roughly the same function, but the one on the chassis is a little more potent. On Dorados, there is a lot more going on. There are really two computers involved,
the main Dorado processor and a separate microcomputer called the baseboard. It is the baseboard computer’s job to monitor the power supplies and temperature and to stage-manage the complex process of powering up and down the main processor, including the correct initialization of all of its RAM’s. The boot button on a Dorado is actually a way of communicating with this baseboard computer. You encode your request to the baseboard computer by pushing the boot button repeatedly: each number of pushes means something different. For details, see Ed Taft’s memo on the subject <DORADOBOOT>. If the baseboard computer of the Dorado has gone west for some reason (as occasionally happens), your only hope is to push the real boot button, a little white button located on the processor chassis itself, far, far away. Just as the boot button on the keyboard is essentially a one-bit input device for the baseboard computer, the baseboard computer also has a one-bit output device: a green light located on the processor chassis. Various patterns of flashing of this light mean various things, as detailed in <DORADOBOOT>.

DLions have a boot button located right under the Maintenance Panel. It’s labeled B-reset. There’s another button next to it, labelled Alt-B, which is used in conjunction with B-reset to boot the machine in various ways -- you hold down both, let up on B-reset, and the maintenance panel lights cycle with numbers 0000, 0001, 0002, 0003, etc. When you let up, you get the "boot option" that you let up on: 0000 (or 0-boot) usually boots Lisp from the disk (or just B-reset), 1-boot boots Mesa from the disk, 2-boot boots from floppy, 3-boot boots from ethernet, 4-boot boots something that I forget, 5-boot gets "diagnostics" from a floppy, 6-boot gets an alternate Ethernet Mesa, and a few others. (0010-boot with a floppy-cleaning-diskette in the floppy drive will clean the floppy heads. This is useful you have a broken machine with a broken ethernet, and you want to floppy boot diagnostics but can’t because of dirty heads!)

There is one more bit of folklore about booting Dorados that’s fun to mention--every once in a while, I have to throw in some subtle tidbit to keep the wizards who read this from getting bored. Our subject this time is the "long push boot". Suppose that you have been working on a Dorado for a while, and you walk away to go to the bathroom. When you return and reach toward your keyboard, you get a static shock. You are only mildly annoyed at this until you notice that the cursor is no longer tracking the mouse, and the machine doesn’t seem to hear any of your keystrokes. The screen looks OK, but the Dorado is ignoring all input. What has probably happened is that the microprocessor in your terminal has been knocked out by the static shock. Yes, Virginia! In addition to the Dorado itself, and the baseboard computer, there is also a microprocessor in your terminal (located in the display housing), which observes your input actions and sends them on to the main processor under a protocol referred to as "the seven-wire interface". What you want to do now is to reboot the terminal microprocessor without disturbing the state of the Dorado at all--after all, you were in the process of editing something, and you are now in danger of loosing those edits. What you should do is to depress the boot button and hold it down for quite a while (more than 2.5 seconds); and then release it. This is known as a "long push boot", and it does just what you want under these conditions: it reboots your terminal without affecting anything higher up.

Local Programming Environments

Various programming environments have grown up around the various pieces of hardware mentioned above. You can get a software merit badge simply by writing one non-trivial program in each envirnoment.

Mesa

Mesa is a strongly typed, PASCAL-like implementation language designed and built locally. It first ran on Altos. Herein, I shall call that system Alto/Mesa. Dolphins and Dorados (but not Dandelions) can run Alto/Mesa by impersonating an Alto at some level. More recent instances of Mesa now run on all of our D-machines under the Pilot operating system. In passing, I should observe that Pilot is an operating system written in Mesa by folk in SDD. It is a heavier-weight operating system than the Alto OS, providing its clients with multiprocesssing, virtual memory, and mapped files.

The Pilot version of Mesa is the home to lots of active programming in several locations. First, it is the system in which the Star product was and is being implemented by OSD. The programmers in OSD have developed a set of tools for programming in Mesa variously called the "Tools Environment" or "Tajo" or "XDE" or "Basic Workstation". This body of software may soon be marketed under the name "the Xerox Development Environment". In addition, Pilot Mesa is the current base of the Cedar project in CSL. More on Cedar later. Although Mesa programs look a lot like PASCAL programs when viewed in the small, Mesa although Mesa provides and enforces a modularization concept that allows large programs to be built up out of smaller pieces. The Mesa language is described by a manual [MESA].

Smalltalk

Smalltalk was developed by the folk who now call themselves the Software Concepts Laboratory (formerly known as the Learning Research Group and then the Software Concepts Group). The Smalltalk language is the purest local embodiment of "object-oriented" programming:

A computing world is composed of "objects".
The only way to manipulate an object is to be polite, and ask it to manipulate itself. One asks by sending the object a message. All computing gets done by objects sending messages to other objects.

Every object is an "instance" of some "class".

The class definition specifies the behavior of all of its instances--that is, it specifies their behavior in response to the receipt of various messages.

Genealogists will recognize that ideas from both Simula and Lisp made their way into Smalltalk, together with traces of many other languages.

For some years now, the folk in SCG have been working at trying to get the Smalltalk language and system out into the great wide world. The first public event that came out of this effort was the August 1981 issue of Byte magazine; it was devoted to Smalltalk-80, including a colorful cover drawing of the now famous Smalltalk balloon.

In addition, the SCG folk are writing several books about Smalltalk, and they are planning to license the system itself to various outside vendors. The first of the books, entitled Smalltalk-80: The Language and Its Implementation, emerged from the presses at Addison-Wesley just recently [21]. Future books will include Smalltalk-80: The Interactive Programming Environment, and Smalltalk-80: Bits of History, Words of Advice.

Interlisp-D

LISP is the standard language of the Artificial Intelligence community. Pure LISP is basically a computational incarnation of the lambda calculus; but the LISP dialects in common use are richer and bigger languages than pure LISP. Interlisp is one dialect of LISP, an outgrowth of an earlier language called BBN-LISP; for more historical details, read the first few pages of the Interlisp Reference Manual [22]. One of the biggest strengths of Interlisp is the large body of software that has developed to assist people programming in Interlisp. Consider the many features of Interlisp: an interpreter, a compatible compiler, sophisticated debugging facilities, a structure-based editor, a DWIM (Do What I Mean) error correction facility, a programmer's assistant, the CLISP package for Algol-like syntax, the Masterscope static program analysis database, and the Transor LISP-to-LISP translator, to name a few.

Interlisp itself has been implemented several times. Interlisp-10 is the widely-used version that runs on PDP-10's. Interlisp-D is an implementation of Interlisp on the D-machines [23], produced by folk at PARC. In the process of building Interlisp-D, the boundary between Interlisp and the underlying virtual machine was moved downward somewhat, to minimize the dependencies of Interlisp on its software environment; that is, functions that were considered primitive in Interlisp-10 were implemented in Lisp itself in Interlisp-D. But the principal innovations of Interlisp-D are the extensions that give the Interlisp user access to the personal machine computing environment: network facilities and high-level graphics facilities (including a window package) among them.

[MORE]

Cedar

Back in 1978, folk in CSL began to consider the question of what programming environment we would use on the emerging D-machines. A working group was formed to consider the programming environments that then existed (Lisp, Mesa, and Smalltalk) and to form a catalog of programming environment capabilities, ranked by both by value and by cost. A somewhat cleaned-up version of the report of that working group is available as a blue-and-white for your perusal [EPE]. After pondering the alternatives for a while, CSL chose to build yet another programming environment, based on the Mesa language. That new environment was named "Cedar". The programming language underlying Cedar is essentially Mesa with garbage collection added. Now, adding garbage collection actually changed things quite a bit. First of all, it changes programming style in large systems tremendously. Without garbage collection, you have to enforce some set of conventions about who owns the storage. When I call you and pass you a string argument, we must agree whether I am just letting you look at my string, or I am actually turning over ownership of the string to you. If we don't see eye to eye on this point, either we will end up both owning the string (and you will aggravate me by changing my string!) or else neither of us will own it (and its storage will never be reclaimed--a storage leak). Once garbage collection is available, most of these problems go away: God, in the person of the garbage collector, owns all of the storage; it gets reclaimed when it is no longer needed, and not before. But there is a price to be paid for this convenience. The garbage collector takes time to do its work. In addition, all programmers must follow certain rules about using pointers so as not to confuse the garbage collector about what is garbage and what is not.

Thus, programs in the programming language underlying Cedar look a lot like Mesa programs, but they aren't really Mesa programs at all, on a deeper level. To avoid confusion, we decided to use the name "Cedar" to describe the Cedar programming language, as well as the environment built on top of it. Cedar is really two programming languages: a restricted subset called the safe language, and the unrestricted full language. Programmers who stick to the safe language can rest secure in the confidence that nothing that they can write could possibly confuse the garbage collector. Their bugs will not risk bringing down the entire environment around them in a rubble of bits. Those who choose to veer outside of the safe language had better know what they are doing.
Those who want to know more about Cedar are once again encouraged to dredge up a copy of the Cedar Manual <25>. It includes documentation on how Cedar differs from Mesa, annotated examples of Cedar programs, manuals for many of Cedar’s component parts, a Cedar catalog, and lots of other good stuff. By the way, the most authoritative source for what the current Cedar compiler will do on funny inputs can be found in a document called the Cedar Language Reference Manual, also known by the acronym CLRM. This is logically part of the Cedar Manual, but it is currently bound separately, and only available in draft form. The CLRM suggests a particular design philosophy for building a polymorphic language that is a superset of the current Cedar, since that is the direction in which the authors of the CLRM, Butler Lampson and Ed Satterthwaite, would like to nudge the Cedar language.

Local Software

This section is a once-over-lightly introduction to some of the major software systems that are available in the Interlisp world.

In Interlisp, the current best sources are the Interlisp Manual mentioned above.

Filing

When programming in the Alto world, or in current Cedar, you are dealing with two different types of file systems: local and remote. The local file system sits on your machine’s hard disk. Remote file systems are located on file servers, machines with big disks that are willing to store files for you. Local file systems have several unpleasant characteristics in comparison with the remote systems: they are small, and they aren’t very reliable. Both of these problems have consequences.

Some people believed that, because local file systems are small, it wasn’t in general practical to store more than one version of a file on the local disk. Thus, some local file systems don’t support versions, and in programs that use them, writing a "new version" of a file really means writing on top of the old one. Nearly everyone who isn’t accustomed to this (particularly Interlisp programmers) gets burned by it at least once. Some text editors in XDE and the Alto world *do* maintain one backup copy of each file being edited as a separate file, whose name ends with a dollar sign. That is, the backup copy of "foo.bravo" is stored in the file "foo.bravo$". Note that our remote file servers do maintain multiple versions of files. Letting old versions of things accumulate is one easy way to overflow your disk usage allocation on a remote server.

No disk is completely reliable. Our remote file servers have automatic backup facilities that protect us from catastrophic disk failures. But the local file systems have no such automatic protection. Since this protection isn’t provided automatically, it behooves you to adjust your behavior appropriately: make sure that, on a regular basis, backup copies of the information on your local disk are put in some safe place, such as on a remote file server where suitable precautions are constantly being taken by wizards to protect against disk failure. Doing this is one facet of what is meant by the phrase Living Cleanly, which deserves its own section.

Living Cleanly

The phrases "living cleanly" refer to a particular style of use of your local file system. In order to understand the cosmic issues involved, we should pause to discuss the ways in which local and remote file systems have been used over the years.

Back in the Alto days, personal files were usually stored on one’s Alto disk pack, while project-related and other public files were stored on remote servers. Careful folk would occasionally store backup copies of their personal files on remote servers as well, in case of a head crash. But, as a general rule, one thought of one’s Alto pack as the repository of one’s electronic state. This made sharing Altos quite convenient, since you could turn any physical Alto into 'your Alto' just by spinning up your disk pack.

In the glorious world of the future, all of your personal files as well as all public files will live on file servers in the network. The disk attached to your personal computer will, from time to time, contain copies of some of this network information, for performance reasons; but you won’t have to do anything to achieve this, and you won’t have to worry about how it is done. From the user’s point of view, all files will act as if they were remote at all times. Indeed, except in a few funny cases, there won’t even be any notion of "local file"; "file" will mean "remote file".

At the moment, we are sitting in an unpleasant transitional phase somewhere between these two styles of usage of the local disk: we are attempting to simulate the latter state by means of manual methods and social pressure. We want you to think of your data as really living out on the file servers. That is the proper permanent home for your personal files as well as for public files. You will have to bring copies of these files, both private and public, to your local disk in order to work on them. But, at the end of each editing session, you should store the new versions of files that you have created back out to their permanent remote homes. None of this happens automatically at present; you have to make it happen manually by using various file shuffling tools, such as the "DF files" discussed below. Using these tools is a hassle, and learning how to use them can be confusing. But, there are four important benefits to be reaped from adopting a clean living life-style.
First, you are taking a step towards the glorious future.

Secondly, you are protecting yourself against failures of the local disk. A clean liver only holds information on her local disk for the duration of an editing session. This puts a reasonable bound on the amount of information that she can lose because of a disk crash.

Local file systems

The local file system in the Alto world is called either the "Alto file system" or the "BFS", the latter being an acronym for Basic File System. The biggest that a BFS can be is 22,736 pages. This is substantially bigger than the entire disk on an Alto. However, Dolphins and Dorados have much bigger local disks. Hence, when a Dolphin or Dorado is emulating an Alto, its local disk is split up into separate worlds called partitions, each containing a maximum-sized BFS. Dolphin disks can hold two full partitions, while Dorado disks can hold nineteen. What partition you are currently accessing is determined by the contents of some registers that the disk microcode uses. There is a command called "partition" in the Executive and the NetExec that allows you to change the current partition -- it necessarily "boots" the machine.

When operating in the Pilot world, a disk pack is called a physical volume, and it is divided into worlds called logical volumes.

All of our local file systems use a representation for files that drastically reduces the possibility of a hardware or software error destroying the disk’s contents. The basic idea is that you must tell the disk not only the address of the sector you want to read or write, but also what you think that sector holds. This is implemented by dividing every sector into 3 parts: a header, a label, and a data field. Each field may be independently read, written, or compared with memory during a single pass over the sector. The Alto file system stuffs a unique identification of the disk block, consisting of a file serial number and the page number within the file, into the label field. Now, when the software goes to write a sector, it typically asks the hardware to compare the label contents against data in memory, and to abort the writing of the data field if the compare fails. This makes it pretty difficult, though not impossible, to write in the wrong place. Furthermore, it distributes the structural information needed to reconstruct the file system over the whole disk, instead of localizing it in one place, the directory data structures, where a local disaster might wipe it out. Each local file system also has a utility program called a Scavenger that rebuilds the directory information by looking at all of the disk labels.

Remote file systems

The most important local file servers are IFS’s, an acronym for Interim File System (one of the crown jewels of the BCPL programming environment). Like I always say, "temporary" means "until it breaks", and "permanent" means "until we change our minds". Indigo and Ivy are two prominent local IFS’s: Indigo stores mostly project files, while Ivy stores mostly personal files. MAXC also serves as a file server for some specialized applications. Juniper was CSL’s first attempt to build a distributed transactional file server; it was one of the first large programs written in Mesa. Alpine is a new effort to build such a beast in the context of Cedar, in support of distributed databases and other such wonderful things. Some Walnut users have been storing their mail databases on Alpine for a month or more.

There is no coherent logic to the placement of "general interest" files and directories, nor even to the division between Maxc, Indigo, and Ivy. Browse through the glossary at the end of this document to get a rough idea of what’s around. If something was made available to the universities in the University Grant program, then it is probably on Maxc (or archived off of Maxc), since Maxc is the machine that the university folk can access.

IFS supplies a general sub-directory structure which the Maxc file system lacks, and as a result there are lots of place to look for a file on an IFS. For example, on Maxc you might look for

\[\text{[Maxc]} \langle \text{AltoDocs} \rangle \text{MyFavoritePackage.press}\]

while on IFS you would probably look for

\[\text{[Indigo]} \langle \text{Packages} \rangle \text{Doc} \langle \text{MyFavoritePackage.press}, \text{or} \langle \text{Packages} \rangle \text{MyFavoritePackage} \rangle \text{Documentation.press},\]

or perhaps some other permutation. This requires a bit of creativity and a little practice. However, if you get in the habit of using "*"s in file name specifications, you will find all sorts of things you might not otherwise locate. Note that a "*" in a request to an IFS will expand into all possible sequences of characters, including right angle brackets and periods. Thus, for example, a request for

\[\text{<Packages>*press}\]

refers to all files on all subdirectories of the Packages directory that end with the characters "press". A "*" won’t match a left angle bracket, by the way. Thus, if you ask for "*.press", you are referring to all Press files on the current directory. If you ask for "<*.press", you are referring to all of the Press files on the entire IFS (expect such a search to take a long time!).
There is a movement afoot in the Cedar world to simplify our file naming conventions by replacing the various flavors of brackets with a UNIX-like slash. Thus, in some Cedar systems, such as the FileTool, the documentation file mentioned above could be referred to as

/Indigo/Packages/MyFavoritePackage/Documentation.press.

File Properties

The "size" of a file is its length measured in disk pages; the "length" of a file is its length measured in bytes. The "create date" of a file is the date and time at which the information in that particular version of the file was "created", that is, the date when that sequence of bytes came into being. Copying a file from one file system to another does not change the create date, since the information in the file, the sequence of bytes, is not affected. The create date is almost always what you want to know about a file. Some of our systems also maintain a "write date" or a "read date", but they are less well defined, and not as interesting.

Editing and Typesetting

In the outside world, document production systems are usually de-coupled from text editors. One normally takes the text that one wants to include in a document, wraps it in mysterious commands understood by a document processor, feeds it to that processor, and puzzles over the resulting jumble of characters on the page. In short, one programs in the document processor's language using conventional programming tools--an editor, a compiler, and sometimes even a debugger. Programmers tend to think this is neat; after all, one can do anything with a sufficiently powerful programming language. (Remember, Turing machines supply a sufficiently powerful programming language too.) However, document processors of this sort frequently define bizarre and semantically complex languages, and one soon discovers that all of the time goes into the edit/compile/debug cycle, not careful prose composition.

Bravo is the editor and typesetter in the Alto world, and it represented a modest step away from the programming paradigm for document production. A single program provided both the usual editing functions and a reasonable collection of formatting tools. You can't program Bravo as you would a document "compiler", but you can get very tolerable results in far less time. The secret is in the philosophy: what you see on the screen is what you get on paper. You use the editing and formatting commands to produce on the screen the page layout you want. Then, you tell Bravo to ship it to a print server and presto! You have a hardcopy version of what you saw on the screen. Sounds simple, right?

Of course, it isn't quite that easy in practice. There are dozens of subtly defined fonts and sizes, tabs, headings, and on and on. Bravo was a success because most of these issues are resolved more or less by fiat--someone prepared a collection of configuration parameters and a set of forms that accommodated most document production. Many of the configuration options aren't even documented, so it is hard to get enough rope to hang yourself. The net effect is that one spent more time composing and less time compiling.

In Bravo's wake, several new editors of unformatted text appeared: the Laurel editor, and the editor in the Tools Environment are prominent examples. The Laurel editor is particularly noteworthy in that it pioneered the development of a modeless (or at least less modal) user interface for an editor. The Star product editor, Tedit and Tioga are more recent local editors in the full Bravo tradition: they can handle formatting and multiple fonts. Tioga is the editor within Cedar, and its user interface is very close to the widely beloved Laurel modeless interface--try going back to Bravo after using Tioga for a while, and see how horrible it feels to have to remember to type "i" and "ESC" all the time. Tioga shows formatted text on the screen. To get a hardcopy of that text, the current path involves running a companion program called the TSetter, which will compose your pages for printing and send them to a print server. Tioga's documentation is particularly convenient, since it usually available in iconic form at the bottom of the Cedar screen <29>.

Dealing with editor bugs

All text editors have bugs. Furthermore, you are often most likely to tickle one of the remaining bugs in an editor when you are working furiously on a hard problem, and hence, have been editing for a long time without saving the intermediate results. As fate would have it, these are exactly the times when it is most damaging and most upsetting to lose your work. There is nothing quite like the sinking feeling you get when a large number of your precious keystrokes gurgle away down the drain. Both Bravo and Tioga have mechanisms that can, in some cases, save you from the horrible fate of having to do all those hours of editing over again. Bravo attempts to safeguard you by keeping track of everything that you have done during the editing session in a log file; in case of disaster, this log can be replayed to recapture most of the effects of the session. If you have a disaster when editing in Bravo, be careful NOT to respond by running Bravo again to assess the damage. By running Bravo again in the normal way, you will instantly sacrifice all chance of benefiting from the log mechanism, since the log allows replay only of the most recent session. What you want to do instead is run the program "BravoBug" ("Bravo/R" is not an adequate substitute). It wouldn't be a bad idea to ask a wizard for help also. While you are looking for a wizard, try and think of some good answer to the question "Why are you using Bravo, anyway?", which said wizard will almost certainly ask.

Printing
In general, our printers are built by taking a Xerox copier and adding electronics and a scanning laser that produce a light image to be copied. There are many different types of such printers, and there are multiple instances of each printer type as well. There are also many different programs that would like to produce printed output. The Press print file format was our first answer to the problem of allowing every printing client to use every printer. Press files are the Esperanto of printing. Most print servers demand that the documents that you send to them be in Press format. This means you have to convert whatever you have in hand (often text) to Press format before a server will deign to print it.

Press file format <PRESS> is hairy, and some print servers don’t support the full generality of Press. Generally, however, such servers will simply ignore what they can’t figure out, so you can safely send them any Press file you have.

A Press file can ask that text be printed in one of an extensive collection of standard fonts. Unfortunately, you must become a wizard in order to print with your own new font. You can’t use a new font unless it is added to the font dictionary on your printer, and adding fonts to dictionaries is a delicate operation: a sad state of affairs. If the Press file that you send to a printer asks for a font that the printer doesn’t have, it will attempt a reasonable substitution, and, in the case of Spruce, tell you about the substitution on the break page of your listing. If you have chronic font difficulties of this sort, contact a wizard.

There is a new print file format, called Interpress. The print servers that are part of the Star product speak a dialect of Interpress as will most other new Xerox printers. A print file in Interpress format is called a master. CSL’s local plans for printing Interpress masters involve converting them first into a printer-dependent print file in so-called PD format (with conventional extension .pd”). From there, a relatively simple driver program on each printer should be able to produce the final output.

PARC has a variety of printers available for your hardcopy needs. We have high volume printers for quantities of text, listings, and documentation; we have slower printers with generally higher quality for more complex files; and we have very slow printers for extremely high quality. All of our current printers except Platemaker offer 384 spots per inch and share a common font dictionary. We use two different software systems for printing Press files, both running on Altos: one is called Spruce, and the other is called (confusingly) Press. Spruce offers speed and spooling, but it can only image characters and rules, and not too many of them. This makes it limited in graphics applications. Furthermore, Spruce is limited to the particular sizes of fonts that it has stored in its font dictionary: it does not know how to build new sizes by converting from splines. Press is slower, but can handle arbitrary bitmaps, and can produce odd-sized fonts from splines.

CSL is developing Interpress printing capabilities. Printing .pd” files is now an option on most Press printers (that is, on printers running the program Press as opposed to Spruce). Just ship your .pd” file to the printer in the standard way: it is smart enough to figure out whether what you have sent it is in PD or Press format, and it will invoke PDPrint or Press as appropriate. Documentation on these two printing programs is available, by the way <PDPRINT, PRESS>. PD printing should not be undertaken without consultation with a wizard.

Dover printers run Spruce for high volume printing, producing a page per second. CSL’s Dover, named Clover, is found in room 2106; ISL’s Dover, named Menlo, is in room 2305. Samples of the Dover font dictionary may be found next to Clover and Menlo. Instructions for modifying the queue and generally running these Spruce printers are to be found next to their Alto terminals.

Lilac is CSL’s color Press printer and may be found in room 2106 with Clover. It is a three color, composite-black machine; it generally produces good quality output, but is occasionally temperamental. Anyone interested in color printing or the state of Lilac should join the distribution list LilacLovers@pa.

In room 2301, there are an assortment of black and white Press printers, answering variously to the names of RockNRoll, Quoth, and Stinger. The printers are two Ravens (Raven is a Xerox product), one Hornet, and one Gnat (the latter two are prototypes). The print quality is normally excellent. Instructions for interpreting status displays are posted locally. To be informed of which printer is functioning and where, join the list ISLPrint@pa. There should be three printers up for most of the summer. Periodically one or another of these or Lilac are pre-empted for debugging.

Our best quality printer is Platemaker, which is normally operated at 880 spots per inch, but can be run up to 2200 spi; it is not normally useful to go beyond 1600. Platemaker uses a laser to write on photographic paper or film. Color images can be done in individual separations, which are then merged using the Chromalin process. The Platemaker printing process is used for final prints of fine images or for printing masters for publication. If you wish to have something printed, speak to Julian Orr, Eric Larson, or Gary Sturkweather.

Sending and Receiving Mail

We rely very heavily on an electronic mail system. We use it for mail and also for the type of announcement that might, in other environments, be posted on a physical or electronic bulletin board. In our environment, a physical bulletin board is pretty useless, since people spend too much of their days staring at their terminals and too little wandering the halls. Electronic bulletin boards might work satisfactorily. But a bulletin board, being a shared file
to which many people have write access, is a rather tricky thing in a distributed environment. It probably presupposes a distributed transactional file server, for example. Mumble. For whatever reason, the fact remains that we don’t have an electronic bulletin board facility at the moment. As a result, announcements of impending meetings, "for sale" notices, and the like are all sent as messages directed at expansive distribution lists. If you don’t check your messages once a day or so, you will soon find yourself out of touch (and saddled with a mailbox full of obsolete junk mail). And conversely, if you don’t make moves to get on the right distribution lists early, you may miss lots of interesting mail. This business of using the message system for rapid distribution of announcements can get out of hand. One occasionally receives notices of the form: "meeting X will start in 2 minutes--all interested parties please attend".

Grapevine is the distributed transport mechanism that delivers the local mail [33]. When talking to Grapevine, individuals are referred to by a two-part name called an "R-name", which consists of a prefix and a registry separated by a dot; for example, "Ramshaw.pa" means Ramshaw of Palo Alto. In addition to delivering the mail, Grapevine also maintains a distributed database of distribution lists. A distribution list is also referred to by an R-name, whose prefix conventionally ends in the character up-arrow, as in "CSL^.pa". Distribution lists are actually special cases of a construct called a Grapevine "group". Groups can be used for such purposes as controlling access to IFS directories. There is a program named Maintain that allows you to query and update the state of the distribution list database. In fact, there are two versions of Maintain: the documented one with the unfortunate teletype-style user interface is used from within Laurel or the Mesa Development Environment <34>; the undocumented one with the futuristic menu interface is used from within Cedar. Some distribution lists are set up so that you may add or remove yourself using Maintain. If you try to add yourself to Foo^.pa and Maintain won’t let you, the proper recourse is to send a message to the distribution list Owners-Foo^.pa, asking that you please be added to Foo^.

At the moment, Grapevine pretty much has a monopoly on delivering the mail. But there are several different programs that give users access to Grapevine’s facilities from different environments. From an Alto, one uses Laurel, which is mentioned elsewhere as a pioneer of modeless editor interfaces. Even if you aren’t a Laurel user, I recommend that you read Chapter 6 of the Laurel Manual [35], which is an enlightening and entertaining essay on proper manners in the use of the mail system. In the Mesa Development Environment, the program Hardy provides services analogous to Laurel’s. From within Interlisp, most folk use Lafite, whose documentation appears as <LAFITE.PRESS>. Finally, in case travel should take you away from your multi-function personal workstation, there are servers on the Internet known by the name "Lily" to whom you can connect from any random teletype in order to peruse the mail sitting in your Grapevine mailbox.

Some Tidbits of Lore

About CSL

CSL has a weekly meeting on Wednesday afternoons called Dealer, starting at 1:15. The name comes from the concept of "dealer’s choice"--the dealer sets the ground rules and topic(s) for discussion. When someone says she will "give a Dealer on X", she means that she will discuss X at some future weekly meeting, taking about 15 minutes to do so (plus whatever discussion is generated). Generally, such discussions are informal, and presentations of half-baked ideas are encouraged. The topic under discussion may be long-range, ill-formed, controversial, or all of the above. Comments from the audience are encouraged, indeed, provoked. More formal presentations occur at the Computer Forum on Thursday afternoons; the Forum is not specifically a CSL function, and it is open to all Xerox employees, and sometimes also to outsiders. Dealers are also used for announcements that are not appropriate for distribution by electronic mail. Members of CSL are expected to make a serious effort to attend Dealer.

Some Code Phrases

You may occasionally hear the following incomprehensible phrases used in discussions, sometimes accompanied by laughter. To keep you from feeling left out, we offer the following translations:

"Committing error 33"

(1) Predicating one research effort upon the success of another. (2) Allowing your own research effort to be placed on the critical path of some other project (be it a research effort or not). Known elsewhere as Forgie’s principle.

"You can tell the pioneers by the arrows in their backs."

Essentially self-explanatory. Usually applied to the bold souls who attempt to use brand-new software systems, or to use older software systems in clever, novel, and therefore unanticipated ways ... with predictable consequences. Also heard with "asses" replacing "backs".

"We’re having a printing discussion."

Refers to a protracted, low-level, time-consuming, generally pointless discussion of something peripherally interesting to all. Historically, printing discussions were of far greater importance than they are now. You can see
why when you consider that printing was once done by carrying magnetic tapes from Maxc to a Nova that ran an XGP.

Fontology

The body of knowledge dealing with the construction and use of new fonts. It has been said that fontology recapitulates file-ogeny.

"What you see is what you get."

Used specifically in reference to the treatment of visual images by various systems, e.g., a Bravo screen display should be as close as possible to the hardcopy version of the same text. Also known is some circles by the acronym "WYSIWYG", pronounced "whiz-ee-wig".

"Pop!"

THIS phrase means that the conversation has degenerated in some respect, often by becoming enmeshed in nitty-gritty details. Feel free to shout out one or more of these phrases if you feel that a printing discussion has been going on long enough. If two participants in a large meeting begin discussing details that are of interest to them but not of interest to the group as a whole, shout "Off-line!" instead.

"Life is hard"

Two possible interpretations: (1) "While your suggestion may have some merit, I will behave as though I hadn’t heard it." (2) "While your suggestion has obvious merit, equally obvious circumstances prevent it from being seriously considered." The charm of this phrase lies precisely in this subtle but important ambiguity.

"What’s a spline?"

"You have just used a term that I’ve heard for a year and a half, and I feel I should know, but don’t. My curiosity has finally overcome my guilt.” Moral: don’t hesitate to ask questions, even if they seem obvious.

Hints for Gracious Living

There are a couple of areas where life at PARC can be made more pleasant if everyone is polite and thoughtful enough to go to some effort to help out. Here are a few words to the wise:

Coffee

Most groups have coffee alcoves where tea, cocoa, and several kinds of coffee are available. All coffee drinkers (not just the secretaries or some other such barbarism) help out by making coffee. If you are about to consume enough coffee that you would leave less than a full cup in the pot, it is your responsibility to make a fresh pot, following the posted instructions. There are lots of coffee fanatics around, and they get irritated beyond all reason if the coffee situation isn’t working out smoothly. For those coffees for which beans are freshly ground, the local custom is to pipeline grinding and brewing. That is, you are expected to grind a cup of beans while brewing a pot of coffee from the previous load of ground beans. This speeds up the brewing process for everyone, since a load of ground beans is—at least, had better be—always ready when the coffee pot runs out.

Sharing Office Space

Be warned as well that some people are unbelievably picky about the state of their offices. The convention is that any Alto in an empty office is fair game to be borrowed. Private machines may be borrowed only by prior arrangement with their owners, because of the problems of sharing disk space. If you use someone’s office for any reason, take care to put everything back exactly the way it was. Don’t spill crumbs around, or leave your half-empty cocoa cup on the desk, or forget to put the machine back in the state that you found it, or whatever. Of course, lots of people wouldn’t mind even if you were less than fanatically careful. But some people do mind, and there is no point in irritating people unnecessarily.

Sharing printers

When you pick up your output from a printer, it is considered antisocial merely to lift your pages off the top of the output hopper, and leave the rest there. Take a moment to sort the output into the labelled bins. Sorting output is the responsibility of everyone who prints, just as making coffee is the responsibility of everyone who drinks coffee. Check carefully to make sure that you catch every break page: short outputs have a way of going unnoticed, and hence being missorted, especially when they come out right next to a long output in the stack. The rule for determining which bin is to use the first letter that appears in the name on the break page. Thus, "Ramshaw, Lyle" should be sorted under "R", while "Lyle Ramshaw" should be sorted under "L". A trickier question is what to do with output for "Noname", or the like. Following the rule would suggest filing such output under "N", but that doesn’t seem very helpful, since the originator probably won’t find it. Check the contents and file it in the right box if you happen to recognize whose output it is; otherwise, either leave it on top of the printer or stick it back in the output hopper.
The phone system

If you make a significant number of personal long-distance phone calls from Xerox phones, it is your responsibility to arrange to reimburse Xerox for them. This may not be that easy, either, since phone bills take quite a while (six weeks or so) to percolate through the bureaucracy upstairs, and the said bureaucracy also has a lot of trouble figuring out where to send the phone bills of new people, and people who move around a lot. Just because it is easy to steal phone service from Xerox doesn't make it morally right; if you think you aren’t being paid enough, you should start agitating for a raise. If enough suspicious calls are made without restitution, PARC (being a bureaucracy) will impose some bureaucratic “solution” on all of us.

So as not to end on a sour note, let’s discuss how the phone system works, anyway. The offices within PARC have four-digit extensions within the 494 exchange, a system known as Centrex; to dial another office, those four digits suffice. Dialing a single 9 as the first digit gives you an outside line, and you are now a normal customer of Ma Bell: see a phone book for more details (Oh, come now, surely you know about phone books!). Dialing a single 8 gives you different sounding dial tone, and puts you onto the IntelNet (not to be confused with the InterNet). The IntelNet is a Xerox-wide company phone system, complete with its own phone book, and its own phone numbers. If you are calling someone in some remote part of Xerox, you can save Mother Xerox some bread by using the IntelNet instead of going straight out over Ma Bell’s lines. On the other hand, you may not get as good a circuit to talk over--although this situation is frequently said to be improving. Furthermore, through the wonders of modern electronics, you can dial any long-distance number over the IntelNet. Just use the normal area code and Ma Bell number: the circuitry is smart enough to take you as far as possible towards your destination along IntelNet wires, and then switch you over to Ma Bell lines for the rest of the trip. Using the IntelNet doesn’t start to save money until the call is going a fair distance; therefore, the IntelNet doesn’t let you call outside numbers in area codes 408, 415, and 916--better to just dial 9.

One more thing: after you have dialed a number on the IntelNet, you will hear a funny little beeping. At that point, you are being asked to key in a four-digit number to which the call should be billed. You should use the four-digit extension number for your normal office phone under most circumstances. Calls made by dialing 9 instead of 8 are always charged to the phone from which they are placed.

The first three rings (roughly speaking) of an incoming call occur only in your office. The next roughly three rings happen both at your office phone and at a receptionist’s phone, centrally located in the laboratory. During normal business hours, the receptionist’s phones are staffed; thus, someone will at least take a message for you, and leave it on a little slip of paper in your physical message box. If the second three rings go by without either of those two phones answering, the call is then forwarded to the guards desk downstairs (I believe).

If you are expecting a call but won’t be near your normal phone, a call forwarding facility exists: dial 106 and then the number to which you want your calls to be forwarded. Later on (try not to forget), you dial 107 on your normal phone to cancel the forwarding. When I forward my phone, I turn the phone around physically, so that the touch-pad faces the wall. This helps me to remember to cancel the forwarding again later, at which point I turn the phone back the normal way. There is also a way to transfer incoming calls to a different Xerox number: Depress the switch hook once, and dial the destination number; when the destination answers, you will be talking to the destination but the original caller won’t be able to hear your conversation; depressing the switch hook again puts all three of you on the line; then you can hang up when you please. If the destination doesn’t answer, depressing the switch hook once again will flush the annoying ringing or busy signal.

References

Reference numbers in [square brackets] are for conventional hardcopy documents. Many of them are Xerox reports published in blue and white covers; the CSL blue-and-whites are available on bookshelves in the CSL Alcove. Reference numbers in <angle brackets> are for on-line documents. The path name for such files is given herein in the form

[FileServer]\<Directory>\SubDirectory>\FileName.Extension

for backward compatibility with earlier systems. Recently, the simpler alternative form

/FileServer/Directory/SubDirectory/FileName.Extension

has begun to come into local currency, but some systems still demand brackets rather than slashes.

<n>: The generic form for a reference to an on-line document.

[n]: The generic form for a reference to a hardcopy document.

[SUNSET]: Sunset New Western Garden Book. Lane Publishing Company, Menlo Park, CA, 1979. The definitive document on Western gardening for non-botanists; 1200 plant identification drawings; comprehensive Western plant encyclopedia; zoned for all Western climates; plant selection guide in color.

The Call-C-Function MISCN opcode

This opcode calls the specified C function, performing conversion of arguments and result as needed, and returning an indication of any errors it encounters.

\[(\text{MISCN CALL-C Function Conversion-spec Return-Code \&REST Args-To-C-Fn})\]

Function is a Lisp integer (FIXP or SMALLP) containing the address of the function to be called. CALL-C checks for some special values, 0 (meaning the function was never loaded) and -1 (meaning the function was loaded once, and subsequently unloaded at user request), and -2 (meaning that the function has been loaded, but there are unresolved externals).

Conversion-spec specifies how the arguments and function-result are to be converted.

This is a Lisp pointer to a block of 16-bit entries:

\[
\begin{array}{c}
+------------------------+ \\
| Result Conversion Spec | \\
+------------------------+ \\
| Arg 0 Conversion | \\
+------------------------+ \\
| Arg 1 Conversion | \\
+------------------------+ \\
| etc. | \\
+------------------------+ \\
| -0- | \\
+------------------------+ \\
\end{array}
\]

Possible values for the conversion fields:

0 VOID (return only, return NIL)
1 int (Lisp SMALLP/FIXP <=> 32-bit integer)
2 char (Lisp SMALLP/CHARACTER <=> char)
3 float
4 long
5 short
6 lisp
7 cpointer

Return-Code is a FIXP cell into which CALL-C places a return value. Possible values are:

0 Successful call and return
+n conversion error on argument n
-1 conversion error on result
-2 signal encountered while running C??
DEFFOREIGN—Define a foreign function for lisp.

This macro tells Medley about a foreign function—its arguments, what type of result it returns, etc. It also creates a Medley function you can call to invoke the foreign function.

(DEFFOREIGN  Function Result-Type ArgList &KEY :function-name)

Function is a symbol, the Lisp name for the function. Function is given a definition that results in the foreign function being called. Function returns what the foreign function returns, after conversion to a Lisp datatype.

Result-Type is a symbol specifying what type of data the foreign function returns, and how it is to be converted to a Lisp type. Possible values are:

- :void The function returns no interesting value. Function will always return NIL.
- :long
- :short
- :int The function returns an integer. It is converted to a FIXP or a SMALLP.
- :char The function returns a character. It is converted to a SMALLP.
- :float The function returns a floating-point number. It is converted to a Lisp FLOATP.
- :lisp The function returns a lisp-pointer, which isn't converted, but DOES get reference counted.
- :byte ?? same as character, but converted to what??
- :cpointer The function returns a pointer to a block of storage not in the Lisp virtual memory image. This may be a pointer to a C structure, or whatever. It is intended for use with CBLOCKRECORD and DEFCSTRUCT

<c type> Where <C type> is a type defined using DEFCSTRUCT. The result is a pointer to a block of storage no in the Lisp virtual memory image....

ArgList is a list of symbols, each specifying what kind of data the foreign function expects for a given argument. The possible values are as above.

Function-name is a symbol or string containing the true name (as far as the foreign language is concerned) of the function you want to call when the Lisp Function is called.
Chat Streams

A chat stream is a connection between two processes oriented towards terminal service, but not necessarily restricted to that. A chat stream is inherently bi-directional so it is represented by two Interlisp-D streams; one each for input and output. The input stream is considered the primary handle on the connection and is used wherever operations are preformed that are not inherently only input or output. The following operations are available for chat streams (as well as the normal stream operations). In general these operations return true if the operation was successful, NIL if it could not be done:

(CHAT.SETDISPLAYTYPE INSTREAM CODE) tells the remote process that a particular type of terminal (designated by the numeric parameter CODE) is being emulated.

(CHAT.LOGININFO INSTREAM HOST NAME) determines if LOGIN or ATTACH should be used when logging into HOST with username NAME. This fn is only called by CHAT if it knows how to ATTACH. Returns LOGIN, ATTACH, NIL, or WHERE (when there are multiple jobs to attach to).

(CHAT.SENDSCREENPARAMS INSTREAM WIDTH HEIGHT) sends the dimensions of the virtual screen to the remote process.

(CHAT.FLUSH&WAIT INSTREAM) insures that the remote process as seen (but not necessarily acted upon) all data written so far.

(CHAT.OPTIONMENU INSTREAM) returns a MENU of protocol specific options that can be presented to the user.

Adding a new protocol

To add a new type of chat stream a filter function should be added to the list CHAT.PROTOCOLS which, when given a host name, will return a function. When this function is applied to the host name, it should return a dotted pair (INSTREAM . OUTSTREAM). STREAMPROP should be used to associate the methods for implementing the chat stream operations with INSTREAM. The property names are SETDISPLAYTYPE, LOGININFO, FLUSH&WAIT, SENDSCREENPARAMS, and OPTIONMENU. Only methods for implemented operations need be present.

The function (ADD.CHAT.MESSAGE STREAM MSG) is available for getting protocol specific messages to the user. Messages will be typed out on chat window by CHAT, or can be found on the STREAM property MESSAGE by programs. Delimiting white space is added to MSG.

Caveat: CHAT changes the ENDOFSTREAMOP of INSTREAM to return -1 the first time it is called, and then restore the original ENDOFSTREAMOP with the expectation that the -1 will get returned as the value of the BIN that caused the EOS op to be called. While this works for all the protocols I’ve tried so far, it might not work in general. This kludge is necessary in order to avoid the time-consuming alternative of looping on READP and EOFP. It also did not seem appropriate that the chat stream "interface" implement this kludge, though it might be necessary to resort to that.
This proposal represents an attempt to provide a set of control primitives for CommonLoops which will

1) Support the existing Interlisp error handling mechanisms (including ERROR and friends, ERRORSET and friends, RESETLST and friends, ERRORTYPELST, BREAKCHECK and its consequences, and the relationships between ERRORX, FAULT1 and BREAK1, all in the context of spaghetti stacks and the existing process mechanisms;

2) Support the CommonLisp constructs catch, throw, unwindprotect, the relationship of unwindprotect to go and return(-from), error, cerror and warn;

3) Substantially reproduce the functionality of the ZetaLisp signalling facility;

4) Be a reasonably plausible attempt to take the high ground wrt whatever proposals the CommonLisp working party on error handling come up with;

5) Be a Good Thing in its own right.

Needless-to-say trying to satisfy all these goals simultaneously is not possible without some compromises, but I think what follows is a good first cut.

The starting point for this design is the Mesa signal and error mechanism, with one key idea borrowed from ZetaLisp. We start with the notion that it must be possible to unwind the stack, either as a part of non-local transfers of control, or as a consequence of abnormal termination. We add to this the notion that at certain points on the stack we may wish to take some action if such an unwinding is underway. Finally we discriminate between actions mandated at some point on the stack but taking place before the unwinding actually starts, and actions which occur at a point on the stack as the unwinding goes by.

Some terminology is in order at this point.

We call the unwinding process **unwinding**. We call the points on the stack at which action wrt unwinding may be specified Unwind Control Points, or UWCPs for short. The process by which the user or the system announce circumstances which may provoke unwinding is called signalling, and the concrete representation of the circumstances at issue is called a condition. A condition is a CommonLoops class, and should be a sub-type of class Condition.

**Unwind Control Points**

UWCPs are central to this proposal. They provide a vehicle for all activities associated with unwinding, both before the fact in the context of signalling, and as the stack unwinds. A UWCP is created with a call to the spread lambda UWCP:

```
(uwcp body catch exit always-do-exits).
```

Its definition is simple:

```
[progl
 (apply body nil)
 (cond (always-do-exits
        (apply exit '(normal nil)))]
```

but it is what goes on behind the scenes which is important. A UWCP is basically a way of evaluating body (actually applying it as a function of no arguments, to allow for closures) in a context which affects what happens in the case of signalling and/or unwinding occurring within the dynamic extent of that UWCP. If no signalling or unwinding occurs, the value of uwcp is the value of body. If the stack is unwound past this point, `(apply exit '(unwind <condition>))` will be performed on the way past.
This suffices for unwindprotect and RESETLST (note I use (f:l args . body) throughout as short for (function (lambda args . body))):

(unwindprotect form . cleanups) =>
(uwcp (f:l () form)
  nil
  (f:l (exit-key c)
    (selectq exit-key
      ((unwind normal) . cleanups)
      nil))
t)

(RESETLST . forms) =>
(LET ((LISPXHIST LISPXHIST)
       (RESETX RESETVARSLST))
  (DECLARE (SPECVARS RESETX))
  (uwcp (f:l () . forms)
    nil
    (f:l (exit-key c)
      (selectq exit-key
       (normal (RESETRESTORE RESETX))
       (unwind (RESETRESTORE RESETX 'ERROR))
       nil))
t))

RESETSAVE and RESETRESTORE are exactly as before. Note that this means that closures may appear on RESETVARSLST in case of e.g.

(RESETSAVE xx (LIST (f:l ...) yy))

but this is presumably just what is wanted.

Unwinding
The actual unrolling of the stack is performed by the spread lambda UNWIND!:

(unwind! frame exit-key condition).

frame is a stack pointer to the frame to unwind to. condition is an instance of some subclass of Condition, descriptive of what is causing the unwinding. In the simple case frame will be a UWCPoint, in which case exit-key will determine what happens when we get there.

unwind! works by scanning the stack upwards via c-links [Larry - should this be a-links? I notice that e.g. GO and RESET chase a-links, not c-links?] from its own frame until it gets to frame. Along the way, whenever it encounters a UWCPoint, it applies the exit argument of that UWCPoint to (list 'unwind condition). When it gets to frame there are two cases. If frame is a UWCPoint, then the unwinding completes with (retapply frame <the exit argument of frame> (list exit-key condition) t). If frame is not a UWCPoint, then the unwinding completes with (apply exit-key (list frame)). This latter case is for non-local 'go's and 'return(-from)'s, see Note on Non-local Xfers below.

A crucial implementation point is that unwind! releases frame before scanning the stack, and uses raw pointers during its scan. This is to prevent the stack from inadvertently being tied down if some unwind clause pre-empts the unwinding by doing its own non-local transfer, something which cannot (and indeed probably should not) be ruled out. This has the further consequence that if frame is not a UWCPoint then it must be reconstituted before being having exit-key applied to it, see above. What would make sense is for unwind! to be defined to get the raw pointer out of the stack pointer, invoke an opcode which does the actual stack scan in microcode, and then reconstruct the stack pointer and do the final apply or retapply.

Signalling
Conditions are signalled with the spread lambda raise-signal:

\((\text{raise-signal} \ \text{condition} \ \text{can-resume} \ \text{neednt-catch})\).

condition must be an instance of some sub-class of Condition. It identifies the circumstances which provoked the signalling, and may contain relevant parameters. If can-resume is non-nil, then the signal may be resumed, otherwise not (see below). If neednt-catch is non-nil, then the signal need not be caught, otherwise a condition Uncaught will be signalled if it is not caught.

raise-signal works by scanning the stack upwards looking for UWCPPoints. When it finds one it applies the catch argument thereof to (list condition). If the result is nil, it continues the scan. If the result is non-nil we say the signal has been caught at that UWCPPoint.

What happens next depends on the type of the result. If it is not a list it is called the exit key, and raise-signal exits the signal by causing the stack to unwind to the UWCPPoint which caught the signal by calling (unwind! <the UWCPPoint> <the exit key> condition).

If it is a list then its first element is considered a resume value. If can-resume is non-nil, then the resume value is returned as the value of the call to raise-signal, otherwise an error condition CantResume will be signalled.

If the stack is scanned all the way to the top without the signal being caught, then if neednt-catch is non-nil, the value of raise-signal is nil. Otherwise, the condition Uncaught will be signalled, with instance variables recording the parameters to raise-signal. If it is exited, fine. If it is resumed, the value returned is the value of the call to raise-signal. Otherwise a break is caused around the call to raise-signal.

Note that the application of the catch argument at each UWCPPoint is done in the dynamic context of the call to raise-signal, but as the catch argument is lexically in the context of the call to uwcp, if it is a closure its non-special variable references will be to that context.

Three macros are provided for the common cases:

\((\text{signal} \ \text{condition}) \Rightarrow (\text{raise-signal} \ \text{condition} \ \text{t} \ \text{nil})\) - can resume, must be caught

\((\text{error} \ \text{condition}) \Rightarrow (\text{raise-signal} \ \text{condition} \ \text{nil} \ \text{nil})\) - can’t resume, must be caught

\((\text{notify} \ \text{condition}) \Rightarrow (\text{raise-signal} \ \text{condition} \ \text{t} \ \text{t})\) - can resume, needn’t be caught

**ERROR! and ERRORSET**

ERROR! and control-E are now defined as \((\text{error} \ \text{"\text{Abort}"})\), where \text{"\text{Abort}"} is an instance of class Abort.

ERRORSET is now defined as

\((\text{lambda} (\text{form} \ \text{flag})\)

\((\text{uwcp} (f:l () (\text{list} (\text{eval} \ \text{form}))))\)

\((f:l \ (\text{condition}))\)

\((\text{select-type} \ \text{condition})\)

\((\text{Abort} \ \text{t}))\)

\((f:l \ (\text{exit-key} \ \text{condition})\)

\((\text{nil})))\).

\(\text{t}\) is by convention the ‘do-nothing’ exit key. Note the semantics of ERRORSET are subtly changed by this definition. It is no longer the case that ERRORSET flatly stops the stack from unwinding. What it does is catch Abort, which means it short-stops ERROR!/control-E/\text{^}, as it used to, but not unwinding associated with other signals which have been caught overhead. This seems to me to be what is wanted. One could
of course write a catch phrase for Condition to insure catching anything and everything, but that would be pretty dangerous.

**catch and throw**

These CommonLisp functions are implemented in terms of a sub-class of Condition called Throw:

```
(catch tag . body) =>
(uwcp (f:l () body)
  (f:l (condition)
    (select-type condition
      (Throw (cond ((eq condition:tag tag) 'caught)))))
  (f:l (exit-key condition)
    (selectq exit-key
      (caught condition:value)
      nil)))
  (throw tag form) =>
  (let ((value form))
    (raise-signal (create Throw tag_tag value_value) nil nil))
```

**ERROR, ERRORX and BREAKCHECK**

ERROR has a name conflict with the new (and CommonLisp) error - I propose changing its name to old-error and in the short term discriminating on the basis of the type of the first argument. The only change to old-error is that it now passes its nobreak argument on to ERRORX, which passes it to ERRORX2. ERRORX is unchanged except for that. FAULT1 calls ERRORX2 instead of replicating it - more on this later. ERRORX2 calls BREAKCHECK as before, and then constructs an instance of class SystemError, which is a sub-class of condition, including the error number, message, position, BREAKCHK and PRINTMSG as instance variables, and signals it.

At the top of every process there is a UWCPPoint, which inter alia catches Abort, and also handles most of what used to be in ERRORX2. It catches SystemError in order to implement both the built-in and user specified error type list clauses, declining to catch the signal if they don't apply. It catches Uncaught if what wasn't caught was a SystemError, and then either produces the appropriate call to BREAK1 or raises Abort, depending on the recorded value of BREAKCHK. BREAK1, however invoked, signals AboutToBreak before doing anything else. This is all a bit hairy, but the code has been worked out and will be forthcoming.

**Non-Local Transfers of Control**

Lexical scoping of goto tags and block labels in CommonLisp represents a bit of bother in the Interlisp context. For instance

```
(prog     ((damnFun (f:l (arg)
    (if (weird arg)
      then (go bother)
      else (process arg)))))
  (return (unwindprotect (apply* damnFun 'foo) (cleanup)))

bother
  (return 'lost))
```

works not only in the sense that if 'foo is weird, the value of the prog is 'lost, but also that in that case the unwindprotect is observed and cleanup is called. Now I don't understand how closures are to be implemented in CommonLoops, but I assume the following must be true:

1) The interpreter will continue to exist independently of the compiler (if this is false that just simplifies things a bit).
2) There is a way of identifying on the stack lexical scoping boundary points - that is to say, I presume, frames created by the application of a function definition or a non-quoted argument to apply.

3) The definition of function is such that a closure knows of every non-local lexical variable reference, goto tag and block label within it. This implies inter alia that when running interpreted all macros are expanded by function, and that evaluating or compiling calls to function may produce uba, no such tag or no such label errors.

4) The stack entry for a local variable which is referenced by a closure contains not its value but an invisible pointer to a 'free-floating' value cell, which is also pointed to by the closure.

5) When the interpreter needs the value of a lexical variable, it scans the stack up to the first boundary point and no further. The compiler will presumably be pretty much as now - collapsing all bindings upwards to the boundary frame in so far as possible, and building in references to the right points in the right frames.

6) Thus when a closure is applied to anything, a frame can be built which has entries for all its non-local lexical variable references which will do the right thing.

7) A similar, although messier, approach will work for labels and tags. Messier because although such 'free-floating' value cells may persist after their 'home' frame has gone, 'free-floating' labels and tags must be invalidated when the frame they are based on goes away (see e.g. page 41 of the CommonLisp book). Most of this hair is probably necessary simply to allow 'go's from inside nested progs in any case:

   a) Compiled PROG and interpreted \PROG0 frames have two new sorts of entry for tags and labels. Each has two fields, an atom number and a pointer. Every PROG or \PROG0 frame has one tag entry with the atom number for each goto tag it owns, and one label entry for the label of the block, usually nil. In the case where no closures are involved, the pointer field of each entry corresponding to a goto tag contains the appropriate p-counter to transfer to in the case of compiled PROG frames, and the appropriate tail of the PROG body in the case of interpreted \PROG0 frames. The pointer field of the label entry contains nil. By convention (see page 120 of the CommonLisp book) every bounding frame also has a label entry for its frame-name.

   b) When a go, return, or return-from is evaluated, the stack is scanned to the first boundary point looking for an appropriate tag/label entry. When one is found we call

         (unwind! <the frame> (f:l (frame) (do-go frame tag <value of entry>)))

   if evaluating a go, otherwise

         (unwind! <the frame> (f:l (frame) (do-return frame label <value of entry> <arg to return>)))

   c) When a closure is constructed whose body refers to non-local tags or labels, it constructs (or finds, see below) a stack pointer for the frame in which the tag/label is bound, and includes that together with the tag/label in the closure. A pointer to this stack pointer is left in a distinguished part of the frame, so that it can be re-used by other closures, and so that it can be released when the frame goes away. Note that this means it is a special sort of stack pointer, in that its reference to the frame must not be counted.
This also implies an additional cost both in size and time to return for every frame, but I don’t see how it can be avoided.

d) When a closure is applied which includes such tags/labels, tag and label entries containing the appropriate atom numbers and the associated stack pointer are included in the constructed frame.

e) It follows from all this that do-go and do-return implement the distinction between local and non-local transfers. If the value of the entry they are passed is not a stack pointer, then they effect the local transfer, via retfrom for do-return, and by appropriate hacking of the PROG (compiled) or 
PROG0 (interpreted) frame followed by retto in the case of do-go. If they do get a stack pointer, then they convert themselves into the local case by getting the entry from for the tag/label from the frame pointed to, and doing a further unwind! to that frame with an appropriate re-call of themselves as the exit-key argument. Needless-to-say, if the stack pointer has been released, we get an error.

f) All this is unnecessary for compiled transfers which don’t cross any frame boundaries, which can still be coded open.

g) It is not clear to me what will happen in the case of e.g. (eval '(go foo)). If we take the CommonLisp manual seriously, this will fail, as it probably should, because eval will set up a bounding frame with no lexical variables or tags, but then so will most existing uses of eval... I guess this gets beyond what I can reasonably hope to second-guess...

 enable

A special form is provided which will be the standard way of producing UWCPPoints. It is modelled on the Cedar Mesa ENABLE form, and looks like this:

(enable
  c1 => a1 a2 a3 ...  
    . . . 
  cn => n1 n2 n3 ...  
form  
  k1 -> ea1 ea2 ... 
    . . . 
  kn -> en1 en2 ...) 

The double arrow lines above are called catch phrases, the single arrow lines are called exit phrases. Evaluates form so as to catch conditions c1, ... cn if they are signalled during its evaluation. If e.g. c1 is signalled, the forms a1 ... an (the catch phrase for c1) will be evaluated in the context of the call which signalled c1. Catch phrases are implemented with select-type, so the order of the condition names is significant. For a catch phrase to be well formed, all control paths through it must end with one of the following four quit forms:

(exit)
Causes the stack to unwind back through the enclosing enable form, which is exited with value NIL.
(resume form)
Returns from the call which did the signalling with the value of form as the value of that call, if it is resumable, otherwise generates an error.
(goto exit-key)
Causes the stack to unwind back to the enclosing enable form, where the exit phrase for exit-key is evaluated. The value of the last form in the phrase is the value of the enable. Exit phrases are implemented with SELECTQ, so lists of exit keys may precede ->.
(reject)
Causes the signal handling process to act as if the catch phrase had not been there at all.

There is a special exit key whose name is unwind, which has a special meaning. The exit clause for the unwind key will be evaluated whenever the stack unwinds upwards past this point.

There is another special exit key whose name is normal. Its exit clause will be executed in case of a normal return from the enclosed form, without affecting the value of the enable, which will still be the value of the enclosed form.

There is another special exit key whose name is always. always is a just a synonym for (normal unwind). Thus its exit clause will be executed if the stack ever unwinds past it and it will also be executed in case of a normal return from the enclosed form.

Calls to enable translate into calls to uwcp as follows, taking the above template for enable as the input:

(uwcp (f:l () form)
 (f:l (condition)
  (select-type condition
   (c1 a1 a2 a3 ...)
   . . .
   (cn n1 n2 n3 ...))
  (f:l (exit-key condition)
   (selectq exit-key
    (k1 ea1 ea2 ...)
    . . .
    (kn en1 en2 ...)
    (t nil)
    nil))
 <if normal or always appeared then t else nil>)

(exit) =>
 t
(resume form) =>
(list form)
(goto exit-key) =>
(quote exit-key)
(reject) =>
nil

Built in Condition classes
Here follow the definitions of class Condition and its built in sub-classes:

(defstruct Condition "an unspecialised condition")

[Note: It may turn out to be useful to include here instance variables can-resume and neednt-catch which are used instead of the arguments to raise-signal.]
(defstruct (Abort (:include Condition)) "an abort condition")
(defstruct (Throw (:include Condition)) "a condition for throwing to a catch"
  tag value)
(defstruct (SystemError (:include Condition))
  "a condition resulting from a call to ERRORX"
  number message stack-pos breakchk printmsg)
(defstruct (Uncaught (:include Condition))
"a condition resulting from an uncaught signal" condition)
(defstruct (AboutToBreak (:include Condition))
    "a condition signalled by BREAK1 on entry")

Relation to CommonLisp
This proposal supports everything relevant in the CommonLisp book.
Interlisp to Common Lisp Concordia

Chapter 2 IRM (Datatypes)

<table>
<thead>
<tr>
<th>Interlisp Form</th>
<th>Common Lisp Form</th>
</tr>
</thead>
<tbody>
<tr>
<td>(DATATYPES --)</td>
<td>??</td>
</tr>
<tr>
<td>(TYPENAME datum)</td>
<td>??? (type-of datum) -- except for strings and arrays Note that the result types are different, however, and it is necessary to check for literals in the program, e.g., (IL:TYPENAME 123) =&gt; IL:SMALLP yet (IL:TYPE-OF 123) =&gt; LISP:FIXNUM. Also LISP:TYPE-OF is definitely non-portable except for structures.</td>
</tr>
<tr>
<td>(TYPENAMEP datum typename)</td>
<td>??? (typep datum typename) -- except for strings and arrays and the problem of non-portability of the type names.</td>
</tr>
</tbody>
</table>

2.1 Datatype Predicates

For many of these, the translation should look at the value/effect context. If used for effect only, no need to insert the (and (<test> x) x).

- (LITATOM x) (symbolp x)
- (SMALLP x) (and (typep x 'fixnum) x)
- (FIXP x) (and (integerp x) x)
- (FLOATP x) (and (floatp x) x)
- (NUMBERP x) (and (numberp x) x) -- but includes more sorts of numbers
- (ATOM x) (and (or (symbolp x) (numberp x)) x) Often users wrote IL:ATOM when they meant the LISP:ATOM interpretation, however.
- (LISTP x) (and (consp x) x)
- (NLISTP x) (not (consp x)) or (atom x)
- (STRINGP x) (and (stringp x) x)
- (ARRAYP x) ?? How are arrays to be represented? possibly (and (vectorp x) x) BVM - "ARRAYP probably translates as vectorp. Again, the real question is how ARRAY translates, at least when the origin is 1 (the default). You could translate to make-array with a size one greater than specified (wasting the zero element), but then you can’t translate ARRAYSIZE as length. Sigh."
- (HARRYP x) (and (hash-table-p x) x) -- Not quite strong enough since Interlisp hash tables are more general than CL ones BVM - "hash-table-p is probably good enough; it’s the translation of HASH-ARRAY that will need more strength."

2.2 Datatype Equality
(EQ x y) (eq x y)
(NEQ x y) (not (eq x y))
(NULL x) (null x)
(NOT x) (not x)
(EQP x y) (or (eq x y)
(and (numberp x) (number y)
 (= x y)))
Probably (= x y) will suffice in most cases
BVM - "EQP also compares compiled code, but there’s not much hope there."

(EQUAL x y) ??
Probably (equal x y) will suffice in most cases (differ on number comparisons and the CL version descends more datatypes)

(EQUALALL x y) ??
Probably (equalp x y) will suffice in most cases (differ on string comparisons)

2.3 Fast and Destructive Functions

2.4.1 Using Litatoms as Variables

(BOUNDP var) (boundp var)

(SET x y) (set x y)
Note that this is a place where free variable references might "sneak" in and ruin the automatic "only declare special things that are used free." algorithm.

(SETQ x y) (setq x y)

(SETQQ x y) (setq x 'y)

(GETTOPVAL var) ??
(symbol-value atom)
-- no concept to top level value in CL
BVM -- "I would translate GETTOPVAL and SETTOPVAL as symbol-value and set (not identity and setq), with a warning that they're wrong."

(SETTOPVAL var value) ??
(set var value)

(GETATOMVAL atom) (symbol-value atom)
BVM - "[GET|SET]ATOMVAL are exactly symbol-value and set, with the implicit declaration, irrelevant to common lisp, that the variable is not dynamically bound."

(SETATOMVAL atom value) (set var value)

2.4.3 Property Lists

(GETPROP atom prop) (get atom prop)
BVM -- "GETPROP is really (and (symbolp atom) (get atom prop)), though you'll usually want it translated directly as get. Fortunately, PUTPROP does not suffer this brain damage."

(PUTPROP atom prop val) (setf (get atom prop) val)
(ADDPROP atom prop new flg) ??
-- no direction translation (runtime?)
(REMPROP atom prop) (remprop atom prop)
(REMPROPLIST atom prop) ??
-- no direction translation (runtime?)
(CHANGEPROP x prop1 prop2) ??
-- no direction translation (runtime?)
(PROPNAMES atom) ??
-- no direction translation (runtime?)
(DEFLIST l prop) ??
-- no direction translation (runtime?)
LMM -- "Surely obsolete and not necessary."
(GETPROPLIST atom) (symbol-plist atom)
(SETPROPLIST atom list) (setf (symbol-plist atom) list)
(GETLIS x props) ??
(multiple-value-bind (prop value tail)
  (get-properties (symbol-plist x) props)
  tail)

2.4.4 Print Names

Most of this section is extremely problematic -- especially since, although functions may be written that capture much of the semantic content, they tend to much more cons'y then their Interlisp counterparts, hence will disrupt the performance profile of any translated program that exploits these features.

AD -- "I'd be tempted to leave most of the atom-building functions untranslated and flag them as something that the programmer should deal with himself. Except for very simple things, you will probably want to do whatever you were doing with atoms in some other way in CL."

BVM -- "I tend to agree with Andy. However, some of these are common enough that it might be worthwhile having approximate definitions in the library. E.g., write a version of MKATOM that does ordinary strings and numbers (the definition I wrote is close; slightly better might be one that did read-from-string while binding *readtable* to a table in which all the special characters have been given alphabetic syntax). Translate SUBATOM, PACK, PACK* as (MKATOM something), and then just flag all the MKATOMs uniformly.

It doesn't seem worth even trying for UNPACK, as any use is highly likely to need manual intervention anyway."

BVM -- "Given that IL is so willing, and CL so unwilling, to coerce to strings, you might introduce a coerce-to-string macro to make some "translations" more palatable. If the translator knows how to evaluate it for constant forms (such as strings), so much the better."

(MKATOM x) ?? This is hard to capture exactly -- but here's one attempt
(defun mkatom (arg)
  (if (numberp arg)
      arg
      (values
       (intern
        (typecase arg
           (symbol (string arg))
           (string arg)
           (otherwise
            (prin1-to-string arg)))))
  )
)
and another (due to BVM)
(defun mkatom (arg)
  (let ((string (typecase arg
                   (symbol (string arg))
                   (string arg)
                   (otherwise (prin1-to-string arg)))))
    (multiple-value-bind (n end)
      (parse-integer string :junk-allowed t)
      (if (and n (= end (length string)))
        n
        (values (intern string))))))
)

BVM -- "Of course, this still doesn’t do (mkatom "123Q") or
(mkatom "12E3") correctly (yecch)."

(SUBATOM x n m)

Again here’s a (long and cons’y) attempt at translation
(defun subatom (x n &optional (m -1))
  (let* ((string (symbol-name x))
         (start (if (< n 0)
                   (+ (length string) n)
                   (1- n)))
         (end (if (< m 0)
                (+ 1 (length string) m)
                m)))
    (values (intern (subseq string start end))))
)

or

(MKATOM (subseq
          (string x)
          (if (< n 0 )
            (+ (length string) n)
            (1- n))
          (if (< m 0 )
            (+1 (length string) m)
            m)))
)

(PACK x)

But try
(defun pack (arglist)
  (let ((new-arglist
         (mapcar
          #'(lambda (arg)
             (typecase arg
                        (symbol (string arg))
                        (string arg)
                        (otherwise (prin1-to-string arg))))
          arglist)))
    (values (intern (apply #'concatenate 'string new-arglist))))
)

or

(MKATOM
  (apply
   #'concatenate
   'string
   (mapcar
    #'(lambda (arg)
       (typecase arg
                 (symbol (string arg))
                 (string arg)
                 (otherwise
                  (prin1-to-string arg))))))
(PACK* x1 x2 .. xn) 
??
But try
(values
  (intern (apply #'concatenate
    'string
    (mapcar #'princ-to-string
      (list x1 x2 .. xn)))))
or
(MKATOM
  (apply
    #'concatenate
    'string
    (mapcar #'princ-to-string
      (list x1 x2 ".." xn)))))

(UNPACK x flg rdtbl) 
??
But try
(defun unpack (arg)
  (let ((string (typecase arg
    (symbol (string arg))
    (string arg)
    (otherwise (prin1-to-string arg))))
    (result nil)
    (ch nil))
  (with-collection
    (dotimes (i (length string))
      (setq ch (char string i))
      (collect
        (or (digit-char-p ch)
          (intern
            (string (char string i)))))))
)

A more Common Lisp’y version is:
(defun unpack (arg)
  (let ((string
    (typecase arg
      (symbol (string arg))
      (string arg)
      (otherwise (prin1-to-string arg))))
    )
  (coerce string ’list) ))

(DUNPACK x scatchlist flg rdtbl)

"BVM -- "I see no need for DCHCON and DUNPACK to translate
differently than CHCON and UNPACK, though the translations may
want to be flagged (but then, you need to flag them anyway)"

(NCHARS x flg rdtbl) 
??
(defun nchars
  (arg &optional (flg nil)
    (*readtable* *readtable*)
    (length
      (if flg
        (prin1-to-string arg)
        (princ-to-string arg))))
)
If flg is nil, this can be optimized to cut down on the consing.
(NTHCHAR x n flg rdtbl)
??
(let (("*readtable* (or rdtbl "*readtable*))
  (if flg
    (values (intern
      (aref (prin1-to-string x) (1- n))))
    (values (intern
      (aref (princ-to-string x) (1- n))))
  ))
Use of this function almost surely indicates
a stylistic problem -- single letter symbols being
used as character objects

(L-CASE x flg)
??
(typecase x
  (string (if flg
       (string-upcase x)) ;;not quite
    (string-downcase x))
  (symbol
    (values (intern
      (if flg
        (string-upcase x)
        (string-downcase x))))
    (cons
      (mapcar #'L-CASE x)))))

(U-CASE x)
??
(typecase x
  (string (string-upcase x))
  (symbol
    (values (intern
      (string-upcase x))
    (cons
      (mapcar #'U-CASE x)))))

(GENSYM char)
(gensym (if char (string char)))
Although this translation may well in subtle ways

GENNUM
?? -- no corresponding var in Common Lisp

(MAPATOMS fn)
(do-all-symbols (dummy-var)
  (funcall fn dummy-var))
Although do-all-symbols is not guaranteed to touch each symbol only once.

2.4.5 Character Code Functions

This section forces to face squarely the problem of Interlisp’s penchant of representing character objects as symbols with single letter p-names.

(PACKC x)
??
(MKATOM (coerce
  (mapcar #'code-char x) 'string))

(CHCON x flg rdtbl)
??
(mapcar #'(lambda (sym)
    (char (symbol-name sym) 0))
  (UNPACK x flg rdtbl))

(DCHCON x scatchlist flg rdtbl)
"

(NTHCHARCODE x n flg rdtbl)
??
(char-code (char (symbol-name
  (NTHCHAR x n flg rdtbl)) 0))
Not quite right since NTHCHARCODE may return NIL in some circumstances

(CHCON1 x)

??
(char-code (char (symbol-name x) 0))
BVM - "Your translation of CHCON1 oddly assumes the arg is a symbol, rather than an arbitrary printable object"

(CHARACTER n)

??
(MKATOM (string (code-char x)))

(FCHARACTER n)

"

(CHARCODE c)

??
(defun charcode-1 (c)
  (etypecase c
    (symbol
      (case symbol
        (CR 13)
        ...
        (otherwise
          (char-code (char
                        (symbol-name c)
                        0))))))
    (string
      (char-code (char c 0)))
    (cons
      (cons (charcode-1 (car c))
            (charcode-1 (cdr c))))
  )
(defmacro charcode (c)
  (charcode-1 c ))

or in many cases
(char-code "some character object")
BVM - "CHARCODE should probably *always* translate as (char-code #\somechar), to facilitate conversion to the character idiom."

(SELCHARQ e c1 .. cn default)

(defmacro (e &rest args)
  (let ((default (car (last args)))
        (clauses (butlast args 1)))
    '(SELECTQ e
             ,(mapcar #'(lambda (clause)
                           '(, (CHARCODE (car clause)) .
                            ,(cdr clause))) clauses)
             ,default))
)

2.5 Lists

(CONS x y) (cons x y)
(CAR x) (car x)
(CDR x) (cdr x)
(CAAR x) (caar x)
......
(CDDDDR x) (cdddr x)
(RPLACD x y) (rplacd x y)
(FRPLACD x y) "
(RPLACA x y)  (rplaca x y)
(FRPLACA x y)  

(RPLNODE x a d)  (rplacd (rplaca x a) d)
(FRPLNODE x a d)  

(RPLNODE2 x y)  (rplacd (rplaca x (car y)) (cdr y))
(FRPLNODE2 x y)  

2.5.1 Creating Lists

(MKLIST x)  (if (listp x) x (list x))
(LIST x1 x2 .. xn)  (list x1 x2 .. xn)
(APPEND x1 x2 .. xn)  (append x1 x2 .. xn)
(APPEND x)  (copy-list x)
(NCONC x1 x2 .. xn)  (nconc x1 x2 .. xn)
(NCONC1 lst x)  (nconc lst (list x))
(ATTACH x l)  ?? -- probably obsolete
(defun attach (x l)
  (if (null l)
    (cons x l)
    (progn
      (setf (cdr l)
        (cons (car l) (cdr l)))
      (rplaca l x))))

2.5.2 Building Lists from Left to Right

(TCONC ptr x)  ??
(defun tconc (ptr x)
  (let ((head (car ptr))
       (tail (cdr ptr)))
    (if (null head)
      (let ((result (list x)))
        (cons result result))
      (progn
        (setf (cdr ptr)
          (cdr (rplacd tail (list x))))
        ptr))))

(LCONC ptr x)  ??
(defun lconc (ptr x)
  (let ((head (car ptr))
       (tail (cdr ptr)))
    (if (null head)
      (cons x (last x))
      (progn
        (setf (cdr ptr)
          (last (rplacd tail x))))
        ptr))))

(DOCOLLECT item lst)  ??
(ENDCOLLECT item tail)  ??
2.5.3 Copying Lists

(COPY x)  (copy-tree x)
(COPYALL x) ??
(HCOPYALL x) ??

Note from LMM:

"I've no trouble with your LIST translations. Are you sure CL has RPLACD? I thought you have to do (progn (SETF (CDR x) y) x).

I think the Interlisp character functions point up a kind of design choice that will come up again and again, in situations where the fundamental mechanism for getting something done in CL and IL differ.

I think the translator might offer three choices:

(a) leave the functions alone (e.g., translate to IL:DCHCON and IL:MKATOM which are defined in a "compatibility" package). This gives code that works.

(b) produce "interim" translations, which have the same effect, e.g., as you've identified in your last message.

(c) attempt to produce "natural" Common Lisp style (examples follow.)

In the case of an Interlisp program that does PACKC, CHCON, DCHCON, in some cases the "native" CL program would use strings, and others, it would use symbols. (Interlisp programmers use symbols where CL programmers would use strings.)

Usually, the "native" translation of CL functions that deal in character codes is to translate them to deal in character objects. Sometimes, where an IL programmer deals with a list of characters or character codes, the CL programmer would leave it as a string; the problem was that IL didn't have the breadth of sequence functions and so IL programmers would frequently hack lists.

If IL:character/code/atom/list == CL: character/character/string/list

then
(PACKC x) => (coerce 'string x)
(CHCON x) => (coerce 'list x)
(CHCON x flg rdtbl) => (coerce 'list (write-to-string x))

Ignore & flag RDTBL argument

(DCHCON ...) => ignore & use CHCON

(NTHCHARCODE ...) => SCHAR

CHCON1 => SCHAR ... 1

CHARACTER => no-op

FCHARACTER

CHARCODE => use #. \n
SELCHARQ => CASE with #\ as case elements"

2.5.4 Extracting Tails of Lists
(TAILP x y) (tailp x y)

(NTH x n) ((lambda (list index) (nthcdr (1- index) list)) x n)
BVM - "NTH returns tails, is one-based and has stupid behavior for n < 1"

(FNTH x n) "

(LAST x) (last x)
Although the behavior of last on non-list is not defined

(FLAST x) "

(NLEFT l n tail) ??
(defun nleft (l n tail)
  (if (and tail (tailp tail l))
      (let* ((length (length l))
             (sub-length (length tail))
             (diff (- length sub-length n))
             (if (>= diff 0)
                 (dotimes (i diff l)
                       (setq l (cdr l))))
      )
BVM - "The CL translation of the Interlisp definition of NLEFT would be substantially better than the one you give."

(LASTN l n) ?? is LASTN destructive?

2.5.5 Counting List Cells

EQLENGTH, COUNTDOWN, and EQUALN are applicable to circular lists.
BVM - "I think worrying about il:equal is a waste of energy. The subtle difference between il:equal and cl:equal should be globally noted as a potential, albeit unlikely, source of incompatibility."

(LENGTH x) (length x)
Although length is only defined for true lists

(FLENGTH x) "

(EQLENGTH x n) (eql (length x) n)
Although would fail to return if x were circular
BVM - "For its non-circularity consideration, a more faithful translation might be ((lambda (tail) (and (consp tail) (atom (cdr tail)))) (nthcdr (1- n) x)), but it is less obvious what is going on."

(COUNT x) ??
(defun count (x)
  (+ (length x)
      (let ((sum 0))
        (dolist (a x)
          (if (consp a)
              (incf sum (count a)))))))
)

(COUNTDOWN x n) ??

(EQUALN x y depth) ??
(defun equaln (x y depth)
(cond ((eq depth 0) t)
  ((consp x)
   (and (consp y)
     (equaln (car x) (car y) (1- depth)))
      (t
        (and (not (consp y))
          (equal x y)))))))

NB equal not equivalent to IL:EQUAL

2.5.6 Logical Operators

(LDIFF x y) (ldiff x y)
Except if y is not a tail of x. (LDIFF would signal an error in this case while ldiff would return (copy-list x))
NB -- if y is nil (LDIFF x y) - x
BVM - "You might want to recognize the idiom (LDIFF lst (NLEFT lst n)) as (butlast lst n)"

(LDIFFERENCE x y) (set-difference x y :test #'equal)
NB. equal is not equivalent to IL:EQUAL.

(INTERSECTION x y) (intersection x y :test #'equal)
NB. equal is not equivalent to IL:EQUAL.
Elimination of duplicate entries is not guaranteed by CLtL.
BVM - "The fact that INTERSECTION advertises duplicate removal suggests that the conservative translation should be (remove-duplicates (intersection x y :test #'equal) :test #'equal)"
BVM - "Recognize the common idiom (INTERSECTION x x) as (remove-duplicates x :test #'equal)"

(UNION x y) (union x y :test #'equal)
NB. equal is not equivalent to IL:EQUAL.
Again -- treatment of duplicate entries may not be identical.

2.5.7 Searching Lists

(MEMB x y) (member x y :test #'eq)
Not defined if y is not a true list

(FMEMB x y) "

(MEMBER x y) (member x y :test #'equal)
NB. equal is not equivalent to IL:EQUAL

(EQMEMB x y) (or (eq x y) (and (consp y)
  (member x y :test #'eq)))

2.5.8 Substitution Functions

(SUBST new old expr) (subst new old expr :test #'equal)
NB. equal is not equivalent to IL:EQUAL.
With this translation, if new is a consp, then new will NOT be copied on each substitution.

(DSUBST new old expr) (nsubst new old expr :test #'equal)
Same caveat as for SUBST

(LSUBST new old expr) ??
(sort of an nconc subst)
(SUBLIS alst expr flg)
(if (null flg)
  (sublis alst expr :test #'equal)
??)
NB. The usual equal caveat holds. If (eq flg t) then SUBLIS is required
to cons an entirely new tree

(DSUBLIS alst expr flg)
(if (null flg)
  (nsublis alst expr :test #'equal)
??)
Same caveat as SUBLIS

(SUBPAIR old new expr flg)
??
ignoring flg and the strange behavior with respect to non-nil final tails
of old, roughly equivalent to:
(sublis (mapcar #'cons old new) expr :test #'equal)

2.5.9 Association Lists and Property Lists

(ASSOC key alst)
(assoc key alst :test #'eq)
But not equivalent if alst is not a true list

BVM - "For ASSOC, DREMOVE, etc, I think you should use test eql
instead of eq (in fact, isn't that the default in cl?). This is actually a
more widespread and difficult problem with translating IL code--the
hidden assumption that a substantial class of integers are immediate
and hence testable by eq."

JOP - "I'm not sure I agree with the rational for using eql rather than eq
in ASSOC (and friends), for the following reasons: (a) the keys for
ASSOC (etc.) are usually symbols, and (b) Although not explicitly
stated in CLtL -- it's probably fairly safe to assume that eq comparisons
are valid for fixnums."

BVM - "I thought CLtL did explicitly state (p. 193) that it is NOT safe
to assume that eq comparisons are valid for fixnums. This is not to say
that I am aware of any implementations in which eql fixnums are not
eq. However, there are certainly implementations in which the fixnum
range is considerably smaller than ours, another subtle obstacle in
porting. As for your point (a), it is my impression that people are fairly
sloppy about whether assoc keys are symbols or not. Aside from all
that, there's a reason that CLtL's default for assoc, etc, is eql. I think
that translating il:assoc directly as cl:assoc is appropriate style; at
worst, it performs slightly less efficiently than with an eq test, but you
know it won't be wrong."

LMM - "The decision of EQ vs EQL in ASSOC is probably one of
those decisions to made interactively at translation time..."

(FASSOC key alst)
"

(SASSOC key alst)
(assoc key alst :test #'equal)
Usual caveat about equal -- non NIL tails of alst

(PUTASSOC key val alst)
??
(defun putassoc (key val alst)
  (let ((entry (assoc key alst :test #'eq)))
    (if entry
      (setf (cdr entry) val)
      (progn (nconc alst (cons key val))
        val)))
)
LMM - "I’ve found on more than one occasion that to do a "natural" translation, I wound up changing an ALIST into a property list, e.g., so I could use (SETF (GETF x y) z) instead of (PUTASSOC x y z)."

(LISTGET lst prop) (GETF lst prop)

(LISTPUT lst prop val) (SETF (GETF lst prop) val)

(LISTGET1 lst prop) (CDR (MEMBER prop lst :TEST #'EQ))

NB. Order of evaluation not preserved

(LISTPUT1 lst prop val) (SETF (CDR (MEMBER prop lst :TEST #'EQ)) val)

NB. Order of evaluation not preserved

2.5.10 Other List Functions

(REMOVE x l) (REMOVE x l :TEST #'EQUAL)

NB. equal not equivalent to IL:EQUAL

(DREMOVE x l) (DELETE x l :TEST #'EQ)

Not guaranteed to return an eq list if the result is non-nil

(REVERSE l) (REVERSE l)

Not equivalent if l is not a list

(DREVERSE l) (NREVERSE l)

Same caveat as REVERSE

2.6 Strings

Some thorny issues arise here. Among them: (a.) Some Interlisp string functions will clearly not be applicable to all types of strings (eg GNC GLC), (b.) Some agreement must be attained between the allowable set of character objects and string-chars -- this may confine us to the 96 standard characters, excluding control characters, NS characters, etc. (c.) Reusing string headers is a fairly inoperative idea -- although doable if the reusable string is adjustable (d.) It may be nice to have some general technology for mapping from a index-origin-one indexing scheme to a index-origin-zero indexing scheme. This may include fairly global source modifications

2.7 Arrays

Suppose Interlisp arrays are represented by Common Lisp vectors, then two strategies present themselves for
translation of the array facilities.
a.) Perform everywhere suitable subtractions -- but attempt global code simplification
b.) Use an addition vector cell and preserve origin-1 indexing
I will attempt to list translations appropriate for both strategies

NB. The index origin of a translated Interlisp vector will not be knowable at run-time.

BVM - "Since you can’t tell by looking at a call to ELT or SETA whether the array is 0- or 1-origin, you can only use
method "a" (subtract 1 from all indices) if the user is willing to globally declare "I never use zero-origin arrays". Note
that when using method "b", you have to inflate the size of the vector by 1 even on calls to ARRAY with origin
constant zero, unless you never care about ARRAYSIZE translating correctly."

Interlisp array element-types may be translated as follows

BIT   bit
BYTE (unsigned-byte 8)
WORD (unsigned-byte 16)
FLOATP float
POINTER t
DOUBLEPOINTER ??
XPOINTER ??
FLAG (member t nil)
(BITS n) (unsigned-byte n)
FIXP (signed-byte 32) or t
SIGNEDWORD (signed-byte 16)

One might imagine two functions -- translate-type and inverse-translate-type -- to move from Interlisp types to
Common Lisp types and back again

(ARRAY size type init)  a.) (make-array size :element-type
                      (translate-type type) :initial-element
                      init)
b.) (make-array (1+ size) :element-type
                      (translate-type type) :initial-element
                      init)
Of course, if the array origin is explicitly specified as zero (0), then
translation a.) may always be employed
(ELT a n)  
  a.) (aref a (1- n))  
  b.) (aref a n)  

(SETA a n v)  
  a.) (setf (aref a (1- n)) v)  
  b.) (setf (aref a n) v)  

(ARRAYTYP a)  
  (inverse-translate-type  
      (array-element-type a))  

(ARRAYSIZE a)  
  a.) (array-total-size a)  
  b.) (1- (array-total-size a))  

(ARRAYORIG a)  
  ??  
  always 1?  
  BVM - "I can’t imagine any use for ARRAYORIG other than as an ORIGIN argument to ARRAY, where it will be fine to throw it out; any other use is untranslatable. Well, maybe some index checker would use it, in which case zero would be a safe translation."  

(COPYARRAY a)  
  (copy-seq a)  

(ARRAYP a)  
  (vectorp a)  

2.7 Arrays Interlisp-10 Arrays

Probably, no functions in this section need be supported by the translator. I list those not mentioned elsewhere here for completeness.

(ELTD a n)  
  ??  
  BVM - "ELTD and SETD can only be used on arrays of type DOUBLEPOINTER. You could tediously translate them as index (+ n (/ (1- (length a)) 2) 1), but it doesn’t seem worth it. ARRAYBEG is blatantly untranslatable."

(SETD a n v)  
  ??

(ARRAYBEG a)  
  ??

2.8 Hash Arrays

Interlisp Harryp’s will most likely be represented as Common Lisp hash-tables even though Interlisp Harryp’s support options more extensive then those of their counterparts.

BVM - "All the hash functions need to watch out for harray = NIL for the bogus SYHASHARRAY feature. Probably a global note in the translator’s guide is sufficient; anyone who actually wrote a program depending on the feature deserves to lose."

(HARRAY len)  
  (make-hash-table :size len :test #’eq)  
  or  
  (make-hash-table :size len)  
  BVM - "In the case of HARRAY, you need to watch out for (list (harray len)) and (cons (harray len) overflow) and turn them into (make-hash-table :size len :rehash-size overflow). HARRAY all by itself is strictly speaking untranslatable, because it implicitly has overflow action ERROR."

(HASHARRAY minkeys)  
  "

(HASHARRAY minkeys overflow )  
  (make-hash-table :size minkeys :rehash-size overflow)  
  BVM - "I believe the overflow arg to HASHARRAY is a superset of
the allowable values to :rehash-size, though the commonly-used numeric values are compatible (hasharray also supports the values ERROR and arbitrary function)."

(HASHARRAY minkeys overflow nil nil nil rehash-threshold)
(make-hash-table :size minkeys :rehash-size overflow :rehash-threshold rehash-threshold)

(HASHARRAY minkeys overflow hashbitsfns equivfn nil nil rehash-threshold)
(make-hash-table :size minkeys :test (get-know-test-fn hashbitsfns equivfn) :rehash-size overflow :rehash-threshold rehash-threshold)

(HARRAYSIZE harray)
??

(CLRHASH harray)
(clrhash harray)

(PUTHASH key val harray)
((lambda (x y z)
    (if y (setf (gethash x z) y)
        (remhash x z)))
    key val harray)
BVM - "This is another good place for a simplifier, since val=nil is usually a constant. (Unfortunately, you can rarely get rid of the remhash arm--only if the value being stored is a non-nil constant.)"

(GETHASH key harray)
(values (gethash key harray))
BVM - "I hope the simplifier knows about eliminating (values &) in non-mv context."

(REHASH oldharray newharray)
??

(MAPHASH harray maphfn)
((lambda (x y)
    (maphash #'(lambda (key val) (funcall y val key)) x))
    harray maphfn)
BVM - "Yet another place where a simplifier with sufficient smarts about lambdas would make the translation more pleasant in the common case where the maphfn is a lambda expression. Alternatively, arrange for the translator to manually permute the arg list."

(DMPHASH harray1 ... harrayn)
(progn (print '(setq harray1 ,harray1))
    ...
    (print '(setq harrayn ,harrayn)))

(HARRAYPROP harray prop)
??
BVM - ".. the only instance of which we can translate is (HARRAYPROP a 'NUMKEYS) => (hash-table-count a)."

(HARRAYPROP harray prop nv)
??

2.9 Numeric and Arithmetic Functions

Since Common Lisp arithmetic functions are fully generic -- the type specific Interlisp arithmetic functions pose a problem. They can either be a.) Correctly translated with a substantial cost in performance and complexity or b.) incorrectly translated to their generic counterparts. I will give translation for both possibilities.

BVM - "I suspect most people will want the type-specific operations to translate generically (in code I've looked at, I virtually always do), even though this will occasionally cause subtle bugs."

There may be redundancy in the following section for completeness.

Many of the following predicates could be simplified in a test context.

(SMALLP x)
((lambda (x) (and (typep x 'fixnum) x))) x)
(FIXP x) ((lambda (x) (and (integerp x) x)) x)

(FLOATP x) ((lambda (x) (and (floatp x) x)) x)

(NUMBERP x) ((lambda (x) (and (numberp x) x)) x)

MIN.SMALLP
MAX.SMALLP
   most-negative-fixnum
   most-positive-fixnum
   BVM - "MAX.SMALLP is often used as a synonym for 2^16-1, so this translation should be flagged."

MIN.FIXP
MAX.FIXP
   ??

MIN.INTEGER
MAX.INTEGER
   ??
   BVM - "MIN.INTEGER & MAX.INTEGER are obviously untranslatable, but I think we've even de-documented them."

(OVERFLOW flg) ??

  )
Daybreak Software Installation and Operation

This document is preliminary. It probably won't really be the way things work when the product is released.

The power switch and reset button are located on the front of the daybreak. There is no "ALT-B" button to specify alternate booting choices. Instead, the blank function keys along the top of the keyboard are used to specify the boot device.

When the daybreak is first turned on, the screen will be filled with a gray pattern with a solid white cursor in the upper left corner. Press one of the function keys according to the following table:

- F1: Disk boot (Lisp)
- F2: Floppy boot (doesn't work)
- F3: Ethernet boot
- F4: Alternate ether boot
- F5: Diagnostic Disk boot
- F6: Diagnostic Floppy boot
- F7: Diagnostic Ether boot
- F8: Reserved

Getting into Othello:

To get into othello, boot the machine then do an Alternate Etherboot-6 by pressing F4 followed by the number 6 (not F6 and not the keypad’s 6). Sometime later, the cursor will change to 0900 and Othello will come up.

Installing Lisp:

The physical volume is partitioned into at least 3 volumes for Lisp.

- uCode: This is where the Lisp microcode lives (about 150 pages)
- Lisp: Where the sysout lives.
- LispFiles: For those who want to use the local file system.

Lisp booting on the daybreak is similar to Mesa, so the microcode is stored as "Pilot Microcode" and there is a dummy "germ" file which is there just so the microcode can load something for the germ.

To bring up a new lisp on a fresh volume, do the following:

```
> Initial Microcode Fetch
Drive Name: RD0
File Name: <LispCore>Dove>DiskInitialDove.db

> Germ Fetch
Logical Volume Name: uCode
File Name: <LispCore>Dove>Dummy.Germ

> Lisp Microcode Fetch
Logical Volume Name: uCode
File Name: <LispCore>Dove>LispDove.db
```

Finally, fetching the Lisp sysout is more or less normal:

```
> Lisp Sysout Fetch
Logical Volume Name: Lisp
```
File Name: <LispCore>Next>Full.sysout
Shall I expand this lisp to fill the volume? Yes
Shall I make this the default? Yes

To boot Lisp:

Press the reset button and then press F1

Lisp caveats:

If you need the local file system, do:

(DEFINEQ (MACHINETYPE ())'QUOTE DOVE))
then DIR DSK or (CREATEDSKDIRECTORY 'LISPFILES)

MACHINETYPE will return DOVE later, but the file system’s eventfn crashes on daybreaks and I’m afraid to touch the file system code to disable it any other way.

LOGOUT doesn’t work right. If you want to save work and resume it later, do a SAVEVM. However, if you want to resume a frozen sysout, it must be expanded and the file system must be disabled (redefine MACHINETYPE to return DAYBREAK).

If the ethernet seems to go away, use (RESTART.ETHER) to start it up again.

Lots of programs like LAFITE create their status windows off the screen.

I’m not sure what will happen if you SYSOUT from a daybreak and load into a DLion/dorado.
The Implementation of Device-Independent Graphics Through Imagestreams

The Interlisp-D system does all image creation through a set of functions and data structures for device-independent graphics, known popularly as DIG. DIG is achieved through the use of a special flavor of stream, known as an imagestream.

An imagestream, by convention, is any stream that has its IMAGEOPS field (described in detail below) set to a vector of meaningful graphical operations. Using imagestreams, we can write programs that draw and print on an output stream without regard to the underlying device, be it window, disk, Dover, 8044 or Diablo printers. For example, the following have imagestreams backing them: windows, Press streams, Interpress streams, and Iris streams.

Imagestream structure

As indicated above, imagestreams use a field that no other stream does: IMAGEOPS. IMAGEOPS is an instance of the IMAGEOPS datatype, and contains a vector of the stream’s graphical methods. The methods contained in the IMAGEOPS can make arbitrary use of the stream’s IMAGEDATA field, which is provided for their use, and may contain any data needed.

IMAGEOPS

The IMAGEOPS datatype has the following fields:

IMAGETYPE The name of image type. Monochrome display streams have an IMAGETYPE of DISPLAY; color display streams are identified as (COLOR DISPLAY). The IMAGETYPE is informational, and can be set to anything the implementor chooses.

IMFONTCREATE The device name to pass to FONTCREATE when fonts are created for the stream.

The following fields are all stream methods, and are presented with their arguments, in the manner of a function definition. With the exception of IMCLOSEFN, each method that follows has a corresponding function that consists of the method’s name with the "IM" prefix removed. All coordinates that refer to points in a display device’s space are measured in the device’s units. (The IMSCALE method provides access to a device’s scale.)

(IMCLOSEFN STREAM)

What to do before stream is CLOSEFed, e.g. flush buffers, write header or trailer information, etc.

(IMDRAWLINE STREAM X1 Y1 X2 Y2 WIDTH OPERATION COLOR)

Draws a line of width WIDTH from (X1, Y1) to (X2, Y2). (Dashing is currently handled at a higher level, and thus is not an argument).

(IMDRAWCURVE STREAM KNOTS CLOSED BRUSH DASHING)

Draws a curve through KNOTS.

(IMDRAWCIRCLE STREAM CENTERX CENTERY RADIUS BRUSH DASHING)

Draws a circle of radius RADIUS around (CENTERX, CENTERY).

(IMDRAWELLIPSE STREAM CENTERX CENTERY SEMIMINORRADIUS SEMIMAJORRADIUS ORIENTATION BRUSH DASHING)
Draws an ellipse around (CENTERX, CENTERY).

(IMFILLCIRCLE STREAM CENTERX CENTERY RADIUS TEXTURE)

Draws a circle filled with texture TEXTURE around (CENTERX, CENTERY).

(IMBLTSHADE TEXTURE STREAM DESTINATIONLEFT DESTINATIONBOTTOM WIDTH HEIGHT OPERATION CLIPPINGREGION)

The texture-source case of BITBLT. DESTINATIONLEFT, DESTINATIONBOTTOM, WIDTH, HEIGHT, and CLIPPINGREGION are measured in STREAM’s units. This method is invoked by the functions BITBLT and BLTSHADE.

(IMBITBLT SOURCEBITMAP SOURCELEFT SOURCEBOTTOM STREAM DESTINATIONLEFT DESTINATIONBOTTOM WIDTH HEIGHT SOURCETYPE OPERATION TEXTURE CLIPPINGREGION CLIPPEDSOURCELEFT CLIPPEDSOURCEBOTTOM)

The bitmap-source cases of BITBLT. SOURCELEFT, SOURCEBOTTOM, CLIPPEDSOURCELEFT, CLIPPEDSOURCEBOTTOM, WIDTH, and HEIGHT are measured in pixels; DESTINATIONLEFT, DESTINATIONBOTTOM, and CLIPPINGREGION are in the units of the destination stream.

(IMSCALEDBITBLT SOURCEBITMAP SOURCELEFT SOURCEBOTTOM STREAM DESTINATIONLEFT DESTINATIONBOTTOM WIDTH HEIGHT SOURCETYPE OPERATION TEXTURE CLIPPINGREGION CLIPPEDSOURCELEFT CLIPPEDSOURCEBOTTOM SCALE)

A scaled version of IMBITBLT. Each pixel in SOURCEBITMAP is replicated SCALE times in the X and Y directions; currently, SCALE must be an integer.

(IMMOVETO STREAM X Y)

Move to (X,Y). This method is invoked by the functions MOVETO and RELMOVETO. If it is not supplied, a default method composed of calls to the IMXPOSITION and IMYPOSITION methods is used.

(IMTERPRI STREAM)

(As yet unused.) Issue a newline. When implemented, this method will be invoked by the function TERPRI. It defaults to (\OUTCHAR STREAM (CHARCODE EOL)).

(IMSTRINGWIDTH STREAM STR RDTBL)

Returns the width of string STR in STREAM’s units, using STREAM’s current font. If this method is not supplied, it defaults to calling \STRINGWIDTH.GENERIC.

(IMCHARWIDTH STREAM CHARCODE)

Returns the width of character CHARCODE in STREAM’s units. If this method is not supplied, it defaults to calling \STRINGWIDTH.GENERIC.

The following methods all have corresponding DSPxx functions (e.g. IMYPOSITION corresponds to DSPYPOSITION) that invoke them. They also have the property that they return their previous value; when called with NIL they return the old value without changing it.

(IMXPOSITION STREAM XPOSITION)

Sets new x-position on STREAM.

(IMYPOSITION STREAM YPOSITION)

Sets new y-position on STREAM.

(IMFONT STREAM FONT)

Sets STREAM’s font to be FONT.
(IMLEFTMARGIN STREAM LEFTMARGIN)

Sets STREAM's left margin to be LEFTMARGIN. The left margin is defined as the x position set after newline.

(IMRIGHTMARGIN STREAM RIGHTMARGIN)

Sets STREAM's right margin to be RIGHTMARGIN. The right margin is defined as the maximum x position at which characters will be printed; printing beyond it causes a newline.

(INLINEFEED STREAM DELTA)

Sets STREAM's linefeed distance (distance to move vertically after a newline) to be DELTA.

(INNEWPAGE STREAM)

Causes a new page to be started; the position is set to (DSPLEFTMARGIN, DSPTOPMARGIN). If not supplied, defaults to (\OUTCHAR STREAM (CHARCODE ^L)).

(IMSCALE STREAM SCALE)

Returns the number of device points per screen point (a screen point being ~1/72 inch). In a later release of Interlisp-D the conversion factor will be specifiable. (I.e. right now SCALE is ignored.)

(IMTOPMARGIN STREAM YPOSITION)

Sets STREAM's top margin (the y-position of the tops of characters that is set after newpage) to be YPOSITION.

(IMBOTTOMMARGIN STREAM YPOSITION)

Sets STREAM's bottom margin (the y-position beyond which any printing causes a newpage) to be YPOSITION.

(IMSPACEFACTOR STREAM FACTOR)

Sets the amount by which to multiply the natural width of all following space characters on STREAM: used for justification of text. The default value is 1. For example, if the natural width of a space in STREAM's current font is 12 units, and the spacefactor is set to 2, spaces will appear 24 units wide. The values returned by STRINGWIDTH and CHARWIDTH will also be affected.

(IMOPERATION STREAM OPERATION)

Sets the default BITBLT OPERATION argument. See the DSPOPERATION and BITBLT documentation for more information.

(IMBACKCOLOR STREAM COLOR)

Sets the background color of STREAM.

(IMCOLOR STREAM COLOR)

Sets the default color of STREAM.

In addition to the IMAGEOPS-borne methods described above, there are two other important methods, which are contained in the stream itself.

STRMBOUTFN [Stream Method]
Function called by BOUT. You can install a STRMBOUTFN in a stream STREAM using the form (replace (STREAM STRMBOUTFN) of STREAM with (FUNCTION MYBOUTFN)).

OUTCHARFN  [Stream Method]

This is the function that is called to output a single byte. This is like STRMBOUTFN, except for being one level higher: it is intended for text output. Hence, this function should convert (CHARCODE EOL) into the stream's actual end of line sequence, and should adjust the stream’s CHARPOSITION appropriately before invoking the stream’s STRMBOUTFN (by calling BOUT) to actually put the character. Defaults to \FILEOUTCHARFN, which is definitely NOT what you want. OUTCHARFNs are installed using a form like (replace (STREAM OUTCHARFN) of STREAM with (FUNCTION MYOUTCHARFN)).

IMAGEDATA  [Record field]

Used to hold data pertaining to this type of imagestream; the content is completely up to the implementor. For Interpress devices, this is an instance of the datatype INTERPRESSDATA; for Press, PRESSDATA; for the display, \DISPLAYDATA.

Creating imagestreams

(OPENIMAGESTREAM FILE IMAGETYPE OPTIONS)  [function]

Opens and returns an output stream of type IMAGETYPE (PRESS, INTERPRESS, DISPLAY or other types) on a destination specified by FILE. FILE can name a file either on a normal storage device or on a printer device. In the latter case, the file is sent to the printer when the stream is closed. Because of the way that defaulted arguments are interpreted, OPENIMAGESTREAM provides a convenient and standard interface for interpreting user output-destination specifications.

If IMAGETYPE is NIL, the image type is inferred from the extension field of FILE and the EXTENSIONS properties in the list PRINTFILETYPES. Thus, a PRESS extension denotes a Press-format stream, while IP, IPR, and INTERPRESS indicate Interpress format. If FILE has no extension but is a file on the printer device \{LPT\}, then IMAGETYPE will be the type that the indicated printer can print. If FILE has no extension but is not on the printer device, then IMAGETYPE will default to the type accepted by the first printer on DEFAULTPRINTINGHOST.

FILE = NIL is equivalent to FILE = \{LPT\}. Names for printer files are of the form \{LPT\}PRINTERNAME.TYPE, where PRINTERNAME, TYPE, or both may be omitted. PRINTERNAME is the name of the particular printer to which the file will be transmitted on closing; it defaults to the first printer on DEFAULTPRINTINGHOST that can print IMAGETYPE files. As just described, the TYPE extension supplies the IMAGETYPE when it is defaulted. OPENIMAGESTREAM will generate an error if the specified printer does not accept the kind of file specified by IMAGETYPE.

Examples assuming IP: is an Interpress printer, P is a Press printer, and DEFAULTPRINTINGHOST is (IP: P):

(OPENIMAGESTREAM) returns an Interpress image stream on printer IP:

(OPENIMAGESTREAM NIL 'PRESS) returns a Press stream on P

(OPENIMAGESTREAM '{LPT}.INTERPRESS) returns an Interpress stream on IP:

(OPENIMAGESTREAM '{CORE}FOO.PRESS) returns a Press stream on the file \{CORE\}FOO.PRESS

For completeness and consistency, if IMAGETYPE is inferred to be DISPLAY, then the user is prompted for a window to open. The file name in this case will be used as the title of the window.
OPTIONS is a list in property list format that may be used to specify certain attributes of the image stream; not all attributes are meaningful or interpreted by all types of streams. Among the properties are:

REGION value is the region on the page (in stream scale units, 0,0 being the lower-left corner of the page) that text will fill up. It establishes the initial values for DSPLEFTMARGIN, DSPRIGHTMARGIN, DSPBOTTOMMARGIN and DSPTOPMARGIN.

FONTS value is a list of fonts that are expected to be used in the stream. Some streams (e.g. Interpress) are more efficient if the expected fonts are called out in advance, but this is not necessary. The first font in this list will be the initial font of the stream, otherwise the DEFAULTFONT for that image type will be used.

HEADING the heading to be placed automatically on each page, NIL means no heading.

IMAGESCHEMA (a-list)

Describes how to create a stream for a given image type. Contains OPENSTREAM, FONTCREATE, FONTSAVAILABLE methods. The main a-list is indexed by the image-stream type name (e.g., DISPLAY, PRESS, or INTERPRESS) to get another a-list that associates device-dependent functions with generic operation names.

Format of a single a-list entry:

(imagetype
  (OPENSTREAM function-to-open-the-stream)
  (FONTCREATE function-to-create-a-fontdescriptor)
  (FONTSAVAILABLE function-to-return-available-fonts))

For example, for Interpress, the a-list entry is:

(INTERPRESS
  (OPENSTREAM OPENIPSTREAM)
  (FONTCREATE CREATEINTERPRESSFONT)
  (FONTSAVAILABLE SEARCHINTERPRESSFONTS))

The OPENSTREAM function is called with arguments:

(openstreamfn FILE OPTIONS)

FILE is the file name as it was passed to OPENIMAGESTREAM, and OPTIONS is the OPTIONS property list passed to OPENIMAGESTREAM. The result must be a stream of the appropriate imagetype.

The FONTCREATE function is called with arguments:

(fontcreatefn FAMILY SIZE FACE ROTATION DEVICE)

FAMILY is the family name for the font, e.g. MODERN. SIZE is the body size of the font, in printer’s points. FACE is a 3-element list describing the weight, slope, and expansion of the face desired, e.g. (MEDIUM ITALIC EXPANDED). ROTATION is how much the font is to be rotated from the normal orientation, in minutes of arc. For example, to print a landscape page, fonts would have rotation 5400 (=90 degrees). The function’s result must be a FONTDESCRIPTOR with the fields filled in appropriately.

The FONTSAVAILABLE function is called with arguments:

(fontavailablefn FAMILY SIZE FACE ROTATION DEVICE)

This function returns a list of all fonts agreeing with the FAMILY, SIZE, FACE, and ROTATION arguments; any of them may be wildcarded (i.e. equal to ‘*’, which means "any"). Each
element of the list should be a 5-tuple of the form (FAMILY SIZE FACE ROTATION DEVICE).

Where the function looks is an implementation decision: the fontsavailablefn for the display device looks at DISPLAYFONTDIRECTORIES, the Interpress code looks on INTERPRESSFONTDIRECTORIES, and implementors of new devices should feel free to introduce new search path variables.

**Imagestream predicates**

(IMAGESTREAMP X IMAGETYPE) [function]

Returns X (possibly coerced to a stream) if it is an output image stream of type IMAGETYPE (or of any type if IMAGETYPE = NIL), otherwise NIL.

(IMAGESTREAMTYPE STREAM) [function]

Returns the image type of STREAM.

(IMAGESTREAMTYPEP STREAM TYPE) [function]

Returns T if STREAM is an imagestream of type TYPE.

**Creating your own flavor of imagestream**

In accomplishing a task as complex as building a new flavor of imagestream, no document can contain all of the answers, tricks, or shortcuts. There is no substitute for studying a working implementation in doing your own. Therefore, we recommend you look at the FX80STREAM package as an example of how to create a new imaging device. FX80STREAM is a DIG interface for the Epson FX-80 printer – a device simple enough to drive that its details will not obscure the fundamentals of how its imagestream works.
The dld-link SUBR opcode

This opcode links in a relocatable object file or a library file. The return value is an error code.

(SUBR DLD-LINK path)

Path is the path of the file to be loaded expressed as a string.

Return-Code is a FIXP cell into which DLD-LINK places a return value. See below for possible values.

Opcode is #0250
The dld-unlink-by-file SUBR opcode

This opcode unlinks in a relocatable object file or a library file. The return value is an error code.

(SUBR DLD-UNLINK-BY-FILE string hard-flag)

String is the name of the file to be unlinked. Hard-flag is zero if the file shouldn’t be unlinked if it is referenced by others. A nonzero value means that the file should be unlinked regardless of other references.

Return-Code is a FIXP cell. See below for possible values.

Opcode is #o251
The dld-unlink-by-symbol SUBR opcode

This opcode unlinks in a relocatable object file or a library file. The return value is an error code.

(SUBR DLD-UNLINK-BY-SYMBOL string)

String is the name of a symbol contained in the file to be unlinked. Hard-flag is zero if the file shouldn’t be unlinked if it is referenced by others. A nonzero value means that the file should be unlinked regardless of other references.

Return-Code is a FIXP cell. See below for possible values.

Opcode is #0252
The dld-get-symbol SUBR opcode

This opcode returns a pointer to a symbol in C-space.

(SUBR DLD-GET-SYMBOL string)

String is the name of a symbol.

Opcode is #o253
The dld-get-func SUBR opcode

This opcode returns a pointer to a function in C-space.

(SUBR DLD-GET-FUNC string)

String is the name of a function.

Opcode is #0254
The dld-function-executable-p SUBR opcode

This opcode returns 0 if the function contains undefined references.

(SUBR DLD-FUNCTION-EXECUTABLE-P string)

String is the name of a function.

Opcode is #o255
The dld-list-undefined-sym SUBR opcode

This opcode returns a list of the undefined symbols in the system.

(SUBR DLD-LIST-UNDEFINED-SYM)

Opcode is #0256
The dld-create-reference SUBR opcode

This opcode forces the system to load the library containing this symbol.

(SUBR DLD-CREATE-REFERENCE string)

Fasl format change log.

Version 3 (10-Nov-86)
   Added opcode 149, FASL-INTERLISP-SYMBOL pname(V).
   Upward compatible with version 2.
INTRODUCTION

You are reading the Introduction. First comes a section on the low level 1108 floppy implementation. This includes discussion of FLOPPYIOCBs, DISKADDRESSes, and FLOPPYRESULTs. The low level floppy command functions are described in this section.

Next comes a section on Pilot floppy basics. This section describes file device \PFLOPPYFDEV and the functions installed on \PFLOPPYFDEV which are called by generic FILEIO functions. We describe the peculiar marker pages (PMPAGES)...

LOW LEVEL FLOPPY

This section describes the lowest level code of the 1108 FLOPPY implementation.

Miscellaneous Global Variables

\FLOPPY.CYLINDERS (Variable)

\FLOPPY.TRACKSPERCYLINDER (Variable)

\FLOPPY.SECTORSPERTRACK (Variable)

The number of cylinders on the floppy, the number of tracks per cylinder on the floppy, and the number of sectors per track in the DATA part of the floppy. On the 1108, \FLOPPY.CYLINDERS=77, \FLOPPY.TRACKSPERCYLINDER=2, and \FLOPPY.SECTORSPERTRACK=15. Some of these values are different for the 1186.

\FLOPPYIOCB and 1108 Input Output Control Blocks

\FLOPPYIOCB (Variable)

Points to the 1108 floppy input output control block. Lisp is run by the CP Central Processor and must communicate via the input output control block to the IOP Input Output Processor the various floppy commands that need to be executed.

It will appear that \FLOPPYIOCB is bound to CURSORBITMAP.EM. This is just a peculiarity of how the Lisp virtual memory works.

An input output control block looks like

FLOPPYIOCB (Datatype)
(DATATYPE FLOPPYIOCB
  ((\BUFFERLOLOC WORD)
   (\BUFFERHILOC WORD)
   (NIL WORD)
   (SECTORLENGTHDIV2 WORD)
   (TROYORIBM BITS 12)
   (DENSITY BITS 4)
   (DISKADDRESS FIXP)
   (SECTORCOUNT WORD)
   (FLOPPYRESULT WORD)
   (SAMEPAGE FLAG)
   (COMMAND BITS 15)
   (SUBCOMMAND WORD)
   (SECTORLENGTHDIV4 BITS 8)
   (ENCODEDSECTORLENGTH BITS 8)
   (SECTORSPERTRACK BITS 8)
   (GAP3 BITS 8)
   (NIL 3 WORD)))

The Lisp code sets up and the IOP reads all fields except for FLOPPYRESULT. The IOP sets and the Lisp code reads the FLOPPYRESULT.

\BUFFERHILOC and \BUFFERLOLOC are the high and low part of the pointer to the page that is being read from or being written to if any. We are not able to put (BUFFER POINTER) instead of (BUFFERLOLOC WORD) and (BUFFERHILOC WORD) because \BUFFERHILOC and \BUFFERLOLOC occur in the wrong order. The reason for this is that Mesa pointers are swapped and Lisp pointers are not.

SECTORLENGTHDIV2 is the length in bytes of the sectors being read or written divided by 2.

TROYORIBM is always IBM.

DENSITY is usually DOUBLE. DENSITY is SINGLE for track CYLINDER=0, HEAD=0 on Pilot floppy.

DISKADDRESS is a FIXP encoding a CYLINDER+HEAD+SECTOR combination. Each DISKADDRESS points to a page (aka sector) on the floppy. The particular format of DISKADDRESSes is described elsewhere in this document.

SECTORCOUNT is looked at by the IOP only when the COMMAND is to format the floppy. SECTORCOUNT indicates how many tracks to format.

FLOPPYRESULT is the status result word which is set by the IOP. The FLOPPYRESULT is a set of flags which can be usefully inspected with the FLOPPYRESULT BLOCKRECORD described elsewhere in this document.

SAMEPAGE is always NIL.

COMMAND can be any of the following constants

C.NOP (Constant)
C.READSECTOR (Constant)
C.WRITESECTOR (Constant)
C.FORMATTRACK (Constant)
C.RECALIBRATE (Constant)
C.INITIALIZE (Constant)

SUBCOMMAND is always SC.NOP.

GAP3, SECTORLENGTHDIV4, ENCODEDSECTORLENGTH, and SECTORSPERTRACK are obscure numbers that need to be set up for the IOP when COMMAND is to format.

1108 Floppy DISKADDRESSes

Locations of pages on a floppy are referred to by the hardware by cylinder+head+sector number combinations called DISKADDRESSes. DISKADDRESSes are represented by FIXPs and are accessed and created with the help of the record declaration

DISKADDRESS (Accessfns)

(ACCESSFNS DISKADDRESS
  (CYLINDER (LRSH DATUM 16))
  (HEAD (LRSH (LOGAND DATUM 65535) 8))
  (SECTOR (LOGAND DATUM 255))
  (CREATE (IPLUS (LLSH CYLINDER 16)
             (LLSH HEAD 8)
             SECTOR)))

CYLINDER can be between 0 and \FLOPPY.CYLINDERS.

HEAD can be 0 or 1 to indicate which side of the floppy should be read.

The part of the floppy pointed to by a CYLINDER+HEAD combination is known as a track. Each track contains a certain amount of redundant operation for self checking purposes conducted by the IOP assembly language code plus actual data stored in pages called sectors.

SECTOR can be between 1 and 15 for tracks that are formatted IBM double density 512 bytes per sector. The upper limit for SECTOR is determined according to the formatting of the track as given by the following table

<table>
<thead>
<tr>
<th>Format</th>
<th>Number of Sectors</th>
</tr>
</thead>
<tbody>
<tr>
<td>IBM S128</td>
<td>26</td>
</tr>
<tr>
<td>IBM S256</td>
<td>15</td>
</tr>
<tr>
<td>IBM S512</td>
<td>8</td>
</tr>
<tr>
<td>IBM S1024</td>
<td>4</td>
</tr>
<tr>
<td>IBM D128</td>
<td>36</td>
</tr>
<tr>
<td>IBM D256</td>
<td>26</td>
</tr>
<tr>
<td>IBM D512</td>
<td>15</td>
</tr>
<tr>
<td>IBM D1024</td>
<td>8</td>
</tr>
</tbody>
</table>

The table above can be found coded into the function \FLOPPY.SECTORSPERTRACK.

Pilot converts between Pilot page numbers and DISKADDRESSes by using the functions \PFLOPPY.PAGENOTODISKADDRESS and \PFLOPPY.DISKADDRESSTOPAGENO.
\FLOPPYRESULT and 1108 Result Words

\FLOPPYRESULT (Variable)

Points to the 1108 floppy result word offsetted into the \FLOPPYIOCB input output control block. Lisp is run by the CP Central Processor and must communicate via the input output control block to the IOP Input Output Processor the various floppy commands that need to be executed. After a command is executed, the Lsip code looks at the status word to see if any error conditions were signalled indicating a failed operation.

It will appear that \FLOPPYRESULT is bound to MOUSEX.EM. This is just a peculiarity of how the Lisp virtual memory works.

An 1108 result word looks like

\FLOPPYRESULT (Blockrecord)

(BLOCKRECORD \FLOPPYRESULT
  ((DOOROPENED FLAG)
   (MPERROR FLAG)
   (TWOSIDED FLAG)
   (DISKID FLAG)
   (ERROR FLAG)
   (NIL FLAG)
   (RECALIBRATEERROR FLAG)
   (DATALOST FLAG)
   (NOTREADY FLAG)
   (WRITEPROTECT FLAG)
   (DELETEDDATA FLAG)
   (RECORDNOTFOUND FLAG)
   (CRCERROR FLAG)
   (TRACK0 FLAG)
   (NIL FLAG)
   (BUSY FLAG)))

It should be pointed out that some of the error bits in the \FLOPPYRESULT are a bit noisy. Certain errors turn out to be transients that can be overcome simply by reissuing the last command. The bits MPERROR and CRCERROR are notably noisy. The Lisp code takes the first occurrence of certain errors as an indication that perhaps the floppy drive has lost its way and needs to be recalibrated. In that case, a recalibrate command is issued and then the command that failed is tried again. After sufficient retrying of a command that fails (the amount of retrying depending on the kind of command and the particular settings of the error bits), the bad news is announced to the user. Most of this retrying and so on has been determined empirically and is coded into the function \FLOPPY.RUN.

DOOROPENED is T if the floppy drive door has opened since the last floppy command. This is an error condition which has to be cleared. (When DOOREOPENED gets set, ERROR also gets set.) To clear this bit, an INITIALIZE command must be issued.

MPERROR is T if the IOP floppy handler tried to crash the machine. We suspect this condition gets set from time to time because of bugs in the IOP assembly language code written by OSD. The MPERROR feature is a patch on top of the OSD assembly language code installed by Mitch Lichtenberg. Instead of crashing the machine the flag MPERROR now gets set and Lisp deals with that. It has turned out to be the case that reissuing the
last command to the IOP without change invariably works. When 
MPERROR is set to T, the remainder of the FLOPPYRESULT word 
is treated as an error code instead of the flags DOOROPENED, 
TWOSIDED, DISKID, ..., BUSY. The MPCODEs stored in the 
remainder of the FLOPPYRESULT word can be

580 Domino NoValidCommand Error
581 Domino UnImplFloppyCmd Error
582 Domino InvalidEscapeCmd Error
583 Domino CommandTrack Error
584 Domino TrackToBig Error
585 Domino BadDmaChannel Error
586 Domino NoDmaEndCount1 Error
587 Domino NoDmaEndCount2 Error
597 Domino Error In NOOP Patch
598 Domino Error in Reset Patch

TWOSIDED is T if the floppy is two sided.

DISKID = T if the floppy drive is Schogart Associated model SA850 
and NIL if the floppy drive is Schogart Associated model SA800.

ERROR = T if there was an error in trying to perform the last 
command issued to the IOP. To clear this bit, an INITIALIZE 
command must be issued.

RECALIBRATERROR = T if there was an error while recalibrating I 
suppose. I don’t think I’ve ever seen this flag set in practice except 
perhaps if you issue a recalibrate command when there is no floppy 
in the floppy drive. The Lisp code in that situation would tend to 
error out on a command preceding any recalibration.

DATALOST = T problem reading or writing. Maybe the track of the 
floppy which is being read from or written into isn’t formatted in the 
way that was expected.

NOTREADY = T implies the IOP is not ready I guess. I’m not sure 
I’ve ever seen this.

WRITEPROTECT = T means the floppy is writeprotected. Any 
attempt to write on the floppy will fail so the Lisp code checks 
whether this flag is on and signals an error if need be before 
attempting to open an output stream or format a floppy.

DELETEDDATA = I have no idea.

RECORDNOTFOUND = T problem reading or writing. Maybe the 
track of the floppy which is being read from or written into isn’t 
formatted in the way that was expected.

CRCERROR = Cyclic Redundancy Check. There is redundant 
information on the floppy which serves as a check to the IOP 
assembly language code that the floppy drive head is where it is 
supposed to be. This error bit is a bit noisy and spurious 
CRCERRORs can be overcome by reissuing the last command to 
the IOP. If after several retries the CRCERROR has not gone 
away, then the CRCERROR is treated as real and the user is hit 
with the bad news. A hard CRCERROR is caused by the track of 
the floppy which is being read from or written into not being 
formatted in the way that was expected.
TRACK0 = T after a recalibrate command. Says that the recalibrate successfully found CYLINDER=0 I guess. Not really paid attention to by the Lisp code.

BUSY = T implies the IOP is busy I guess. I'm not sure if this would mean that the IOP is still preocessing the most recently issued command or not. The official way to wait for the IOP to finish the most recently issued command is with the loop

\[
\text{while (NOT (ZEROP (fetch (IOPAGE DLFLOPPYCMD) of \IOPAGE)))) do (BLOCK))
\]

Low Level 1108 Floppy Command Functions

\(\text{\textbackslash FLOPPY\textbackslash RUN FLOPPYIOCB NOERROR)\)

This function makes the IOP really go.

FLOPPYIOCB should already be prepared by other functions like \FLOPPY.NOP, \FLOPPY.READSECTOR, \FLOPPY.WRITESECTOR, \FLOPPY.FORMATTRACKS, \FLOPPY.RECALIBRATE, or \FLOPPY.INITIALIZE described below.

First, if there is a buffer involved (the command is to read or to write), the buffer is locked down by calling the function \FLOPPY.LOCK.BUFFER.

Next, the FLOPPYIOCB passed in is BLTed on to FLOPPYIOCB. FLOPPYIOCB points to the beginning of the 16 words in real memory that the IOP will look at and interpret as an input output control block to be processed.

Next, the IOP is notified that there is an input output control block in need of processing via

\[
\text{(replace (IOPAGE DLFLOPPYCMD) of \IOPAGE with \FLOPPYIOCBADDR)}
\]

The IOP periodically looks at the \IOPAGE for things to do and acts when it sees a nonzero DLFLOPPYCMD field in the \IOPAGE. After replacing the DLFLOPPYCMD field in the \IOPAGE, the Lisp code must wait until the IOP finishes via the loop

\[
\text{(while (NOT (ZEROP (fetch (IOPAGE DLFLOPPYCMD) of \IOPAGE))) do (BLOCK))}
\]

After this loop finishes, FLOPPY.RUN looks at the FLOPPYRESULT result word to see if any error flags have been set by the IOP. Supposing things have gone well, FLOPPY.UNLOCK.BUFFER is called to unlock the buffer (if any) pointed to by the FLOPPYIOCB and FLOPPY.RUN returns T indicating success.

If error bits in the FLOPPYRESULT result word have been set, then FLOPPY.RUN may try to recover in certain ways. This may involve reissuing a command and/or some intervening recalibration commands.

If an error persists, then FLOPPY.RUN returns NIL if NOERROR = T and otherwise a break and an error message happen to the user.
(\FLOPPY.LOCK.BUFFER FLOPPYIOCB)

Calls \LOCKPAGES on the buffer pointed to by the FLOPPYIOCB \BUFFERLOLOC and \BUFFERHILOC fields. It is necessary that
the buffer be locked down before a command can be issued to the
IOP. This function also does \GETBASEing and \PUTBASEing into
the BUFFER to make the BUFFER look dirty to the IOP. This is
known as "touching pages". A reasonable person would think that
this touching ought not to be forced on the Lisp floppy handler, but
that's just the way it is. If the Lisp floppy handler doesn't touch the
buffer, the IOP will sometimes cause a fatal 510 crash.
\FLOPPY.LOCK.BUFFER gets called by \FLOPPY.RUN before a
command to the IOP is allowed to begin executing.

(\FLOPPY.UNLOCK.BUFFER FLOPPYIOCB)

Calls \UNLOCKPAGES on the buffer pointed to by the
FLOPPYIOCB. \FLOPPY.UNLOCK.BUFFER gets called by
\FLOPPY.RUN after a command to the IOP has finished executing.

(\FLOPPY.NOP NOERROR)

Calls \FLOPPY.RUN to perform a NOP command. This command
can be used to get the state of the DOOROPENED and
WRITEPROTECT flags of the \FLOPPYRESULT without doing
actual operations.

(\FLOPPY.READSECTOR FLOPPYIOCB DISKADDRESS PAGE
NOERROR)

Calls \FLOPPY.RUN to perform a read. PAGE should be a virtual
memor page VMEMPAGEP. Typically PAGE is a virtual memory
page that has worked its way down from FILEIO functions to
\FLOPPY.READSECTOR via the functions \PFLOPPY.READPAGES and \PFLOPPY.READPAGENO.
FLOPPYIOCB will normally be \FLOPPY.IBMD512.FLOPPYIOCB.
Data at the page of the floppy located at DISKADDRESS is read
into PAGE.

(\FLOPPY.WRITESECTOR FLOPPYIOCB DISKADDRESS PAGE
NOERROR)

Calls \FLOPPY.RUN to perform a write. PAGE should be a virtual
memor page VMEMPAGEP. Typically PAGE is a virtual memory
page that has worked its way down from FILEIO functions to
\FLOPPY.WRITESECTOR via the functions \PFLOPPY.WRITEPAGES and \PFLOPPY.WRITEPAGENO.
FLOPPYIOCB will normally be \FLOPPY.IBMD512.FLOPPYIOCB.
The contents of PAGE are written into the page of the floppy
located at DISKADDRESS.

(\FLOPPY.FORMATTRACKS FLOPPYIOCB DISKADDRESS KOUNT
NOERROR)

Calls \FLOPPY.RUN to perform formatting. This function will
format KOUNT tracks on the
(fetch (DISKADDRESS HEAD) of DISKADDRESS)
side of the floppy beginning with cylinder
(fetch (DISKADDRESS CYLINDER) of DISKADDRESS)
The quantity (fetch (DISKADDRESS SECTOR) of DISKADDRESS) is ignored for purposes of formatting.

KOUNT is spelled with a K just because COUNT is a CLISP word and CLISP gets in your way if you spell the word with a C.

The kind of formatting that takes place depends on the kind of FLOPPYIOCB. If FLOPPYIOCB is /FLOPPY.IBMD512,FLOPPYIOCB, then tracks are formatted IBM double density 512 bytes per sector. If FLOPPYIOCB is /FLOPPY.IBMD256,FLOPPYIOCB, then tracks are formatted IBM double density 256 bytes per sector. If FLOPPYIOCB is /FLOPPY.IBMS128,FLOPPYIOCB, then tracks are formatted IBM single density 128 bytes per sector.

Pilot floppies are formatted this way:

CYLINDER=0, HEAD=0 => IBMS128 format

CYLINDER=0, HEAD=1 => IBMD256 format

CYLINDER >0, HEAD=0 or 1 => IBMD512 format

(FLOPPY.RECALIBRATE NOERROR)

This function is called to ask the floppy drive hardware to recalibrate itself. The floppy drive head positions itself over tracks on a floppy with the aid of a stepping motor which steps in from CYLINDER=0 which is specially recognizable. The stepping motor can slip some and it is occasionally necessary to ask the floppy drive hardware to recalibrate itself which means refind CYLINDER=0. CYLINDER = 0 is kind of a light pole on a very dark street for the floppy hardware. Once the hardware is back in the light of CYLINDER = 0, it knows where it is again.

/FLOPPY.RECALIBRATE is sometimes called by the Lisp implementation after certain errors are detected while performing normal commands like reading and writing. The assumption in those situations is that the stepping motor has slipped some and that recalibrating will make things well enough again that the command which failed will succeed if it is reissued after the recalibration. (Of course, after enough times of trying this strategy, the error just has to be announced to the user.)

/FLOPPY.RECALIBRATE is also called at the beginning of certain major operations. For example, /FLOPPY.RECALIBRATE is called several times by the formatting function /PFLOPPY.FORMAT. After all, if we're going to format a floppy which involves writing on to the floppy, we want to do the best job we can.

(FLOPPY.INITIALIZE NOERROR)

/FLOPPY.INITIALIZE initializes the IOP assembly language code floppy handler which Lisp must talk with. This function has to be the first function that is called when FLOPPY is started up. Thus, /FLOPPY.EVENTFN calls /FLOPPY.INITIALIZE after coming back from a LOGOUT, SYSOUT, MAKESYS, or SAVEVM.

/FLOPPY.INITIALIZE also has to be called to clear error conditions as they arise. This might happen, for example, if the user tries to read from the floppy drive but the floppy drive door is open or there is no floppy. This would set the DOOROPENED error bit in the
To clear these error conditions like DOOROPENED, FLOPPY.INITIALIZE needs to be called.

PILOT FLOPPY

This section describes the connection between FLOPPY and FILEIO. FILEIO is the system source file that makes device independent part of operations like OPENSTREAM, READ, PRINT, CLOSEF, RENAMEFILE, DELFILE, and DIRECTORY possible. FILEIO ultimately winds up calling functions stored in the fields of file device records.

\PFLOPPYFDEV

The major FDEV record for floppy is bound to \PFLOPPYFDEV. At the time of this writing, \PFLOPPYFDEV looks like the following image:

(FDEV)#66,3400 Inspector

Pilot Floppy FDEV Functions

The following FLOPPY functions can be called by FILEIO

\(\text{\(\text{\textbackslash PFLOPPY.OPENFILE\ FILE\ ACCESS\ RECOG\ OTHERINFO\ FDEV\ OLDSTREAM}\)}\)

Gets called when FILEIO opens a stream for input or output. If input, then \(\text{\textbackslash PFLOPPY.OPENOLDFILE}\) eventually gets called. If output, then \(\text{\textbackslash PFLOPPY.OPENNEWFILE}\) eventually gets called.

\(\text{\textbackslash PFLOPPY.OPENFILE}\) returns a stream datatype. The DEVICE of the stream will be \(\text{\textbackslash PFLOPPYFDEV}\). Two other fields on the stream, F1 and F2, point to the allocation record (PFALLOC) and leader page (PLPAGE) for the stream. The PFALLOC and PLPAGE can be conveniently accessed by using the FLOPPYSTREAM ACCESSFNS. When other floppy functions are passed the stream to work with, FLOPPY looks at the arguments passed, the fields of the stream, and the fields of the PFALLOC and PLPAGE to determine how to act.

\(\text{\textbackslash PFLOPPY.DIR.GET}\) is called to search for the allocation record of an old FILE. \(\text{\textbackslash PFLOPPY.DIR.PUT}\) is called to store the allocation record of a newly created file.

\(\text{\textbackslash PFLOPPY.READPAGES\ STREAM\ FIRSTPAGE#\ BUFFERS}\)

Reads sectors off floppy into virtual memory pages BUFFERS. FIRSTPAGE# is in FILEIO’s scheme of counting the pages of a file, beginning with 0 for the first page of a file. \(\text{\textbackslash PFLOPPY.READPAGES}\) therefore fills BUFFERS with data read from the floppy beginning with the FIRSTPAGE# of STREAM.

FIRSTPAGE# is in FILEIO’s scheme of counting the pages of a file. FILEIO page numbers are converted into Pilot page numbers lying somewhere between \(\text{\textbackslash PFLOPPYFIRSTDATAPAGE}\) and \(\text{\textbackslash PFLOPPYLASTDATAPAGE}\). Pilot page numbers are in turn converted into DISKADDRESSes which record head, sector, and cylinder of a page on a floppy.

\(\text{\textbackslash PFLOPPY.READPAGES}\) calls \(\text{\textbackslash FLOPPY.READPAGE}\) which computes a Pilot page number from the stream’s PFALLOC and the FILEIO page number passed in as an argument.
\FLOPPY.READPAGE calls \PFLOPPY.PAGENOTODISKADDRESS to convert the Pilot page number into a DISKADDRESS and then calls \FLOPPY.READSECTOR to read the sector at the computed disk address.

\(\text{\{\PFLOPPY.WRITEPAGES STREAM FIRSTPAGE# BUFFERS\}}\)

Other than that writing is taking place instead of reading, \PFLOPPY.WRITEPAGES is similar to \PFLOPPY.READPAGES.

Writes contents of virtual memory pages BUFFERS on to sectors of floppyfills BUFFERS with data. FIRSTPAGE# is in FILEIO’s scheme of counting the pages of a file, beginning with 0 for the first page of a file. \PFLOPPY.WRITEPAGES therefore writes to the floppy beginning with the location corresponding to the FIRSTPAGE# of STREAM.

FIRSTPAGE# is in FILEIO’s scheme of counting the pages of a file. FILEIO page numbers are converted into Pilot page numbers lying somewhere between \PFLOPPYFIRSTDATAPAGE and \PFLOPPYLASTDATAPAGE. Pilot page numbers are in turn converted into DISKADDRESSes which record head, sector, and cylinder of a page on a floppy.

\PFLOPPY.WRITEPAGES calls \FLOPPY.WRITEPAGE which computes a Pilot page number from the stream’s PFALLOC and the FILEIO page number passed in as an argument.

\FLOPPY.WRITEPAGE calls \PFLOPPY.PAGENOTODISKADDRESS to convert the Pilot page number into a DISKADDRESS and then calls \FLOPPY.WRITESECTOR to write the sector at the computed disk address.

\(\text{\{\PFLOPPY.TRUNCATEFILE FILE LASTPAGE LASTOFFSET\}}\)

Called just before closing an output file. The effect as far as FLOPPY is concerned is to take the allocation record (PFALLOC) for FILE and split the allocation record into two records if necessary. The first PFALLOC created this way is just big enough to store the truncated file. The second PFALLOC created this way becomes a free block. Since FLOPPY does not know how big an output file will turn out to be when it is first opened, FLOPPY must go through the process of allocating a reasonable size block, growing the block on occasion when \PFLOPPY.WRITEPAGES is about to cause the block to overflow, and finally truncate--i.e. split--the block into actual file and free block when \PFLOPPY.TRUNCATEFILE gets called.

\PFLOPPY.TRUNCATEFILE calls \PFLOPPY.TRUNCATE which does the actual splitting of a PFALLOC. \PFLOPPY.TRUNCATE splits a PFALLOC into two PFALLOCs equal to file and free block. The list of PFALLOCs cached on the floppy file device is updated and sufficiently many \PFLOPPY.WRITEPAGENO\s of new or updated Pilot marker pages are written out to the floppy.

\(\text{\{\PFLOPPY.CLOSEFILE FILE\}}\)

Called to close a file. Writes out the leader page (PLPAGE) of FILE and the two marker pages that go around the leader page+ file.

\(\text{\{\PFLOPPY.DELETEFILE FILE FDEV\}}\)
Called to delete a file. \PFLOPPY.DIR.GET gets called to search for the allocation record for FILE. \PFLOPPY.DIR.REMOVE gets called to remove the allocation record from the cached directory alist. \PFLOPPY.DEALLOCATE gets called to turn the removed PFALLOC into a free block. The two marker pages surrounding FILE are updated to indicate that there is a free block between the marker pages and then they are written out. (Otherwise, at least until the free block gets used for other purposes, the contents of the file are still there, but have become inaccessible.)

\(\text{\(\text{\texttt{\textbackslash PFLOPPY\textbackslash NAMEFILE OLDDEVICE OLDFILE NEWDEVICE NEWFILE OLDRECOG NEWRECOG}}\text{\texttt{)}}\text{\texttt{)}}\)
Called to rename a file. \PFLOPPY.DIR.GET gets called to search for the allocation record for FILE. The PFALLOC found in the directory alist is removed with \PFLOPPY.DIR.REMOVE and then reentered with \PFLOPPY.DIR.PUT under the new file name which \PFLOPPY.RENAMEFILE computes. Finally, the leader page for the PFALLOC is changed to have the new file name and then is written out to the floppy.

\(\text{\(\text{\texttt{\textbackslash PFLOPPY\textbackslash GETFILEINFO FILE ATTRIBUTE FDEV}}\text{\texttt{)}}\text{\texttt{)}}\)
Called by GETFILEINFO. All file attributes like WRITEDATE, CREATIONDATE, LENGTH, and TYPE are stored on the leader page of a file. \PFLOPPY.GETFILEINFO returns values, sometimes suitably converted, out of the leader page.

\(\text{\(\text{\texttt{\textbackslash PFLOPPY\textbackslash SETFILEINFO FILE ATTRIBUTE VALUE}}\text{\texttt{)}}\text{\texttt{)}}\)
Called by SETFILEINFO. All file attributes like WRITEDATE, CREATIONDATE, LENGTH, and TYPE are stored on the leader page of a file. The VALUE for ATTRIBUTE, sometimes suitably converted, is stored into the leader page. The updated leader page is then written out to the floppy if FILE is not open. (If FILE is open then the leader page will be written out to the floppy when FILE is closed.)

\(\text{\(\text{\texttt{\textbackslash PFLOPPY\textbackslash GETFILENAME FILE RECOG FDEV}}\text{\texttt{)}}\text{\texttt{)}}\)
Called by FINDFILE and INFLEP. This function can get called if \(\text{\(\texttt{\textbackslash FLOPPY}\)}\) (or a directory name like \(\text{\(\texttt{\textbackslash FLOPPY}\text{\textless MYDIR}\text{\texttt{\rangle}}\)}\) is on the user's DIRECTORIES search path. When a function like OPENSTREAM fails to find a file on the user's connected directory, \PFLOPPY.GETFILENAME may get asked about FILE to see if FILE is on \(\text{\(\texttt{\textbackslash FLOPPY}\)}\).

\PFLOPPY.GETFILENAME is coded very similar to \PFLOPPY.DIR.GET which searches the floating directory alist stored in (fetch (PFLOPPYFDEV DIR) of \texttt{\textbackslash FLOPPYFDEV}).

\PFLOPPY.GETFILENAME returns NIL if no file is found. NIL is also returned if there is no floppy in the floppy drive or if there is no floppy drive on the machine that the user is using.

\(\text{\(\text{\texttt{\textbackslash PFLOPPY\textbackslash GENERATEFILES FDEV PATTERN DESIREDPROPS OPTIONS}}\text{\texttt{)}}\text{\texttt{)}}\)
Called by DIRECTORY and the DIR LISPXMACRO. Like all corresponding GENERATEFILES functions installed on other file devices, \PFLOPPY.GENERATEFILES returns a file generator FILEGENOBJ which is a record that contains a GENFILESTATE
plus two function names--in FLOPPY's case, PFLOPPY.NEXTFILEFN and PFLOPPY.FILEINFOFN.

The GENFILESTATE is a record that amounts to a stack of all the desired FLOPPY files according to the PATTERN, DESIREDPROPS, and OPTIONS that have been supplied. The files that go into the GENFILESTATE are collected by walking along the floppy directory alist which is stored on (fetch (PFLOPPYFDEV DIR) of \FLOPPYFDEV). A lot of the work is done by calling the function DIRECTORY.MATCH.

PFLOPPY.NEXTFILEFN takes a GENFILESTATE, pops a file name out of the GENFILESTATE which also side effects the GENFILESTATE, and then returns the file name. If the GENFILESTATE has gone empty, then PFLOPPY.NEXTFILEFN just returns NIL.

PFLOPPY.FILEINFOFN is asked to supply information about the file that is at the top of the GENFILESTATE stack. This is done quite easily by calling the same function (PFLOPPY.GETFILEINFO1) that PFLOPPY.GETFILEINFO calls.

(FLOPPY.HOSTNAMEP NAME FDEV)

This kind of function is intended for file devices that have nicknames. The HOSTNAMEP functions get called when the user specifies a file name containing a nickname as the host part of the file name. Since {FLOPPY} doesn't have any nicknames, FLOPPY.HOSTNAMEP returns T iff NAME is FLOPPY.

(FLOPPY.EVENTFN FDEV EVENT)

This function gets called before and after any LOGOUT, SYSOUT, MAKESYS, or SAVEVM.

Pilot Page Numbers

The hardware refers to locations of pages on a floppy by cylinder, head, and sector numbers. This way of enumerating pages on a floppy is cumbersome and the OSD Pilot design makes the somewhat sensible choice of making up its own numbering system for the pages on a floppy. We refer to these numbers as pilot page numbers.

PFLOPPYFIRSTDATAPAGE  (Variable)

PFLOPPYLASTDATAPAGE  (Variable)

Each cylinder+head+sector combination can be encoded as a single FIXP called a DISKADDRESS. The functions to convert between Pilot page numbers and DISKADDRESSes are

PFLOPPYPAGENOTODISKADDRESS PAGENO

PFLOPPY.DISKADDRESSTOPAGENO DISKADDRESS

The functions to read and write pages to particular pilot page numbers are

PFLOPPY.READPAGENO PAGENO PAGE NOERROR
Pilot Marker Pages

Marker pages delimit the files and free blocks found on a Pilot floppy. The pattern of the data stored on a floppy is

DATA = MP ALLOC MP ALLOC MP ALLOC MP ... MP ALLOC MP

Generally a ALLOC is a free block or a leader page + file combination. One ALLOC is the filelist.

The declaration for Pilot floppy marker pages is

```
PMPAGE (Datatype)
(DATATYPE PMPAGE
 ((SEAL WORD)
  (VERSION WORD)
  (* Previous marker page entry *)
  (PLENGTH SWAPPEDFIXP)
  (PTYPE WORD)
  (PFILEID SWAPPEDFIXP)
  (PFILETYPE WORD)
  (NIL 121 WORD)
  (* Next marker page entry *)
  (NLENGTH SWAPPEDFIXP)
  (NTYPE WORD)
  (NFILEID SWAPPEDFIXP)
  (NFILETYPE WORD)
  (NIL 121 WORD)))
```

SEAL.PMPAGE (Constant)
VERSION.PMPAGE (Constant)

The SEAL and VERSION fields of a PMPAGE are the same for all marker pages. The magic constants are SEAL.PMPAGE and VERSION.PMPAGE. The SEAL.PMPAGE magic constant is arbitrary enough that there is only a slight chance that a non marker page would begin with this particular word. Hence, the scavenger can search for marker pages by looking for pages that begin with SEAL.PMPAGE.

The fields PLENGTH, PTYPE, PFILEID, PFILETYPE describe the ALLOC preceding the marker page. The fields NLENGTH, NTYPE, NFILEID, NFILETYPE describe the ALLOC following the marker page.

PLENGTH, NLENGTH = Length of ALLOC in pages.

PTYPE, NTYPE = Free, file, or filelist.

PFILEID, NFILEID = Pretty worthless. Used by Mesa. Each ALLOC has its own fileid number in the Mesa floppy handler. Not used by the Xerox Lisp software.

PFILETYPE, NFILETYPE = Free, file, or filelist. At first glance you might think that there isn’t much point in having both PTYPE, NTYPE and PFILETYPE, NFILETYPE. If you think that, you are
right. Please remember before you throw the rotten oranges that this is not my design. Blame it on OSD.

Pilot Leader Pages

The pattern of the data stored on a floppy is

\[ \text{DATA} = \text{MP ALLOC MP ALLOC MP ALLOC MP \ldots MP ALLOC MP} \]

Generally an ALLOC is a free block or a leader page + file combination. One ALLOC is the filelist. Thus the possible patterns for an ALLOC look like

\[ \text{ALLOC} = \text{FREE} \]
\[ \text{ALLOC} = \text{LP FILE} \]
\[ \text{ALLOC} = \text{FILELIST} \]

We note that all leader pages that occur on a Pilot floppy are immediately preceded by a marker page. All files on a Pilot floppy are preceded by a leader page. Each leader page + file combination is surrounded by two marker pages.

An exception to the rule: Microcode files on boot floppies do not have leader pages. They look like ALLOC = FILE. You may wonder why a microcode file's ALLOC shouldn't also be ALLOC = LP FILE. There isn't any reason for the exception. This is just another feature of the OSD design.

The declaration for Pilot floppy leader pages is

\[ \text{PLPAGE (Datatype)} \]
\[ (\text{DATATYPE PLPAGE} \]
\[ (\text{SEAL WORD}) \]
\[ (\text{VERSION WORD}) \]
\[ (\text{MESATYPE WORD}) \]
\[ (* \text{Offset 6} *) \]
\[ (\text{CREATIONDATE SWAPPEDFIXP}) \]
\[ (\text{WRITEDATE SWAPPEDFIXP}) \]
\[ (\text{PAGELENGTH SWAPPEDFIXP}) \]
\[ (\text{HUGEPAGESTART SWAPPEDFIXP}) \]
\[ (\text{HUGEPAGELENGTH SWAPPEDFIXP}) \]
\[ (\text{HUGELENGTH SWAPPEDFIXP}) \]
\[ (\text{NAMELENGTH WORD}) \]
\[ (\text{NAMEMAXLENGTH WORD}) \]
\[ (* \text{Offset 17} *) \]
\[ (\text{NAME 50 WORD}) \]
\[ (* \text{Offset 67} *) \]
\[ (\text{UFO1 WORD}) \]
\[ (\text{UFO2 WORD}) \]
\[ (\text{DATAVERSION WORD}) \]
\[ (\text{TYPE WORD}) \]
\[ (\text{NIL 183 WORD}) \]
\[ (\text{BYTESIZE WORD})) \]

The SEAL and VERSION fields of a PLPAGE are the same for all marker pages. The magic constants are SEAL.PLPAGE and VERSION.PLPAGE. The SEAL.PLPAGE magic constant is arbitrary enough that there is only a slight chance that a non marker page would begin with this particular word. Hence, the scavenger can search for marker pages by looking for pages that begin with SEAL.PLPAGE.
MESATYPE is fairly obscure. I think it marks the file according to what kind of application produced the file. Each application can register itself with OSD who doles out the numbers.

\CREATIONDATE is the obvious. However, the numeric encryption is according to Mesa’s standards.

\CREATIONDATE is the obvious. However, the numeric encryption is according to Mesa’s standards.

\FILENAME is the obvious. However, the numeric encryption is according to Mesa’s standards.

PAGELENGTH is the length of the file after the leader page in pages.

HUGEPAGESTART, HUGEPAGELENGTH, HUGELENGTH are pretty arcane. For ordinary files, HUGEPAGESTART = 0 and HUGEPAGELENGTH = PAGELENGTH. For all files, HUGELENGTH = the length of the file in bytes. For sysout and huge pilot files, it is possible that HUGEPAGESTART > 0 and HUGEPAGELENGTH < PAGELENGTH. Or some funny business like this.

\FILENAME, \FILENAMEMAXLENGTH, FILENAME indicate the name of the file following the leader page. Oddly enough, FILENAMEMAXLENGTH is just a constant field for all leader pages.

UFO1, UFO2. Flying saucers. Treated as constant fields by Lisp.

\DATAVERSION. Another constant field.

\TYPE = binary or text.

---

**Pilot Sector 9**

The name of the floppy is stored on the page at location CYLINDER = 0, HEAD = 0, SECTOR = 9. All of CYLINDER = 0 is wasted except for sector 9. There is nothing valuable stored on the 8 sectors before sector 9, or any of the sectors on CYLINDER = 0.

All the tracks from CYLINDER=1 to \FLOPPY.CYLINDERS are formatted IBM double density 512 bytes per sector. Strangely, the two sides of CYLINDER = 0 are formatted differently. As part of the OSD design, CYLINDER = 0, HEAD = 0 is formatted IBM single density 128 bytes per sector and CYLINDER = 0, HEAD = 1 is formatted IBM double density 256 bytes per sector.

The pattern of the data stored in sector 9 is conveniently represented by a datatype called PSECTOR9.

PSECTOR9

\begin{verbatim}
(DATATYPE PSECTOR9
 ((SEAL WORD)
  (VERSION WORD)
  (CYLINDERS WORD)
  (TRACKS PER CYLINDER WORD)
  (SECTORS PER TRACK WORD)
  (FILE LIST START WORD)
  (FILE LIST FILE ID SWAPPEDFIXP)
  (FILE LIST LENGTH WORD))
\end{verbatim}
Lisp verifies that the SEAL of the PSECTOR9 that it reads in is equal to magic constant SEAL.PSECTOR9. This action serves to check that the floppy that is being read is in fact a Pilot floppy.

A floppy's name is stored in \LABELLENGTH and \LABEL. The floppy name is accessed by the user through the function FLOPPY.NAME.

Everything else about PSECTOR9 is not useful to Lisp and is not used by any of the Lisp code. However Mesa does use some of this cruft and Lisp has to keep the cruft consistent with what Mesa would like to see.

Occasionally, the filelist (also useless) moves around on the floppy. When this happens, PFILELISTSTART, PFILELISTFILEID, PFILELISTLENGTH also have to be updated.

NEXTUNUSEDFILEID has to do with the Mesa floppy handler's notion of what a fileid is. This notion is irrelevant to the Lisp implementation of FLOPPY, but the Lisp implementation of FLOPPY does have to keep NEXTUNUSEDFILEID equal to one plus the number of files currently stored on the floppy.

Every time a new file is created and closed, NEXTUNUSEDFILEID has to be increased by one, the filelist has to change, and both the PSECTOR9 and the filelist have to be written out to the floppy.

(PFLOPPY.SAVE.PSECTOR9 NOERROR)

Saves the cached PSECTOR9 out to the floppy.

Pilot Filelist

The Pilot filelist is not used by the Lisp FLOPPY but must be maintained by the Lisp FLOPPY code to be compatible with the Mesa floppy handler. The filelist has the form

FILELIST = SEAL VERSION NENTRIES MAXENTRIES ENTRY ENTRY ENTRY ... ENTRY

Every time a new file is created and closed, an ENTRY has to be added to FILELIST and FILELIST has to be written out. Every time a file is deleted, an ENTRY has to be deleted from FILELIST and FILELIST has to be written out. Other than to maintain the FILELIST in this way for Mesa’s benefit, Lisp does not use the
FILELIST. Lisp uses the marker pages on a floppy to find where the files are and could care less about the filelist.

The filelist and filelist entry record declarations are

\[
\begin{align*}
\text{(BLOCKRECORD PFILELIST} & \text{((SEAL WORD)} \\
& \text{(VERSION WORD)} \\
& \text{(NENTRIES WORD)} \\
& \text{(MAXENTRIES WORD)))} \\
\text{(DATATYPE PFLE} & \text{((FILEID SWAPPEDFIXP)} \\
& \text{(TYPE WORD)} \\
& \text{(START WORD)} \\
& \text{(LENGTH WORD)))}
\end{align*}
\]

\(\text{\textbackslash PFLOPPY\.ADD\.TO\.PFILELIST PFALLOC}\)

Create a PFLE file list entry on the filelist for this PFALLOC.

\(\text{\textbackslash PFLOPPY\.DELETE\.FROM\.PFILELIST PFALLOC}\)

Deletes the PFLE file list entry on the filelist corresponding to this PFALLOC.

\(\text{\textbackslash PFLOPPY\.SAVE\.PFILELIST NOERROR}\)

Saves the filelist out to the floppy.

**Pilot Floppy Format**

The overall architecture of a Pilot floppy looks like this

\[
\begin{align*}
\text{FLOPPY} &= \text{CYLINDER0 DATA} \\
\text{CYLINDER0} &= \text{CYLINDER0HEAD0 CYLINDER0HEAD1} \\
\text{CYLINDER0HEAD0} &= \text{GARBAGE SECTOR9 GARBAGE} \\
\text{CYLINDER0HEAD1} &= \text{GARBAGE} \\
\text{DATA} &= \text{DATA = MP ALLOC MP ALLOC MP ... MP ALLOC MP} \\
\text{ALLOC} &= \text{FREE} \\
\text{ALLOC} &= \text{LP FILE} \\
\text{ALLOC} &= \text{FILELIST}
\end{align*}
\]

Exactly one ALLOC is the FILELIST. SECTOR9 and the FILELIST are for the most part useless. However, the Lisp implementation has to maintain SECTOR9 and FILELIST in a way that will make the Mesa floppy handler happy.

The Lisp implementation finds out what files are present on a floppy by following the marker pages (MPs) in the DATA which always begins at \(\text{\textbackslash PFLOPPYFIRSTDATAPAGE}\) and ends at \(\text{\textbackslash PFLOPPYLASTDATAPAGE}\). There are fields on the marker pages telling how long and what kind of ALLOC appears on either side of the marker page.
The formatting function for Pilot floppies is

```lisp
(PFLOPPY.FORMAT NAME AUTOCONFIRMFLG SLOWFLG)
```

PFLOPPY.FORMAT formats the tracks of the floppy according to the peculiar OSD design and then makes the floppy look like it is a Pilot floppy with an empty directory. The DATA on a freshly formatted floppy has the form

```
DATA = MP FILELIST MP FREE MP
```

## Cached Pilot Floppy Information

Duplicate directory information about a floppy is cached in core. This is held on to by a PFINFO datatype.

**PFINFO**

(DATATYPE PFINFO (OPEN PFFILELIST PFALLOCS DIR PSECTOR9))

We may describe the fields of the PFINFO slightly out of order.

OPEN is a flag saying whether directory information for the current floppy has been cached or not in the remaining fields of the PFINFO.

PFFILELIST is the Pilot filelist. The filelist is unimportant except that it must be maintained for Mesa’s benefit. An updated PFFILELIST has to be written out each time a file is written etc.

PSECTOR9 is the Pilot sector 9 record. This is where the floppy name lives. Otherwise, this record is also pretty worthless as far as Lisp is concerned. But there are fields on the PSECTOR9 that have to be maintained for Mesa’s benefit. An updated PFFILELIST has to be written out each time a file is written etc.

DIR is the cached floppy directory alist which is an alist of alists of alists.

PFALLOCS is a list of PFALLOC records which describe successive allocations on the floppy.

## Cached Pilot Floppy DIR Alist

The PFINFO DIR is the cached floppy directory alist which is an alist of alists of alists. It has the form

```
((name (extension (version . PFALLOC) ...) (version . PFALLOC)) ...)
((extension (version . PFALLOC) ...) (version . PFALLOC)) ...)
((name (extension (version . PFALLOC) ...) (version . PFALLOC)) ...)
((extension (version . PFALLOC) ...) (version . PFALLOC)) ...)
```
Say for example that we have 6 versions of the file (FLOPPY)FLOPPY.TEDIT stored on a floppy. Then the cached DIR alist could look like

\[
((\text{FLOPPY} \ (\text{TEDIT} \ (1 \ . \ \{\text{PFALLOC}\#55,72740\}) \\
   (2 \ . \ \{\text{PFALLOC}\#55,72704\}) \\
   (3 \ . \ \{\text{PFALLOC}\#55,72650\}) \\
   (4 \ . \ \{\text{PFALLOC}\#55,72434\}) \\
   (5 \ . \ \{\text{PFALLOC}\#55,72400\}) \\
   (6 \ . \ \{\text{PFALLOC}\#55,72340\}))))
\]

Functions to manage and access the DIR alist are

\[
(\text{PFLOPPY.DIR.GET FILENAME RECOG}) \\
(\text{PFLOPPY.DIR.PUT FILENAME RECOG PFALLOC}) \\
(\text{PFLOPPY.DIR.REMOVE PFALLOC}) \\
(\text{PFLOPPY.DIR.VERSION VERSION RECOG VALIST FILENAME})
\]

Cached Pilot Floppy PFALLOCS

The PFINFO PFALLOCS is a list of PFALLOC records which describe successive allocations on the floppy. Some of the PFALLOCS are leader page+file combinations. Some are free blocks. One of the PFALLOCS is the allocation record for the filelist (this PFALLOC tells us where the contents of PFILELIST should be stored).

Each PFALLOC record has the form

\[
(\text{PFALLOC}) \\
(\{\text{DATATYPE PFALLOC} \ (\text{FILENAME} \ (\text{PREV FULLXPOINTER}) \ \text{NEXT} \ \text{START} \ \text{PMPAGE} \ \text{PLPAGE} \ \text{PFLE} \ (\text{WRITEFLG FLAG}) \ (\text{DELETEFLG FLAG}))\}
\]

FILENAME is the name of the file that the PFALLOC corresponds to. If the PFALLOC does not correspond to a file, then FILENAME will be a list like (FREE) or (PFILELIST).

PREV points back to the preceding PFALLOC in the PFALLOCS list.

NEXT points to the next PFALLOC in the PFALLOCS list.

START is the pilot page number of the first page of storage on the floppy corresponding to the PFALLOC (the page after the marker page preceding the allocation).
PMPAGE is a cached copy of the marker page preceding the allocation corresponding to the PFALLOC.

PLPAGE is a cached copy of the leader page, if any, that begins the allocation. (Only file allocations will have leader pages. If the PFALLOC does not correspond to a file allocation then the PLPAGE field is left NIL.)

PFLE is the file list entry in the Pilot filelist corresponding to this PFALLOC.

WRITEFLG = T if there is a stream writing to the allocation corresponding to this PFALLOC. That is, this PFALLOC corresponds to a file, and a stream is writing to that file.

DELETEFLG = T if the PFALLOC corresponds to a file whose deletion is pending. This may happen if some process is reading a file that a second process DELFILEs. The PFALLOC is deleted for real (i.e. made into a free block) when the first process gives up control of the stream that is reading the file with CLOSEF.

**PILOT FLOPPY STORAGE ALLOCATION**

This section describes the Pilot floppy storage allocation strategy.

\(\texttt{\(\text{PFLOPPY_ALLOCATE LENGTH}\)}\)

This function is called to generate the initial allocation PFALLOC assigned to a stream. The PFALLOC must be of a definite length and so there are other functions like \(\texttt{\(\text{PFLOPPY_TRUNCATE}\)}\) and \(\texttt{\(\text{PFLOPPY_EXTEND}\)}\) which know how to split an incompletely used up PFALLOC or a PFALLOC that is about to overflow.

\(\texttt{\(\text{PFLOPPY_ALLOCATE}\)}\) returns a PFALLOC pointing to a free block of storage that is at least LENGTH pages long. If LENGTH=NIL is supplied, then the length is defaulted to somewhere between DEFAULT.ALLOCATION and MINIMUM.ALLOCATION with preference towards DEFAULT.ALLOCATION.

The strategy is to first select the largest free block available. Not being able to find a free block causes \(\texttt{\(\text{PFLOPPY_GAINSPACE}\)}\) to be called and then \(\texttt{\(\text{PFLOPPY_ALLOCATE}\)}\) retries.

Having obtained the PFALLOC pointing to the largest free block available, \(\texttt{\(\text{PFLOPPY_ALLOCATE}\)}\) determines if the free block is big enough. If the free block is not big enough then \(\texttt{\(\text{PFLOPPY_GAINSPACE}\)}\) is called and \(\texttt{\(\text{PFLOPPY_ALLOCATE}\)}\) retries.

Now being in possession of a PFALLOC pointing to a sufficiently large free block, the question is whether or not to split the PFALLOC. If the length of PFALLOC exceeds LENGTH by MINIMUM.ALLOCATION then PFALLOC is split into two free blocks one of which will have length LENGTH and will be returned. Otherwise, the PFALLOC is returned as is.
Splitting excessively large PFALLOCs is done in order that no stream hog the floppy and thereby be unfair to other streams. It may happen, for example in a freshly formatted floppy, that there is just one or very few but large free blocks. It would be unfair to hand out the only and very large free block to a stream and thereby prevent a second stream from opening.

On the other hand, splitting a PFALLOC whose length exceeds LENGTH by just a little bit is also undesirable because it leads to fragmentation and consumption of storage by the marker page overhead that must occur for each allocation. Thus, the length of PFALLOC not exceeding LENGTH by MINIMUM.ALLOCATION is considered to be close enough.

\PFLOPPY.ICHECK is called at the end of each \PFLOPPY.ALLOCATE to do an integrity check of the cached incore description of the floppy.

\PFLOPPY.DEALLOCATE PFALLOC

Deallocation is fairly easy. The two marker pages surrounding the allocation pointed to by PFALLOC are made to say that the type of the allocation between them is a free block.

\PFLOPPY.ICHECK is called at the end of each \PFLOPPY.DEALLOCATE to do an integrity check of the cached incore description of the floppy.

\PFLOPPY.TRUNCATE PFALLOC LENGTH

Truncation is also fairly easy. If PFALLOC is already of length LENGTH or smaller then nothing needs to be done. Otherwise \PFLOPPY.TRUNCATE changes the local situation on the floppy from one of

MP ALLOC MP

to one of

MP ALLOC MP FREE MP

by setting the length of PFALLOC to LENGTH, creating another PFALLOC to take up the slack and to be considered as a free block, and creating and updating and writing out three marker pages.

\PFLOPPY.ICHECK is called at the end of each \PFLOPPY.TRUNCATE to do an integrity check of the cached incore description of the floppy.

\PFLOPPY.EXTEND PFALLOC

This function gets called when an output stream is about to overflow its initial allocation. \PFLOPPY.EXTEND is charged with extending the length of PFALLOC's storage allocation.

If PFALLOC is followed by a free block, then it suffices to let PFALLOC cannibalize the following free block. The situation

MP ALLOC MP FREE MP
is changed to one of

MP ALLOC MP

by changing the length of PFALLOC to the sum of the length of
PFALLOC's length, one page from the marker page between
PFALLOC and the free block which is eliminated, and the length of
the free block.

If PFALLOC is not followed by a free block, but instead is bumping
up against valuable data, then a different strategy is used.  \
\PFLOPPY.ALLOCATE is called to find a new and larger storage
area NEW for the data stored at the allocation pointed to by
PFALLOC. The data stored in the allocation pointed to by
PFALLOC is then copied into the allocation pointed to by NEW.
This is slightly time consuming, so the Lisp code prints the
message “Reallocating” in the PROMPTWINDOW when this kind of
activity is about to happen. After copying the data pointed to by
PFALLOC into the area pointed to by NEW, NEW nad PFALLOC
are made to exchange places. NEW is changed to point to where
the data used to live and PFALLOC is changed to point to where
the data has moved to. The marker pages around NEW and
around PFALLOC have to be updated and written out to the floppy.
The result, therefore, has the appearance of data crawling out of its
restricted cavity and kicking out the free block living from the bigger
cavity and then the free block moves over to where the data used
to live.

\PFLOPPY.ICHECK is called at the end of each
\PFLOPPY.EXTEND to do an integrity check of the cached incore
description of the floppy.

\(\PFLOPPY.GAINSPACE LENGTH\)

This function is charged with going out and hunting up space on a
floppy, \PFLOPPY.GAINSPACE returns after a free block of length
LENGTH has been made available.

The first thing to be done is to merge adjacent free blocks into
larger free blocks. This is done by calling function
\PFLOPPY.GAINSPACE.MERGE. \PFLOPPY.ICHECK is called
at the end of each \PFLOPPY.GAINSPACE.MERGE to do an
integrity check of the cached incore description of the floppy.

At this point \PFLOPPY.GAINSPACE checks to see if a free block
of length LENGTH has been made available, and if so, returns.

Otherwise, \PFLOPPY.GAINSPACE calls FLOPPY.FREE.PAGES
to determine whether a sufficiently large free block can be gained
just by compacting the floppy. If the number of free pages available
is greater than LENGTH, then compacting the floppy will have as
one of its effects the collection of all free space into a single free
block. Therefore, if the number of free pages available is greater
than LENGTH, then \PFLOPPY.GAINSPACE calls
FLOPPY.COMPACT to compact the floppy and then returns the
single free block that is created by the compactor.

If calling FLOPPY.FREE.PAGES tells \PFLOPPY.GAINSPACE that
there wouldn't be a large enough free block created just by
compactating the floppy, then \PFLOPPY.GAINSPACE generates the
usual contiuable FILE SYSTEM RESOURCES EXCEEDED error
break. If the user responds by deleting some files and typing OK,
then \PFLOPPY.GAINSPACE continues onward by going back to
the top of its list of things to do and retrying its attempt to find a free block of length \( \text{LENGTH} \).

**\( \text{PFLOPPY FREE PAGES} \)**

Just sums up the lengths of all the PFALLOCs pointing to free blocks. This function gets called by the user function \( \text{FLOPPY FREE PAGES} \).

**\( \text{PFLOPPY ICHECK} \)**

Does an integrity check on the Lisp implementation’s incore cached directory information.

The Lisp floppy implementation does not blithely trust itself to always be doing the right thing, at least as far as the incore description of how the floppy is arranged. It is somewhat important that the in core description be absolutely legal and in agreement with reality out on the floppy, because incorrect cached directory structures may cause floppy operations to scramble the user’s floppy confusing contents of files or real directory structure on the floppy.

\( \text{PFLOPPY ICHECK} \) gets called near the end of each major function in the Pilot floppy allocation code.

**SYSOUT**

Sysouting to floppy is kind of a hack. The sysout file that gets written has to be broken into smaller files that will fit on individual floppies. The small files are not ordinary files but are Huge Pilot files. The HUGEPAGESTART and HUGEPAGELENGTH fields in the leader pages of these files become important.

\( \text{SFLOPPYFDEV} \) (Variable)

The usual FLOPPY file device is \( \text{PFLOPPYFDEV} \). The sysout FLOPPY file device is \( \text{SFLOPPYFDEV} \). (FLOPPY.MODE ‘SYSOUT) by the user makes the switch between the two file devices. The function SYSOUT seems to do (FLOPPY.MODE ‘SYSOUT) automatically for the user, but in fact, floppy functions at a lower level detect SYSOUT on the stack of function calls by a certain amount of grungeyness and make the switch between file devices when necessary.

**\( \text{SFLOPPY OPENHUGEFILE} \)**

Installed on \( \text{SFLOPPYFDEV} \) and gets called when FILEIO opens a stream for input or output when FLOPPY is in SYSOUT mode. \( \text{SFLOPPY OPENHUGEFILE} \) returns a stream datatype. The stream can be either input or output.

If the stream is to be an input stream, \( \text{SFLOPPY INPUTFLOPPY} \) is called. If the stream is to be an output stream, \( \text{SFLOPPY OUTPUTFLOPPY} \) is called.

The stream returned is in every way like a Pilot stream returned by \( \text{PFLOPPY OPENFILE} \) with the exception that the DEVICE of the stream is \( \text{SFLOPPYFDEV} \). Two other fields on the stream, F1 and
F2, point to the allocation record (PFALLOC) and leader page (PLPAGE) for the stream. The PFALLOC and PLPAGE can be conveniently accessed by using the FLOPPYSTREAM ACCESSFNS.

\(\$\text{FLOPPY.READPAGES \ STREAM \ FIRSTPAGE# \ BUFFERS}\)

Installed on \$\text{FLOPPYFDEV} and called by FILEIO when FLOPPY is in SYSOUT mode. Reads sectors off floppies into virtual memory pages BUFFERS. FIRSTPAGE# is in FILEIO’s scheme of counting the pages of a file, beginning with 0 for the first page of a file. \$\text{FLOPPY.READPAGES} therefore fills BUFFERS with data read from floppies beginning with the FIRSTPAGE# of STREAM.

\$\text{FLOPPY.READPAGES} is implemented by calling \$\text{PFLOPPY.READPAGE}. When \$\text{FLOPPY.READPAGES} is about to run off the end of a floppy, \$\text{FLOPPY.CLOSEFLOPPY} and \$\text{FLOPPY.INPUTFLOPPY} are called to bring in the next floppy.

\(\$\text{FLOPPY.WRITEPAGES \ STREAM \ FIRSTPAGE# \ BUFFERS}\)

Installed on \$\text{FLOPPYFDEV} and called by FILEIO when FLOPPY is in SYSOUT mode. Writes contents of virtual memory pages BUFFERS on to sectors of floppies. FIRSTPAGE# is in FILEIO’s scheme of counting the pages of a file, beginning with 0 for the first page of a file. \$\text{FLOPPY.WRITEPAGES} therefore writes to the floppy beginning with the location corresponding to the FIRSTPAGE# of STREAM.

\$\text{FLOPPY.WRITEPAGES} is implemented by calling \$\text{PFLOPPY.WRITEPAGE}. When \$\text{FLOPPY.WRITEPAGES} is about to run off the end of a floppy, \$\text{FLOPPY.CLOSEFLOPPY} and \$\text{FLOPPY.OUTPUTFLOPPY} are called to bring in the next floppy.

\(\$\text{FLOPPY.CLOSEHUGEFILE \ STREAM}\)

Installed on \$\text{FLOPPYFDEV} and called by FILEIO to close a sysout file when FLOPPY is in SYSOUT mode.

For output streams, does the usual \$\text{CLEARMAP} plus a \$\text{FLOPPY.CLOSEFLOPPY} on the last floppy being written.

There is some grungeyness to switch back to an old FLOPPY mode if the FLOPPY mode was reset by calling function SYSOUT.

\(\$\text{FLOPPY.INPUTFLOPPY \ FLOPPYNAME \ FILENAME \ OTHERINFO \ OLDSTREAM}\)

Called by \$\text{FLOPPY.READPAGES} when \$\text{FLOPPY.READPAGES} needs to go to the next floppy. \$\text{FLOPPY.INPUTFLOPPY} prompts the user to "Insert floppy" and does a (FLOPPY.WAIT.FOR.FLOPPY 1) until the user does so.

Once the user has inputted the next floppy and FLOPPY.WAIT.FOR.FLOPPY has returned, \$\text{FLOPPY.INPUTFLOPPY} calls \$\text{PFLOPPY.OPENFILE} to open a regular Pilot floppy stream to the piece of sysout file stored on the floppy inserted.

If no OLDSTREAM is supplied, then the Pilot floppy stream created by the call to \$\text{PFLOPPY.OPENFILE} is returned. Otherwise, the PFALLOC and PLPAGE cached in the F1 and F2 fields of the Pilot
floppy stream are pulled out and stuck into OLDSTREAM, after which OLDSTREAM is returned.

\(\text{\texttt{SFLOPPY.OUTPUTFLOPPY FLOPPYNAME FILENAME OTHERINFO OLDSTREAM}}\)

Called by \(\text{\texttt{SFLOPPY.WRITEPAGES}}\) when \(\text{\texttt{SFLOPPY.WRITEPAGES}}\) needs to go to the next floppy. \(\text{\texttt{SFLOPPY.OUTPUTFLOPPY}}\) prompts the user to “Insert floppy” and does a (FLOPPY.WAIT.FOR.FLOPPY T) until the user does so.

Once the user has inputted the next floppy and FLOPPY.WAIT.FOR.FLOPPY has returned, \(\text{\texttt{SFLOPPY.OUTPUTFLOPPY}}\) tries to format the floppy. If there is any problem with formatting the floppy, such as the floppy being writeprotected, then the user is again asked to input a floppy.

Once the new floppy is formatted, \(\text{\texttt{SFLOPPY.OUTPUTFLOPPY}}\) calls \(\text{\texttt{PFLOPPY.OPENFILE}}\) to open a regular Pilot floppy stream which will be used to create a piece of the sysout file being stored on floppies.

If no OLDSTREAM is supplied, then the Pilot floppy stream created by the call to \(\text{\texttt{PFLOPPY.OPENFILE}}\) is returned. Otherwise, the PFALLOC and PLPAGE cached in the F1 and F2 fields of the Pilot floppy stream are pulled out and stuck into OLDSTREAM, after which OLDSTREAM is returned.

\(\text{\texttt{SFLOPPY.CLOSEFLOPPY STREAM LASTFLOPPYFLG}}\)

If the STREAM is an input stream, then \(\text{\texttt{SFLOPPY.CLOSEFLOPPY}}\) just returns without doing anything.

If the STREAM is an output stream, then the leader pages and marker pages for the piece of sysout file stored on this floppy are written out. And as usual with Pilot streams, the updated filelist and PSECTOR9 also have to be written out.

**HUGEPILOT**

HUGEPILOT mode is implemented in a way similar to SYSOUT mode. The Huge Pilot file that gets written has to be broken into smaller files that will fit on individual floppies. The small files are not ordinary files but are Huge Pilot files. The HUGEPAGESTART and HUGEPAGELENGTH fields in the leader pages of these files become important.

\(\text{\texttt{HFLOPPYFDEV}}\) (Variable)

The usual FLOPPY file device is \(\text{\texttt{PFLOPPYFDEV}}\). The Huge Pilot FLOPPY file device is \(\text{\texttt{HFLOPPYFDEV}}\). (FLOPPY.MODE 'HUGEPILOT) by the user makes the switch between the two file devices.

\(\text{\texttt{HFLOPPY.OPENHUGEFILE FILE ACCESS RECOG OTHERINFO FDEV OLDSTREAM}}\)

Installed on \(\text{\texttt{HFLOPPYFDEV}}\) and gets called when FILEIO opens a stream for input or output when FLOPPY is in HUGEPILOT mode.
\HFLOPPY.OPENHUGEFILE returns a stream datatype. The stream can be either input or output.

If the stream is to be an input stream, \HFLOPPY.INPUTFLOPPY is called. If the stream is to be an output stream, \HFLOPPY.OUTPUTFLOPPY is called.

The stream returned is in every way like a Pilot stream returned by \PFLOPPY.OPENFILE with the exception that the DEVICE of the stream is \HFLOPPYFDEV. Two other fields on the stream, F1 and F2, point to the allocation record (PFALLOC) and leader page (PLPAGE) for the stream. The PFALLOC and PLPAGE can be conveniently accessed by using the FLOPPYSTREAM ACCESSFNS.

(\HFLOPPY.READPAGES STREAM FIRSTPAGE# BUFFERS)

Installed on \HFLOPPYFDEV and called by FILEIO when FLOPPY is in HUGEPILOT mode. Reads sectors off floppies into virtual memory pages BUFFERS. FIRSTPAGE# is in FILEIO’s scheme of counting the pages of a file, beginning with 0 for the first page of a file. \HFLOPPY.READPAGES therefore fills BUFFERS with data read from floppies beginning with the FIRSTPAGE# of STREAM.

\HFLOPPY.READPAGES is implemented by calling \PFLOPPY.READPAGE. When \HFLOPPY.READPAGES is about to run off the end of a floppy, \HFLOPPY.CLOSEFLOPPY and \HFLOPPY.INPUTFLOPPY are called to bring in the next floppy.

(\HFLOPPY.WRITEPAGES STREAM FIRSTPAGE# BUFFERS)

Installed on \HFLOPPYFDEV and called by FILEIO when FLOPPY is in HUGEPILOT mode. Writes contents of virtual memory pages BUFFERS on to sectors of floppies. FIRSTPAGE# is in FILEIO’s scheme of counting the pages of a file, beginning with 0 for the first page of a file. \HFLOPPY.WRITEPAGES therefore writes to the floppy beginning with the location corresponding to the FIRSTPAGE# of STREAM.

\HFLOPPY.WRITEPAGES is implemented by calling \PFLOPPY.WRITEPAGE. When \HFLOPPY.WRITEPAGES is about to run off the end of a floppy, \HFLOPPY.CLOSEFLOPPY and \HFLOPPY.OUTPUTFLOPPY are called to bring in the next floppy.

(\HFLOPPY.CLOSEHUGEFILE STREAM)

Installed on \HFLOPPYFDEV and called by FILEIO to close a Huge Pilot file when FLOPPY is in HUGEPILOT mode.

For output streams, does the usual \CLEARMAP plus a \HFLOPPY.CLOSEFLOPPY on the last floppy being written.

(\HFLOPPY.INPUTFLOPPY FLOPPYNAME FILENAME OTHERINFO OLDSTREAM)

Called by \HFLOPPY.READPAGES when \HFLOPPY.READPAGES needs to go to the next floppy. \HFLOPPY.INPUTFLOPPY prompts the user to “Insert floppy” and does a (FLOPPY.WAIT.FOR.FLOPPY T) until the user does so.

Once the user has inputted the next floppy and FLOPPY.WAIT.FOR.FLOPPY has returned,
\HFloppy.InputFloppy calls \PFloppy.OpenFile to open a regular Pilot floppy stream to the piece of Huge Pilot file stored on the floppy inserted.

If no OLDSTREAM is supplied, then the Pilot floppy stream created by the call to \PFloppy.OpenFile is returned. Otherwise, the PFALLOC and PLPAGE cached in the F1 and F2 fields of the Pilot floppy stream are pulled out and stuck into OLDSTREAM, after which OLDSTREAM is returned.

(\HFloppy.OutputFloppy FLOPPYNAME FILENAME OTHERINFO OLDSTREAM)

Called by \HFloppy.WritePages when \HFloppy.WritePages needs to go to the next floppy. \HFloppy.OutputFloppy prompts the user to "Insert floppy" and does a (Floppy.Wait.For.Floppy T) until the user does so.

Once the user has inputted the next floppy and Floppy.Wait.For.Floppy has returned, \HFloppy.OutputFloppy tries to format the floppy. If there is any problem with formatting the floppy, such as the floppy being writeprotected, then the user is again asked to input a floppy.

Once the new floppy is formatted, \HFloppy.OutputFloppy calls \PFloppy.OpenFile to open a regular Pilot floppy stream which will be used to create a piece of the Huge Pilot file being stored on floppies.

If no OLDSTREAM is supplied, then the Pilot floppy stream created by the call to \PFloppy.OpenFile is returned. Otherwise, the PFALLOC and PLPAGE cached in the F1 and F2 fields of the Pilot floppy stream are pulled out and stuck into OLDSTREAM, after which OLDSTREAM is returned.

(\HFloppy.CloseFloppy STREAM LASTFLOPPYFLG)

If the STREAM is an input stream, then \HFloppy.CloseFloppy just returns without doing anything.

If the STREAM is an output stream, then the leader pages and marker pages for the piece of Huge Pilot file stored on this floppy are written out. And as usual with Pilot streams, the updated filelist and PSECTOR9 also have to be written out.
This note provides information about font and character facilities in Interlisp-D. It is organised in two parts:

1) a user level view of the changes involved in including NS characters in Interlisp-D (adapted from the Koto release notes ([Erinyes]<doc>koto>releasenotes*))
2) a description of the underlying data-structures and facilities. (exported macros and fns, etc)

**User-level view**

Interlisp-D now supports the Xerox corporate character code standard, commonly referred to as the NS (Network Systems) encoding, described in the document Character Code Standard [Xerox System Integration Standards, XSIS 058404, April 1984]. Previous to the Koto release, Interlisp-D used the ASCII (American Standard Code for Information Interchange) encoding. While the extended-ASCII encoding provided for 8-bit (256 available) characters (primarily Latin alphabet and computer-specific symbols), the NS encoding supports 16-bit (65536 available) characters comprising many foreign alphabets and special symbols.

The benefit of having this large character set, in contrast to approaches that use a small set of character codes and a multiplicity of fonts (e.g., a Greek font, a math font), is that each semantically distinct character is represented by its own character code, completely independent of the character’s appearance (font). Thus, the Greek character upper-case Beta is always character code 9794, independent of whether it appears in printed form in a serif style, sans-serif style, italic, etc., and it is unrelated to the Roman letter B (character code 66).

NS characters can be used in strings, litatom print names, symbolic files, or anywhere else that characters can be used. All of the standard string and print name functions (RPLSTRING, GNC, NCHARS, STRPOS, etc.) accept litatoms and strings containing NS characters. For example:

```
_(STRPOS "char" "this is an 8-bit character string")
18
```
```
_(STRPOS "char" "celui-ci comporte des caractères NS")
23
```

Characters are organized into 256-member character sets, each of which generally consists of semantically related characters. For example, character set 38 is the Greek character set and contains the Greek alphabet and punctuation characters needed to print Greek text. A 16-bit character code thus consists of an 8-bit character set and an 8-bit character number within that set. The ASCII character set is contained in NS character set zero; thus, ASCII characters are still represented by the same 8-bit character codes as previously (i.e., 16-bit character codes whose high 8 bits are zero). Most strings and atoms still consist entirely of characters from character set zero and are represented just as space-efficiently in memory and on files as in earlier releases of Interlisp-D that used only ASCII characters.
In almost all cases, a program does not need to know that it is dealing with 16-bit characters rather than 8-bit characters—the higher level system functions all treat them transparently. The exception is in character-level input/output, where the important fact to be aware of is that characters are not bytes. The file pointer of a random-access file still counts bytes, and the function NCCHARS still counts characters, but the two are no longer directly related. This is discussed in more detail below.

**Character-level Input/Output**

**Incompatible Change:** BIN and BOUT are no longer appropriate for character input/output.

A character is no longer generally representable in 8 bits. Therefore, characters can no longer, in general, be read or written with the functions BIN and BOUT, which read and write 8-bit quantities. The change is mostly transparent to user programs, especially if those programs use only the higher level functions, such as READ and PRINT. However, it is likely that user programs that manipulated a file character by character using BIN and BOUT should now use the following functions, which may produce or consume more than a single byte:

- `(READCCODE STREAM)` [Function]
- `(PEEKCCODE STREAM)` [Function]
- `(PRINTCCODE CODE STREAM)` [Function]

These functions are documented in the new Interlisp-D Reference Manual. The functions BIN and BOUT are still appropriate for use when reading and writing strictly binary (rather than character) data.

Interlisp-D supports two ways of writing NS characters on files. One way is to write the full 16-bits (two bytes) every time a character is output. The other way, which is the system default, is to use "run-encoding," in which a run of characters in the same character set is written as a sequence of 8-bit character numbers within the character set, preceded by a "change character set" command. The byte 255 (illegal as either a character set number or a character number) followed by a character set number is used to signal a change to a given character set; the following bytes, up until the next change-character set sequence, are all interpreted as coming from the specified character set. Run-encoding can reduce the number of bytes required to encode a string of NS characters, as long as there are long sequences of characters from the same character set, which is usually the case.

Most characters in common use, including those in the ASCII character set, are in character set zero; a file containing only these characters is thus in exactly the same format as in previous releases, viz., one byte per character. However, this should not be relied on.

The fact that the file representation of a character may be more than a single byte has important consequences for any program that uses random access on text files whose characters are run-encoded. First, and most obviously, you cannot count the characters in a string being printed and use that number to derive the file pointer of where the string ends—you must use GETFILEPTR. Second, programs that use SETFILEPTR need to be aware of possible character set changes. At any point when a file is being read or written, it has a "current character set," viz., the character set specified in the most recent "change character set" command written on the file. If the file pointer is changed with SETFILEPTR to a part of the file with a different character set, any characters read or written may have the wrong character set. Programs that use COPYBYTES to copy blocks of characters must ensure both that they are copying on character boundaries and copying to a place that is in the correct character set.

(Internal Note: PRINTCCODE is the user entry to the OUTCHARFN of the stream. It is bounds checked.)

The current character set can be accessed with the following function:

- `(CHARSET STREAM CHARACTERSET)` [Function]

Returns the current character set of the stream STREAM, or T if STREAM is not run-encoded. If CHARACTERSET is non-NIL, the current character set for STREAM is set. For output streams this causes bytes to be written to the stream if CHARACTERSET is different from the current character set; for input streams it merely changes the reader's belief about the current character set. If CHARACTERSET is T, run encoding for STREAM is disabled—henceforth each character printed to the stream is printed as exactly two bytes (the character set and the character number).

Programs that wish to count characters or avoid worrying about character set changes can thus disable run encoding for a particular stream and count each character as two bytes. There is, however, a cost in file space.
Extensions to CHARCODE

CHARCODE has been extended to allow specifying NS Characters.

CHARCODE has been extended to allow the specification of 16-bit NS characters in multiple character sets. It also uses two new variables, CHARACTERNAMES and CHARACTERSETNAMES, so characters and character sets can be specified symbolically. The new definition is the following:

\[
(\text{CHARCODE } \text{CHAR}) \quad \text{[NLambda Function]}
\]

Returns the character code specified by CHAR (unevaluated). If CHAR is a one-character atom or string, the corresponding character code is simply returned. Thus, (CHARCODE A) is 65, (CHARCODE 0) is 48. If CHAR is a multi-character litatom or string, it specifies a character code as described below. If CHAR is NIL, CHARCODE simply returns NIL. Finally, if CHAR is a list structure, the value is a copy of CHAR with all the leaves replaced by the corresponding character codes. For instance, (CHARCODE (A (B C))) => (65 (66 67)).

If a character is specified by a multi-character litatom or string, CHARCODE interprets it as follows:

CR, SPACE, etc. The variable CHARACTERNAMES contains an association list mapping special litatoms to character codes. Among the characters defined this way are CR (13), LF (10), SPACE or SP (32), ESCAPE or ESC (27), BELL (7), BS (8), TAB (9), NULL (0), and DEL (127). Examples: (CHARCODE SPACE) returns 32, and (CHARCODE CR) returns 13.

CHARSET, CHARNUM, CHARSET-CHARNUM If the character specification is a litatom or string of the form CHARSET, CHARNUM or CHARSET-CHARNUM, the character code for the character number CHARNUM in the character set CHARSET is returned. CHARSET is either an octal number, or a litatom in the association list CHARACTERSETNAMES (which defines GREEK, CYRILLIC, etc.). CHARNUM is either an octal number, a single-character litatom, or a litatom from the association list CHARACTERNAMES. Examples: (CHARCODE 12,6), (CHARCODE 12,SPACE), (CHARCODE GREEK,A) and (CHARCODE ^GREEK,A)

Note that if CHARNUM is a single-digit number, it is interpreted as an octal character code, not as a character. Thus (CHARCODE GREEK,3) denotes the fourth character in the Greek character set, not the character "3" in that character set.

^CHARSPEC If the character specification is a litatom or string of one of the forms above, preceded by the character "^", this indicates a "control character," derived from the normal character code by clearing the seventh bit (100Q) of the character code (normally set in alphabetic characters). Example: (CHARCODE ^A)

#CHARSPEC (8-bit character codes) If the character specification is a litatom or string of one of the forms above, preceded by the character "#", the eighth bit (200Q), normally zero for 7-bit ASCII characters, is set. This is the way to get character numbers greater than 127. ^ and # can both be set at once. Examples: (CHARCODE #A), (CHARCODE ^#GREEK,A)

Note: In Intermezzo (and in some other operating systems), characters with the eighth bit set were considered "meta" characters. In the Koto release, however, "meta" means character set 1, and the meta key produces characters with the 400Q bit set, not 200Q.

Internals

Note: The information in this section is advisory only. There is no guarantee of back-compatibility in future changes.

Structure of Font Descriptors

To incorporate the increase in information contained in font descriptors due to NS characters, the structure of font descriptors has changed. The current structure is as follows.
Font Descriptor

<table>
<thead>
<tr>
<th>Font Family</th>
<th>Modern</th>
</tr>
</thead>
<tbody>
<tr>
<td>Font Size</td>
<td>12</td>
</tr>
<tr>
<td>Font Face</td>
<td>(Medium Regular Regular)</td>
</tr>
<tr>
<td>Rotation</td>
<td>0</td>
</tr>
<tr>
<td>Font Device</td>
<td>RandomDIGdevice</td>
</tr>
<tr>
<td>SF Ascent</td>
<td>10</td>
</tr>
<tr>
<td>SF Descent</td>
<td>4</td>
</tr>
<tr>
<td>SF Height</td>
<td>14</td>
</tr>
</tbody>
</table>

Font Charset Vector:

```
0 1
 0 0
 0
254
```
Description:

Font Descriptors:
The figure represents the logical structure of a font descriptor. Clarification of field values:
Face: a list containing the weight, slope and expansion. (expansion is always regular)
Rotation: degrees of rotation
Device: name of the device for which this font is created
Ascent: the maximum distance above the baseline for any character in this font.
Descent: the maximum distance below the baseline for any character in this font. (always positive)
Height: maximum total height of any character in this font. Equals Descent+Ascent.
FontDeviceSpec: this is the font specification actually used to create this font after coercions. Thus, if the fontcreate method substituted something other than the original arguments to fontcreate, then this field shows the real contents of the font descriptor, while the family (etc.) fields contain the ostensible (pre-coercion) contents. For instance, display font substitutions occur in `CREATECHARSET.DISPLAY` according to the variable MISSINGDISPLAYFONTCOERCIONS.
OtherDeviceFontProps: available to the implementation of each stream. Unexamined by the system.
Charsetvector: this is a ptr block pointing to the individual charsetinfo's for each of 255 charsets. These are either NIL or a ptr to the charsetinfo. In the diagram, only the charsetinfo for charset 0 is present. When a fontdescriptor is created the charsetvector will already be present.

Charsetinfo:
A charsetinfo contains all the metrics for a single character set (255 characters) of the font.
Widths: a block of SMALLP's which gives the width in device units for each character (how much to advance the stream xpos after printing this character). This field must be present no matter what the stream type.

Offsets: integer offsets into the bitmap field, showing the xposition of the beginning of the bitmap for this character. Many streams (especially hardcopy streams) have no need of a bitmap or offsets.

Imagewidths: This is the width of the image of this character. Often this will be the same as the width, but it can be less or greater. The field must always be valid.

Bitmap: The bitmap for the characters in this charset. [optional]

YWidths: currently unused, but for forward compatibility, make this be a block giving the y distance to move for each character (i.e. carriage return should move the y position the height of the font.) [**?** is this a positive distance]

Ascent: max ascent in the character set.

Descent: max descent in the character set.

Widths, Offsets, YWidths and Imagewidths are instances of the result of CREATECSINFOELEMENT (see below).

Exported Macros and Functions

\( \text{\texttt{\textbackslash CHARSET \textit{CHARCODE}}} \)
returns the character set (upper 8 bits) of \textit{CHARCODE}.

\( \text{\texttt{\textbackslash CHAR8CODE \textit{CHARCODE}}} \)
returns the offset of \textit{CHARCODE} within the character set (the low 8 bits of the character)

\( \text{\texttt{\textbackslash CREATECHARSET \textit{CHARSET \textit{FONT} NOSLUG?}}} \)
the createcharset method (determined by the value of the variable IMAGESTREAMTYPES) is called. \textit{NOSLUG?} determines the result if the createcharset method returns NIL. If \textit{NOSLUG?} is NIL, then a "slug" charsetinfo (all characters have a slug (black rectangle) as their image) is returned, otherwise NIL is returned. [This needs improvement, to control how a slug is build. Currently \textbackslash BUILDSLUGCSINFO is presumed to know how to build a slug for all imagestreams.]

\( \text{\texttt{\textbackslash GETCHARSETINFO \textit{CHARSET} \textit{FONTDESC} NOSLUG?}}} \)
returns the charsetinfo for \textit{CHARSET} (0..254) from \textit{FONTDESC}. Calls \textbackslash CREATECHARSET if the charsetinfo wasn't cached already.

\( \text{\texttt{\textbackslash SETCHARSETINFO \textit{CHARSETVECTOR} \textit{CHARSET} \textit{CSINFO}}} \)
will install \textit{CSINFO} as the charsetinfo of (smallp) \textit{CHARSET} in \textit{CHARSETVECTOR}. Since \textbackslash CREATECHARSET calls \textbackslash SETCHARSETINFO directly, it usually need not be called.

\( \text{\texttt{\textbackslash CREATECSINFOELEMENT}}} \)
creates a word block for installing as a widths (imagewidths, offsets) field in a csinfo.

\( \text{\texttt{\textbackslash FGETWIDTH \textit{WIDTHSBLOCK} \textit{CHAR8CODE}}} \)
returns the smallp width at index \textit{CHAR8CODE}. e.g. (\textbackslash FGETWIDTH (FETCH (CHARSETINFO WIDTHS) OF csinfo) 55)

\( \text{\texttt{\textbackslash FSETPWIDTH \textit{WIDTHSBLOCK} \textit{CHAR8CODE} \textit{WIDTH}}} \)
sets the smallp width at index \textit{CHAR8CODE}.

\( \text{\texttt{\textbackslash FGETCHARWIDTH \textit{FONTDESC} \textit{CHARCODE}}} \)
returns the width of any character without having to explicitly fetch the correct charsetinfo for the character set of the character.

\( \text{\texttt{\textbackslash FGETIMAGEWIDTH \textit{FONT} \textit{CHARCODE}}} \)
analogous to \textbackslash FGETWIDTH but for imagewidths (the width of the character image rather than the amount the xposition should be incremented when printing this character.)

\( \text{\texttt{\textbackslash FGETCHARIMAGEWIDTH \textit{FONT} \textit{CHARCODE}}} \)
analogous to \textbackslash FGETCHARWIDTH but for imagewidths.
(/FGETOFFSET OFFSETBLOCK CHAR8CODE)
analogous to /FGETWIDTH but for offsets (the position in the bitmap for this character set where the image for this character begins.)

(/FSETOFFSET OFFSETSBLOCK CHAR8CODE OFFSET)
sets the smallp offset at index CHAR8CODE.
The timing results below compare the performance of an 1109 vs an 1188 on a suite of floating point benchmarks. The desire was to measure as closely as possible, using TIMEALL, the relative speeds of various arithmetic opcodes. No attempt was made to benchmark a "real" (e.g. linear algebra) application.

The 1109 was running a lispcore sysout (Makesysdate "21-Aug-86"), a real memory size of 7167 pages, and a set of Weitek floating point chips.

The 1188 was running a lispcore sysout (Makesysdate "25-Aug-86"), a real memory size of 7424 pages, and no floating point hardware, but microcode support for several boxed and unboxed floating point opcodes.

Both boxed and unboxed opcodes were benchmarked. Most benchmarks were a tight loop with the opcode evaluated 10,000 times. The block floating point opcodes were evaluated 1,000 times on arrays of size 100 (for a total of 100,000 arithmetic operations). Some of the boxed opcodes produced no garbage since they returned one of their inputs as an output, or returned T or NIL.

The 1188 had no microcode support for the block opcodes (they ran in lisp using scalar unboxed opcodes).

Cpu time and GC time are recorded separately for the boxed opcodes. Cpu time and CPU less the CPU time for an empty loop are recorded separately for the unboxed opcodes.

NA stands for Not Applicable.

Summary
-------

a.) Unboxed operations are a factor of ten faster than boxed operations across the board.

b.) On an 1109 the block opcodes yield another factor of five to ten.

c.) For scalar operations, the 1188 is never worse than .36% of the 1109, and never better than 1.16% of the 1109.

d.) The 1188 was actually faster than the 1109 for several unboxed opcodes -- and generally faster for the boxed opcodes.

e.) The 1109's floating point hardware really comes to the fore in the block opcodes. Unfortunately, with the exception of polynomial opcode, these opcodes are rarely used.

J.P.
Freemenu Internal Documentation

All names are in the Freemenu package (except old names, which begin with \fm.)

The Freemenu Description Language:

A freemenu description is defined by:

[] optional
{} group of things for some other operator
* 0 or more
+ 1 or more
| or

literals in bold

menu-desc --> menu-element ; can be passed to freemenu

menu-element --> item-desc | group-desc

item-desc --> ({{item-prop value}*:label item-label {{item-prop value}*})

item-prop --> one of the prop keywords described in the user doc

item-label --> string | bitmap | imageobj

group-desc --> ([:group] [prop-spec] {menu-element}*)

prop-spec --> (:prop {group-prop value}*)

group-prop --> one of the group property keywords described in the user doc

Group Formats:

The possible formats are:

:column - the elements in this group are layed out vertically, top to bottom, flush left
:row - the elements in this group are layed out horizontally, left to right, along the same baseline
:table - the elements in this group are layed out vertically, top to bottom, flush left. additionally, the second element of each direct subgroup is positioned at the same horizontal location. the third element of each direct subgroup is positioned at the same horizontal location. and so on, such that each element of each subgroup is both in a row and a column.
:explicit - each element of this group has a :left and :bottom property specifying its position. if the group property :coordinates is :group, then the values of the :left and :bottom property are relative to the lower left corner of the group, and if :menu (the default) they are relative to the lower left corner of the topmost group.
Group Format Defaults:

The format of a group of menu-elements can be specified in the prop-spec for that group. If it is not, the following rules apply:

- The default format for a group-desc passed directly to freemenu is :column.
- When formatting a group in :column format, the default format of each sub group is :row.
- When formatting a group in :row format, the default format of each sub group is :column.
- When formatting a group in :explicit format, the default format of each sub group is :explicit.
- When formatting a group in :table format, the default format of each sub group is :table-element, which signals the formatter to horizontally align each element in the sub group with the other elements in the table. If the format is specified for a sub group, the elements of that sub group will not be aligned with the other elements in the table.

The Formatter:

Entry point:

The entry point to the freemenu formatter is \fm.format (fm::format). It takes a description of the menu to be formatted and returns a group hierarchy structure. In the current version of freemenu, the group structure is just an alist of group id’s and properties, with the topmost group first. The formatter takes the following arguments:

description : a menu-element as defined above
format : the format to be used to lay out this group
font : the default font for each item in this group, must be a fontdescriptor
left, bottom : the lower left corner of the group. format everything relative to this position.
rowspace : the number of pixels to leave between rows, that is, the space to leave between elements in a column
columnspace : the number of pixels to leave between columns, that is, the space to leave between elements in a row
mother : the mother group of the one being passed for formatting. In the current version, this is the ID of the mother group, not the group itself.

The remaining arguments are optional. In the current version they are not specified, but they are SET by the guy who processes the group prop-spec. They might want to be specified in later versions:
id - the ID to use for this group
props - the prop-spec to use for this group

**Group prop-spec:**

The macro `\fm.setupprops` processes the group prop-spec in the description and fills in the slots in group accordingly (currently plist format). At the same time, it sets the arguments above from the values specified in the prop-spec, thus overriding the passed-in default. When the formatter is done with the current group, the function return, and thus all of the arguments are popped off the stack, and the previous state is now dynamically visible. This is how the formatter keeps track of format prop state, and pops back to the previous state when done formatting a group.

`\fm.setupprops` takes a group-spec and a list of group props to set. It generates code that will fill in the group props information, and then sets the format state arguments for the props that are in the list of group props to set.

The :left and :bottom group props in the prop-spec specify offsets for the entire group from where the formatter would otherwise position the group. This is similar to the way :left and :bottom item props specify offsets for an item that is automatically formatted (as opposed to explicitly positioned in the menu description).

**Group boxing:**

The macro `\fm.checkforbox` looks in the props to see if the group is boxed, and if it is, it adjusts the left,bottom position of the group to allow for the width of the box and the boxspace (boxoff = box-width + box-space).

Then the elements in the group are layed out normally.

Finally, the macro `\fm.updateforbox`, if the group is boxed, does the following: save the calculated extent of the group as the interior region of the group, and then adjusts the region to include the box, and saves this region as the region property of the group.

**Layout routines:**

The formatter calls one of the layout routines (`\fm.layout-column \fm.layout-row \fm.layout-table \fm.layout-explicit`) to lay out the elements in the group. The layout routines provide the real guts of the formatting. These functions return multiple values:

1. list of items in all the elements layed out
2. list of groups in all the elements layed out
3. extent region of all the elements layed out
4. list of id’s of all the subgroups layed out (this one would go away if had real group structure, instead of flat alist)

**Layout algorithm:**
Here is a description of the algorithm used in laying out a column of elements. The other routines follow the same procedures, but operate in a different dimension or have other overhead (like layout-table).

bind extent ; the region the elements in this group occupy
   itemlist ; a flattened list of items in this group
   grouplist ; a flattened list of groups in this group
   subgroupids ; a list of id’s of groups in this group
   element-position ; the position of the next element formatted
   element ; temp for hanging onto the element newly formatted

iterate through each element in the group description
   if the element is a group description:
      set element to call format on the group description
      extend: extent, itemlist, grouplist, subgroupids with the results
   otherwise:
      set element to create an item from the item description
      extend extent, itemlist with the item
      increment element-position by the size of element and extra space

return extent, itemlist, grouplist, subgroupids

Putting it all together:

With the information returned by the layout routine in the hands of the formatter, create a new group structure from the group prop-spec and extent, itemlist, and subgroupids. Add this group to the front of the list of groups layed out, and you get a list of groups for the description just formatted.

Freemenu Data Structures:

A Freemenu is currently a window, with all of the necessary properties set to make it behave as a menu when it is open. Eventually a Freemenu probably wants to be an independent structure, which can be enclosed in different display mechanisms, like windows, image-objects, pop up managers, etc.

There are three main data structures composing a Freemenu:

ITEM - Instance of the datatype freemenuitem, one for each item in the menu. The macro itemprop provides access to fetching and replacing fields in the datatype. The macro %itemprop is an internal version of the same macro which doesn’t type check the item and requires the field (property) name to be provided explicitely (not bound to some variable) in the call.

GROUP - A list structure describing a group of items in the menu. List fomat is (<group-id> <group-type-identifier> {<prop> <value>}*). The <group-id> is used for ASSOC purposes on the list of all groups. The <group-type-identifier> is checked by the macro group-p to ensure that this list is a valid freemenu group. The macro groupprop
provides access to getting and setting the props in the cddr of the list.

NWAY - A list structure describing an nway collection in the menu. The list format is the same as that for groups. nway-p and nwayprop are analogous to group-p and groupprop.

A list of all the items in the menu is stored on the ITEMS window property.

A list of all the groups in the menu is stored on the GROUPS window property.

A list of all the nway collections in the menu is stored on the NWAYS window property.

The functions get-item, get-group, and get-nway take an id and search the appropriate list for a matching freemenu item, group, or nway, respectively.

Additionally, many of the freemenu functions, like redisplay-menu, depend on being able to use a flat list of objects in the menu, either items, groups, or nway collections.
Reference counts are not contiguous with their objects, but rather are kept in three tables: \HTMAIN (the hashed main ref count table), \HTCOLL (the collision table), and \HTBIGCOUNT (the big ref count table). \HTMAIN is a hash table, where the hash function is based on the address of the object, while \HTCOLL and \HTBIGCOUNT handle two aspects of hash table overflow.

Since most (?) objects have refcount 1 (e.g. cons cells of a list), they are not explicitly represented; if an object (of a refcountable type) is not present in the tables, its refcount is 1.

If several objects hash to the same entry in \HTMAIN, then the entries are kept in a linked list of ref count entries in \HTCOLL.

If an object has a refcount equal to \MAXHTCNT (63), its refcount is stored in a "big" refcount table (\HTBIGCOUNT).

The Lisp function \HTFIND can handle all cases and is the punt function for the opcode (GCREF), which handles only the simplest case of no collision and no big refcount. Many opcodes call GCREF as a microcode subroutine and if GCREF punts, an entry is made in the table \HTOVERFLOW. Before opcode completion, the microcode calls the Lisp function \GC.HANDLEOVERFLOW, which processes \HTOVERFLOW by explicitly calling \HTFIND on each entry.

\HTMAIN is a locked down table of 32K word sized entries (or 64K bytes).

\HTCOLL is a paged table of 32K double word sized entries (or 128K bytes), where the first word in a pair is a ref count entry and the second is a 16 bit offset to the next entry in the chain.

\HTBIGCOUNT is a linearly searched table of big ref count entries; new pages are allocated as needed.

Hashing:

Given an address, the hash function computes a 15 bit offset into \HTMAIN by logically shifting the low 16 bits of the address right one bit.

GC record structure:

Each entry in \HTMAIN is a word (16 bits) long, and is a record of type GC. Its structure is the following:
REFCOUNT TABLE ENTRY

CNT is the refcount (0 to 63, excluding 1)
STK is on if this object is referenced from the stack.
HIBITS contains the top 8 bits of the PTR address of the object (the offset at which you
found this entry gives you the lower 15 bits (only even objects are refcounted)).
LINKP is on if this entry is a pointer to the collision table.

Organization of \HTCOLL:

\HTCOLL points to a double word entry, the first word of which is a 16 bit offset
from \HTCOLL where the first entry on the linked free list may be found. The second
word is a 16 bit offset from \HTCOLL where the first free double word in sequential
storage may be found.
At startup the first word is zero, indicating an empty free list and the second word
is four, indicating that the first free double word in sequential storage is at offset four
from the top of \HTCOLL.
A new entry is allocated by first looking at the free list. If the free list is empty, a
new entry is allocated from sequential storage.
It is an error to allocate double words from sequential storage at offsets greater
than or equal to \HTCOLLTHRESHOLD (65528 or 177770Q) -- if this occurs the
garbage collector is turned off.
The double word entries in \HTCOLL are similar to those in \HTMAIN in that the
first word in a pair is an instance of record type GC. The adjacent word is a 16 bit link
offset (field name NXTPTR) from the top of \HTCOLL to the next double word entry in
this collision chain. A NXTPTR value of zero indicates end-of-chain.

Algorithm:

\HTFIND is called with two arguments, PTR (a pointer to the object) and CASE
(oneof ADDREFCASE, DELREFCASE, SCANREFCASE or UNSCANREFCASE).
The SCANREFCASE means mark the object as referenced on the stack, likewise
UNSCANREFCASE. \HTFIND returns PTR if the result is zero ref count, else NIL.

First, \HTFIND hashes the address into a 15 bit offset from the top of \HTMAIN,
pointing at a refcount table entry. If the resulting entry is empty (all bits 0) then the
macro .NEWENTRY. handles it.
.NEWENTRY. does the following:
updates the HIBITS.
and by case does:
- \ADDREFCASE sets CNT to 2 (since its absence from the table implied
  previous refcount 1)
- \DELREFCASE leaves the CNT at 0 and returns the PTR
- \SCANREFCASE Sets count to 1 and sets the STK bit.

If the entry from the hash has the same HIBITS then this main table entry is the
entry for PTR, so the macro .MODENTRY. handles it.

.MODENTRY. does the following:
if CNT is \MAXHTCNT, then this entry is superceded by an entry in the big
refcount table (HTBIGCOUNT), so call \GC.MODIFY.BIGREFCNT.
Otherwise, by refcount case:
- \ADDREFCASE if incrementing CNT makes it equal to \MAXHTCNT,
  then call \GC.ENTER.BIGREFCNT, otherwise just increment CNT.
- \DELREFCASE decrements CNT
- \SCANREFCASE sets STK.
- \UNSCANREFCASE clears STK.
If resulting refcount is 1 and no STK (STKCNT = 2), return T signalling removal.

If the HIBITS don’t match, then a new collision has occured. The collision
resolution is basically to construct a linked list of refcount table entries out of cells from
HTCOLL

New collision:
-- Get two double word entries (LINK and PREV) from HTCOLL by calling the
 .GETLINK. macro.
-- Make the ref count contents of PREV equivalent to the ref count contents of
  the entry in HTMAIN and link PREV to the next double word entry, LINK.
-- Smash the HTMAIN entry so that the LINKPTR overlay is an offset to PREV.
-- Mark LINK as empty, and the end of a chain.
-- proceed with LINK as an empty entry (.NEWENTRY.)

where .GETLINK. does the following
-- fetch the FREEPTR field of HTCOLL (should be an offset to the front of
  the free list).
-- if FREEPTR is non-zero, fetch the first free cell and update the
  FREEPTR field of HTCOLL
-- else fetch the NEXTFREE of HTCOLL (should be an offset to the first
  free double word in sequential storage). If NEXTFREE is not GEQ to
  HTCOLLTHRESHOLD, allocate that double word and increment
  NEXTFREE by 2.

If the entry from the hash has LINKP set, then a collision has already occurred
and the entry is a pointer to a chain in the collision table. The LINKPTR overlay is used
as a (16 bit) offset into HTCOLL (the first 15 bits of the entry are used as is, with the
last bit (LINKP) masked to zero). Note that the LINKP test should occur before testing
HIBITS, but we place the explanation here since this case is more complex than a new
collision.
So LINKPTR is an offset to the beginning of a chain of double word entries in \HTCOLL. This chain is searched sequentially (by following NXTPTR offsets down the chain), resulting in either finding an entry for PTR, or hitting the end of the chain (NXTPTR offset equal to zero).

If an entry is found, then .MODENTRY. handles it as before except that if the refcount goes to zero the link is deleted from the chain (by .DELLINK.).

.DEllINK. takes three args, (LINK -- the link to be deleted, PREV the previous link in the chain (can be NIL), and ENTRY -- the \HTMAIN table entry)
-- If PREV, than update PREV to point to the link following LINK, else update ENTRY to point to the link following LINK.
-- Place LINK back on the free list (.FREELINK.)
-- If ENTRY now points to a chain one entry long, then update ENTRY to have the refcount table entry contents of the remaining link, and free the remaining link.

.FREELINK. takes one arg, the LINK cell to be freed
-- zero LINK
-- place LINK on free list of \HTCOLL by update the first word (field name FREEPTR) of \HTCOLL

If no entry in the chain is found for PTR, then allocate an entry (.GETLINK.) and put it on the end of the chain. Treat the new LINK as an empty entry (.NEWENTRY.).

Stay tuned for further updates...
Harmony Release Message to Internal Xerox Users
===============================================

(this text saved: {eris}<lisp>Harmony>Doc>HarmonyReleaseMsg.txt)

This message announces the latest release of Interlisp-D to the Internal Xerox community. This release is known as the "Harmony" release.

The Harmony release is a significant improvement over the last Interlisp-D release (Carol), with changes and improvements in a great number of areas. Over 450 ARs have been closed between Carol and Harmony.

Full release documentation of differences between Carol and Harmony is still in preparation. A draft version is stored in {eris}<Lisp>Harmony>Doc>HarmonyReleaseSpecifics.txt.)

How to Install Harmony
========================

For information on installing the Harmony release of Interlisp-D on your machine, see {eris}<Lisp>Harmony>Doc>GettingStarted.tedit (& .press).

VERY IMPORTANT WARNING FOR DLION USERS: The Harmony release of Interlisp-D is compatible with the Mesa 11.0 (Klamath) version of the Pilot DLion file system. This release of Pilot file system is INCOMPATIBLE with older versions. This means that if you use the Mesa 11.0 tools on a DLion with an old file system, it is possible to DESTROY information on your DLion disk. For example, if you start Othello 11.0 on a machine configured in Mesa 10.0, it may print a message saying that "the disk needs to be scavenged " -- if you scavenge the disk, you may lose the information on it. Before upgrading to Mesa 11.0, be sure that all valuable information on your DLion disk is stored on a file server, or on floppy disks.

Harmony Release Files
======================

All of the files needed to use the Harmony release are in the directory {eris}<Lisp>Harmony>. Specifically:

{eris}<Lisp>Harmony>Basics>*
Contains the Harmony sysouts, initial microcode, sample INIT files (INIT.SAMPLE, INIT.NONET, etc.).

{eris}<Lisp>Harmony>Library>*
Contains all of the supported lisp library packages. Most of these have been revised since the Carol release

{eris}<Lisp>Harmony>Lispusers>*
Contains only a few files. These files are new versions of Lispusers packages which have been updated to run in Harmony. Most of the files on {eris}<lispusers> can run in Harmony unchanged.

{eris}<Lisp>Harmony>Mesa>*
Contains some tools written in Mesa which are useful when running Interlisp on a DLion (1108). These include tools for partitioning a DLion disk, and installing Interlisp. These tools are described in {eris}<Lisp>Harmony>Doc>GettingStarted.tedit.

{eris}<Lisp>Harmony>CM>*
Contains the command files used to partition DLion disks, and install Interlisp on a DLion, from Othello or the new "Hello" tool.
Important Changes in Harmony
================================

Please see the full release documentation \{eris\}<Lisp>Harmony>Doc>HarmonyReleaseSpecifics.txt. There are two important changes which are summarized here.

Printing and Fonts:
The printing and font mechanisms have been extensively revised and cleaned up. Everything that worked before should still work, plus a lot of new functionality has been added. IMPORTANT CHANGE: The global variables which point at font files and font widths files have been changed. Instead of FONTDIRECTORIES, STARFONTDIRECTORIES, etc., the appropriate variables are DISPLAYFONTDIRECTORIES, DISPLAYFONTEXTENSIONS, PRESSFONTWIDTHSFFILES, and INTERPRESSFONTDIRECTORIES. If these variables are not set correctly, you may get FONT NOT FOUND errors when you try to print or display characters in different fonts. The file \{eris\}<lisp>Harmony>Basics>INIT.CIS is a site-specific init file which contains values for all of the variables needed. This file should be modified for each individual site.

Dlion Local File system:

As mentioned above, the Harmony release of Interlisp-D is compatible with the Klamath version of the pilot file system. In order to use the Interlisp-D on a Dlion, it is necessary to upgrade your Dlion to Klamath. While Mesa provides the ability to convert Mesa 10.0 workstations to Mesa 11.0, this "forward scavenge" will NOT convert Interlisp-D disk partitions. The simplest and most fail-safe way of converting your disk is to copy any valuable files from the local file system to a file server or floppies (using Carol Interlisp), upgrade to Klamath, and reload the files.

Besides the changes in the local file system format, a few of the functions have been renamed (MKDIR -> DFSCREATEDIRECTORY, MAKEPILOT -> DFSPURGEDIRECTORY). Also, the mechanism for specifying a particular volume on a Dlion has changed: instead of using \{FOO\}BAR to access the file BAR on the local disk volume FOO, one should use \{DSK\}<FOO>BAR. For compatibility, \{DSK\}FOO will search and use the first local file system volume on the disk after the currently-running Interlisp volume. In the Othello command files provided for partitioning the Dlion disk, the default name of the local file system volume has been changed from DSK to LispFiles.
February, 1989

Movement of Guaranteed Type Numbers, Addition of hashing MISCN subops.

Summary
The type numbers of several Lisp datatypes were moved down into the range that is "known to the microcode," to allow me to write C support for hashing.

Overview
Certain lisp type numbers must be known to the underlying implementation (microcode on 1186's, the C emulator on Suns). One obvious example is that the emulator must be able to detect SMALLPs, so it can do arithmetic quickly.

There is a range of type numbers that are allocated very early in the load-up process, so that they are assigned known numbers. After those "well-known" types, the type numbers for hunked storage are allocated. After that, type numbers are allocated to types as the loadup progresses, in whatever order they are defined.

The New Requirement
I implemented MISCN sub-opcodes for CL:SXHASH, CL::EQLHASHBITSFN, IL:STRINGHASHBITS, and IL:STRING-EQUAL-HASHBITS. CL:SXHASH has special-case code for several data types that were not in the "well-known" range: RATIONAL, COMPLEX, PATHNAME, and BIGNUM. I needed to move the type numbers for those types down.

The New "Well-Known" Type Numbers
The well-known type numbers are defined from the list \BUILD-IN-SYSTEM-TYPES, which is defined in the file LLDATATYPE. Listed below are the old and new type number assignments:

<table>
<thead>
<tr>
<th>Pre-existing</th>
<th>Newly-Added</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 SMALLP</td>
<td></td>
</tr>
<tr>
<td>2 FIXP</td>
<td></td>
</tr>
<tr>
<td>3 FLOATP</td>
<td></td>
</tr>
<tr>
<td>4 LITATOM</td>
<td></td>
</tr>
<tr>
<td>5 LISTP</td>
<td></td>
</tr>
<tr>
<td>6 ARRAYP</td>
<td></td>
</tr>
<tr>
<td>7 STRINGP</td>
<td></td>
</tr>
<tr>
<td>8 STACKP</td>
<td></td>
</tr>
<tr>

</tr>
<tr>
<td>18 RATIO</td>
<td></td>
</tr>
<tr>
<td>19 COMPLEX</td>
<td></td>
</tr>
<tr>
<td>20 PATHNAME</td>
<td></td>
</tr>
</tbody>
</table>

Changes to the C emulator
Moving those four types into the well-known range had the effect of moving the array hunk type numbers up. The C coded garbage collector had several hunk type numbers hard-coded into it (as hex constants!!). I added definitions for all the type numbers in use (both well-known and hunk) to LISPTYPES.H, and changed the GC code (in GCRECLAIMCELL.C, as I recall) to accomodate it.

The new hashing MISCN sub-opcodes

The source for the new opcodes is in sxhash.c. The document {Eris}<Lispcore>Internal>Doc>Opcodes.TEdit has been updated to reflect their addition. I have also reserved opcodes for CL::VALUES and CL::VALUES-LIST.

The Lisp definitions for the functions CL:SXHASH, CL::EQLHASHBITSFN, IL:STRINGHASHBITS, AND IL:STRING-EQUAL-HASHBITS are now written to use the MISCN sub-opcode appropriate; the UFNs are defined in the same files as the original functions, CMLHASH and LLARRAYELT.
Hello 11.0

program:       [eris]<lisp>Harmony>mesa>HelloDlion.boot
documentation: [eris]<lisp>Harmony>Doc>Hello.tedit

Hello 11.0 is a modified version of the Othello 11.0 utility, which is used for managing Pilot disk volumes. It offers most of the Othello commands (documented in the Mesa Users Guide), and adds a few commands which are useful when using Interlisp-D on a Dlion.

Hello is a .boot file, which can be loaded onto a Dlion disk using the Fetch Boot File command of Othello. It can also be booted off of a floppy disk.

Loading Interlisp From a File Server to a Logical Volume:

When Hello starts up, it prints out some information about the machine it is running on, including the Dlion’s host number and memory size, and then prints the prompt “>”, to indicate it is ready to receive a command. The "Online" command, which is automatically printed, tells Hello to bring the physical disk on-line. (Note: all user input is underlined, including confirming carriage-returns)

Hello 11.0 of 6-Sep-84 10:14:03
Processor = ...
Memory Size=1536 bytes
>Online
Drive Name: RD0

Before fetching a lisp sysout from a file server, it is necessary to open a connection to a file server, and login. Note: Hello currently cannot communicate with NS file servers (ones with colons in their names, such as "Phylex:").

>Open
Open Connection to ERIS
>Login
User: Sannella
Password: ******

In order for a lisp sysout to run, it needs to have a special "initial microcode" file installed. This microcode only needs to be installed once for each Dlion.

>Initial Microcode Fetch
Drive Name: RD0
File Name: [eris]<lisp>Harmony>Basics>Lisp11SAx000Initial.db
Formatting...Fetching...Installing...done

Now, fetch the Interlisp sysout file [eris]<lispcore>next>Full.sysout and store it on the logical volume named "Lisp". Depending on the size of the sysout file, and the load on the ethernet, this can take 5-10 minutes.

>Lisp Sysout Fetch
Logical volume name: Lisp
Lisp sysout file name: [eris]<lisp>Harmony>Basics>Full.sysout
Fetching....

Before running a lisp sysout, it is necessary to "expand" the file containing the sysout to the full size of the logical volume. This will allow Interlisp virtual memory to grow as Interlisp needs more space. If this is NOT done, there can be problems with Interlisp on large-memory Dlions. Eventually, the low-level Interlisp virtual memory management system will be improved, so this will not be necessary.

>Expand Vmem file
Volume to expand: Lisp

Finally, the Interlisp image on volume "Lisp" can be started with the boot command.

>Boot
Logical volume name: Lisp
Boot Lisp from this volume? YES

Copying Interlisp From One Logical Volume to Another:

A very useful facility that Hello offers is the capability of copying an Interlisp sysout from one logical volume to another. This is much faster than retrieving a sysout over the ethernet. Many people like to keep a "virgin" sysout on their Dlion, and reload from that. Here is how it is done: Load a sysout onto a volume named "BootLisp", as specified above. This sysout will be the "virgin" sysout used to re-initialize other Interlisp volumes. This volume should not be expanded with the "Expand Vmem file" command, and should never be booted.

>Open
Open Connection to ERIS
>Login
User: Sannella
Password: ****
>Initial Microcode Fetch
Drive Name: RD0
File Name: [eris]<lisp>Harmony>Basics>Lisp11SAx000Initial.db
Formatting... Fetching... Installing... done
>Lisp Sysout Fetch
Logical volume name: BootLisp
Lisp sysout file name: [eris]<lisp>Harmony>Basics>Full.sysout
Fetching....

To re-initialize the Interlisp volume "Lisp", copy the sysout file from the volume "BootLisp". This takes about a minute.

>Copy Lisp from Another Volume
Volume to copy from: BootLisp
Volume to copy to: Lisp

Now, expand and boot the "Lisp" volume as if the sysout had been loaded from a file server.

>Expand Vmem file
Volume to expand: Lisp
>Boot
Logical volume name: Lisp
Boot Lisp from this volume? YES

Determining What is on Your Disk:

It is easy to forget exactly what sysouts are on what volumes of the Dlion disk, or which Interlisp sysouts have been "expanded", etc. The "Describe" command prints out useful information about every volume on the disk.

>Describe.

Volume Lisp (type=normal) 700 of 16200 pages free
starting at physical address 4129
Lisp sysout: [eris]<lispcore>next>Full.sysout (3-Aug-84 10:35:17)

In this example, we can tell what lisp sysout, with which creation date, is stored on the volume "Lisp". The fact that 700 of 16200 pages are free strongly indicates that the sysout has been expanded (expansion doesn’t use ALL of the space).
Additional information on "How-To" can be found on:

{Eris}<Sybalsky>How-to>

such as:

Installing New 1108 ucode
Running AR cleanup
Seding info to Sales
Writing AR test cases
How to write a release note for a fixed AR:

When an AR is fixed, it is important to write a release note for the AR, even if it is just a note saying "Release Note: none needed". There is no better time to do this than when the problem is still fresh in your mind. And there is no better person to do this than the implementer, who knows exactly how important the AR fix is.

Does this AR affect the next release? There are some ARs which are created and closed during the course of development. However, it is hard to tell just from the text of the AR. It is important to put this information in the AR, so the Release master can tell that it shouldn't be collected. The note "Release Note: Don't release -- development bug" is better than nothing.

Does this AR affect outside users? If an AR just affects internal users, put a release note "Release Note: Don't release -- internal info" in the AR.

If there is info in the AR that the outside users should know, compose a release note. It doesn’t have to be perfect, but the implementer is in a better position to know what needs to be told than anyone else.

A single release note item should be talk about one piece of information. If a single AR contains or refers to multiple subjects, compose multiple release notes.

A release note contains a title, telling the substance of the item. Like AR subjects, the release note title should be short and as informative as possible (think of newspaper headlines). Include as many keywords as possible. For example "* New window functions: FOOBAR, BAZ" is better than "* New window functionality". When documenting bug fixes, try to make the titles "positive", saying "* FOOBAR arguments interpreted correctly" rather than "* Bug fixed where FOOBAR ignored argument".

When in doubt about whether a bug fix or new feature is worth documenting in the release notes, please document it. It is a lot easier for the release master to throw away information than to write it from scratch.

-----

How to assemble individual items into the "Release Notes":

If the individual release note items have been written, the primary job is to sort them by subject and importance, and assemble the big document.

For the Harmony release, the "topics" were ordered loosely on the importance of the different areas for that release (a lot of changes were made to I/O, fonts, printing, so they came first). This order is not sacred.

Within each topic area, the items are sorted by importance to the user, a subjective decision. Major new functionality, and incompatible changes obviously want to come first.
Characteristics of the Xerox 1100 Machines
upon which the Gabriel Benchmarks Were Performed

All three members of the Xerox 1100 family are custom microcoded processors. The Interlisp-D virtual machine is built around a compact 8-bit "bytecode" instruction set, the opcodes of which are implemented by a combination of microcode and macrocode. Not all bytecodes are supported directly in each member by microcode; the alternative is a trap out to a standard Lisp function. Above the level of the instruction set, all three members of the family appear identical to the Interlisp-D programmer. The implementation is such that a memory image can be compatibly run on any of the machines, without any change.

An Interlisp pointer is an address in a 24-bit virtual address space; a "quantum map" indexed by the high bits of the address provides information for type decoding. Additionally, litatoms (symbols) and immediate numbers (integers in the range of -2^16 to 2^16-1) live in a reserved portion of the address space; integers of larger magnitude (within the range -2^31 to 2^31-1) are "boxed"; floating-point numbers, which are in IEEE 32-bit format, are also boxed. All three machines have a 16-bit memory bus and 16-bit ALU; however, the bytecodes tend to hide the actual word size from the programmer. The virtual address space is broken down into units of 512-byte pages, and the three machines have different degrees of hardware assist for virtual memory management and instruction fetch.

Cons cells are cdr coded in a manner described in D. Bobrow and D. Clark, "Compact Encodings of List Structure", ACM Trans. on Prog. lang. and Systems, Vol 1 No 2, p266 October 1979. A cell of 32 bits is used to store a cons -- typically 24 bits for the car, and 8 bits for an encoding of the cdr. The encoding covers the four cases where (1) the cdr is NIL, or (2) the cdr is directly on the same page as the cons cell, or (3) the cdr is contained in another cell on the same page as the cons cell, or (4) the cons cell is itself a full indirect pointer, which can address an ordinary two-cell slot on any page (the space normally used for the car is used to address a 64-bit cell elsewhere; this is to allow for RPLACDs when there is no more free cells on the same page as the cell being updated). All cons cells are cdr-coded, independent of how they are created, and as a consequence the "average size" of such a cell is considerably less than 64 bits.

Strings and arrays are implemented as a fixed-length header, with one field pointing to a variable-length memory chunk taken from an area which is separately managed. To run some of the benchmarks, we used Interlisp’s Common Lisp array utility package. Additionally, Interlisp permits the user to define new first-class fixed-length data types, with corresponding entries in the quantum map mentioned above; for example, a STREAM is implemented as a record structure with 19 pointer fields and assorted integer fields of 16 bits or less.

Garbage collection is patterned after Deutsch and Bobrow, "An Efficient, Incremental, Automatic Garbage Collector" CACM, July 1976. A reference count is maintained for every collectible pointer (in addition to immediate pointers, litatoms are not reclaimed in Interlisp-D). Updates to non-stack cells in data structures (i.e., the CAR slot of a CONS cell, or the value-cell of a global variable) require updates to the reference count. The reference counts are maintained separate from the objects in a hash table, which is generally very sparse; and the updating is normally done within the microcode that effects the update operations. Reclamations are performed frequently, and involve scanning the stack area and augmenting the reference counts by a "stackp" bit; then scanning the reference count table reclaiming any entry which has a count of 0 and no reference from the stack (and possibly additional pointers whose reference count goes to zero as a result of such a reclamation); and finally re-scanning the table to clear the "stackp" bits. The scan through the reference count table looking for 0-count entries corresponds roughly to the scan of the marked-bits table in a Mark-and-Sweep collector; however, the scan of
the stack is infinitesimal in time compared to a full "mark" phase, and thus a reclamation typically runs in well under a second.

The internal architecture of the stack is a variant of the "spaghetti stack" model described in Bobrow and Wegbreit "A Model and Stack Implementation of Multiple Environments, Comm. ACM, Vol. 16, No. 10, Oct. 1973, pp. 591-603. The stack area is currently limited to 128KB.

The particular configurations upon which the benchmarks were run are as follows:

Xerox 1100: (Dolphin). 4K words of 40-bit microstore; microinstruction time 180ns; hardware assist for macro-instruction fetch; hardware memory map for up to 8MB of virtual space; hardware stack (for stack tip); memory access is 1-to-4 words (64 bits) in about 2us. The particular unit used in the benchmarking runs had 1.8MB of real memory attached, but 2MB has been in standard delivery.

Xerox 1108: (DandeLion) 4K words of 48-bit microstore; microinstruction time 137ns; hardware assist for macro-instruction fetch; hardware assist for virtual memory management (memory map is kept in non-paged real memory); memory access is 1 non-mapped 16-bit word in 411ns, but a random 32-bit cell access in about 1.2us. The stack is held in real, non-mapped memory. The particular unit used in the benchmarking runs had 1.5MB of real memory attached.

Xerox 1132: (Dorado) 4K words of 34-bit high-speed ECL microstore; microinstruction time 64ns; hardware instruction fetch unit; hardware memory map for up to 32MB of virtual space; 4Kilowords of high-speed ECL memory cache permit memory access of one 16-bit word in 64ns, and a cache-reload of 256 bits takes about 1.8us (additional details on the cache and memory organization may be found in D. Clark, B. Lampson, and K. Pier: "The Memory System of a High-Performance Personal Computer", IEEE Transactions on Computers, vol C-30, no. 10, Oct 1981). The particular unit used in the benchmarking runs had 2MB of real memory attached.

Note that the benchmarks were not run on the 1108-111 (DandeTiger), which has considerably more memory and control store than the basic 1108, and which also has a floating-point processor.

Updating the InterLisp Reference Manual [Sannella]:

Documentation files are kept on {eris}<LispManual>*.im. LispCore members are encouraged to modify these documentation files to reflect the changes made as the system is modified. Please be careful.

One important note: it is necessary to keep track of how the manual is changed, in order to provide a list of changes with the next revision of the manual. Therefore, I would strongly suggest that whenever anyone makes a significant change to the manual (adds/deletes a function definition, adds new arguments to a function, non-trivial rewording, etc.) that they send a short message to me (Sannella, not LispCore^).

The manual is stored in a large number of separate files, and it is difficult to know which file contains a particular function definition. Therefore, I have created a small package that will take an "IM Name" (a function, variable, property name, etc), create a TEdit window on the appropriate IM file, and position the TEdit cursor at the right place.

To use this, do

```lisp
(defun filesload (from lispusers) imname)
(defun inspect.im 'foo)

inspect.im uses the hash file package to search a hash file containing index information for the name FOO. If it is found, it will put up a pop-up menu listing references in different files. Selecting one of the references will move the cursor in the appropriate TEdit window (if there is an active TEdit window to the appropriate file), or create a new TEdit window to the appropriate file.

Sometimes, a particular name is defined as more than one "type" (function, variable, etc.). In this case, a pop-up menu will prompt you to declare which type you are interested in.

A somewhat more convenient way of using this facility, if you want to use it repeatedly, is to do

```lisp
(defun make.im.inspector)

This sets up an "IM Inspector Window", which contains a menu. Initially, this contains the single selection "Type an IM name", which prompts the user to type a name which will be looked up in the database. Below this window will appear type-selection and reference-selection menus, which do not disappear until another selection is made above them. This is hard to describe... try it out. [It works great! -- LMM]"
MAKING A LOADUP:

Loadups can currently only be made on Dorados. Command files, with extension "CM", are read by the Alto exec using the "e" command.

There are various command files on {Eris}<LispCore>CM>:

- LoadFull.CM makes a LISP.SYSOUT and a FULL.SYSOUT from scratch.
- LoadFullFromLisp.CM makes a FULL.SYSOUT directly from the LISP.SYSOUT.
- LoadDemoFromFull.CM makes a DEMO.SYSOUT

[Note that the command files were modified to use standard cache partitions on Dorados (which are?). These are used to load the sysout that the renamed functions run in, and to save the sysouts. The old non-cached behavior can be had by using command files whose names begin with SLOW-. A complication this causes is that changes to the command files must now be made in two places, the SLOW- and caching versions.]

The first part of the command file runs MAKEINIT to create a file INIT.SYSOUT and then DLFIXINIT to make it dandelion bootable by merging in the dandelion microcode to create an INIT.DLINIT.

[FS: THE FOLLOWING INDENTED SECTION HAS BEEN CHANGED. THE CORRECT EVENTS FOLLOW BELOW:

The next part starts up the INIT.DLINIT (which will run on all machines), and calls LOADUP(HUGE). The function LOADUP (on the file APUTDQ which is merged in at MAKEINIT time) has directions on how to do various kinds of loadups. It determines what other files are in the default loadup.

If you have a special kind of loadup that you think should be supported for some applications, it is possible to add a separate clause to LOADUP and include that in the standard source.]

The next part starts up the INIT.DLINIT (which will run on all machines), and the CM script loads LOADUP.LISP and LOADFULL.LISP, which call the function LOADUP on the rest of the files in the LISP.SYSOUT and the FULL.SYSOUT, respectively. (LOADUP 'HUGE) is obsolete and should be deleted.

How MAKEINIT works:

Basically, all the storage-modifying functions are redefined so they make their changes to a file. After some initialization of the blank memory space in the SYSOUT file the normal LOAD code is run, but the effects take place in the new sysout file instead of in memory.

Modification of the low-level storage functions is done by the code in the file RENAMEFNS, based on information in the file FILESETS. The function DORENAME is called with the argument I (for INIT). DORENAME uses the RENAMETYPES variable to determine which files to get low level definitions from,
and how to rename them. \texttt{RENAMETYPES} also indicates how to create an \texttt{R} (for \texttt{READSYS}) type rename, which is used by teleraid to read definitions out of a sysout (or sysout file).

The end result of \texttt{DORENAME} is a file \texttt{I-NEW}, containing the "remoted" definitions. This file is loaded and the "renamed" loaded code is run to load up the earliest parts of the system.

The basic goal of \texttt{MAKEINIT} is to make the \texttt{INIT.SYSOUT} capable of loading files over the ethernet and writing out (as with \texttt{LOGOUT} or \texttt{MAKESYS}) the resulting system. This minimal set of files to load is defined in \texttt{FILESETS} in the variables \texttt{0LISPSET} and \texttt{1LISPSET}.

Once these files are loaded, \texttt{INIT.SYSOUT} is written out. After having the dandelion microcode spliced into the memory image by \texttt{DLFIXINIT} the resulting INIT.DLINIT is run. The first thing done here is to run the "init expressions" of all the files which were loaded renamed. The expressions could not be evaluated remotely earlier in the init (indeed, the evaluator is not fully loaded at this point).

Things to watch out for: The data type \texttt{STREAM} must be the first datatype declared after \texttt{MAKEINIT} time. This means that no file loaded before \texttt{FILEIO} can declare a datatype. Packages are "turned off" in the early part of the init and symbols written into the \texttt{INIT.SYSOUT} are all package qualified. The file \texttt{PACKAGE-STARTUP} makes the switchover (located at the end of \texttt{1LISPSET}).

Now the rest of the files in \texttt{FILESETS} are loaded (those in \texttt{2LISPSET} and up). The greatest number of problems encountered after this point, aside from outright bugs, are dependencies of code on parts of the system which have not yet been loaded.

After this point the \texttt{LOADUP} function loads in the standard sets of files to make \texttt{LISP.SYSOUT} and \texttt{FULL.SYSOUT} (more detail?).
Writing Renamable Code:

Renamed code is used to build loadups and read the format of the resulting memory spaces (see sections above and below).

This is intended as a start at describing what you need to know to write renamable code.

\COPY is called to move something from the local memory space to the remote one.

\UNCOPY brings objects back.

LOCAL can be used to ensure that a function’s effects occur in the local memory image. It inhibits renaming of forms inside of it.

ALLOCAL can be used to ensure that a function’s effects occur in the local memory image. It inhibits renaming of forms inside of it.

UNLESSRDSYS takes two forms, the first to execute normally, and the second to be used when the function is renamed.

Since DTEST doesn’t run renamed, code that is intended to run renamed should use ffetch and freplace
How Teleraid works:

Teleraid runs in two parts: a server, running in microcode on one machine (usually entered by pressing UNDO to a front panel error), and a front-end, running on another machine. The front end machine examines the other over the network using the server.

The teleraid server is actually a simple memory page server written in microcode. It transfers pages of memory (using PUP protocols) to the front-end machine. It is up to the front-end machine to understand the internal format of the other machine's memory. This happens through a reverse version of the init process. Rather than renaming functions to write onto a remote memory space (in a file), teleraid runs functions which are renamed to read a remote memory space (on another machine or in a file; you can teleraid a non-running sysout file).

A variation of the renaming scheme used to build the init is employed in Teleraid. A large number of functions in the system are renamed to call (at their lowest levels) the Teleraid page server on the other machine.

Since the lowest levels of the system can change between releases it is important to have the same sysout running on the two machines.

The actual file that contains teleraid's renamed functions is RDSYS. It is created automatically by DORENAME on the file RENAMEFNS and must be updated whenever low level representation is changed. Details of what to rename for teleraid are contained on the file FILESETS. The functions which get renamed are scattered all through the low level system files (but those are pointed to by FILESETS).
Internal Storage Reference Functions
[Masinter, van Melle]:

There are a number of low-level functions for directly accessing memory as if it were an enormous array of 16-bit words, bytes, 32-bit cells, etc. In general, don't call any of these directly if you can help it. They are generally "unsafe" and can confuse your system in subtle ways if misused. Also, there are often alternatives that, if not completely safe, are at least less prone to error:

(A) Write functions or macros to do the accesses, and have them perform suitable type checking. See the GETPUPWORD and PUTPUPWORD macros, for example.

(B) Define a BLOCKRECORD to overlay a given data structure. This is much better than using \GETBASE et al if you are using fixed offsets—it is safer (less error-prone) and generally produces better code. With creative use of LOCF and ACCESSFNS, you can often avoid using explicit \GETBASEs altogether, and your code is much more readable. Also check out the MESATYPES package, written by Tayloe Stansbury, for producing such expressions from Mesa type declarations.

(ALLOCBLOCK NCELLS GCTYPE INITONPAGE ALIGN)

The basic low level storage allocation function. NCELLS is the number of 32 bit cells to allocate. GCTYPE is an integer, usually stated as the value of either UNBOXEDBLOCK.GCT (NIL is an old style synonym), PTRBLOCK.GCT (T is an old style synonym) or CODEBLOCK.GCT. INITONPAGE is the number of cells at the beginning of the block which must be allocated on the same page. ALIGN is the alignment of the address of this block in memory space. The base address will be evenly divisible by this number.

The argument BASE in the following functions refers to an address, an Interlisp pointer. For example, if the value of X is an instance of a datatype, then X is actually a pointer to the first cell of that instance. There are essentially only two operations that perform "pointer arithmetic": \ADDBASE and \VAG2; these compile directly into the ADDBASE and VAG2 opcodes.

(ADDBASE BASE OFFSET)

Produces a new address that is OFFSET 16-bit words beyond BASE.

(VAG2 HI LO)

Produces an address whose left 8 bits is HI and whose right 16 bits is LO.

There are, however, many other ways to produce addresses that ultimately perform \VAG2 or \ADDBASE, and these are usually preferable. The record POINTER is useful for decomposing pointers into page# and word-in-page or cell-in-page quantities. LOCF is useful in conjunction with BLOCKRECORDS and DATATYPES.

(LOCF (fetch FIELDNAME of datastructure))

[Macro]

Produces a pointer to the first word containing FIELDNAME. E.g., if BAR is declared as a WORD field in a record, then (fetch BAR of X) is equivalent to (\GETBASE (LOCF (fetch BAR of X)) 0).
\INDEXF \(\text{fetch FIELDNAME of T}\))

Returns the word offset to the first word containing \text{FIELDNAME}. Since this is independent of the actual datum being operated on, the datum is often given as \text{"T"}. E.g., if \text{BAR} is declared as a \text{WORD} field in a record, then (\text{fetch BAR of X}) is equivalent to \((\\\text{\textbar{GETBASE} X (INDEXF (\text{fetch BAR of T})}))\). There is rarely any need for \INDEXF.

\text{Note that ADDBASE, LOCF and other pointer-producing operations are not in general safe in Interlisp-D. The garbage collector can get very confused if you save away arbitrary pointers anywhere other than in local variables. This is because the reference count of an object is associated only with the pointer to its beginning, i.e., only with the address that the public traffics in (the pointer returned from create, for example). If you must store away internal pointers, be very careful that you continue to hold on to the pointer to the start of the object for as long as you maintain the internal pointer. This assures that the object will not get garbage-collected out from under you, the most common source of such confusion.}

\text{(\textbar{ADDBASE2} BASE N)}

Equivalent to \((\text{\textbar{ADDBASE} BASE 2*N})\).

\text{(\textbar{GETBASE} BASE OFFSET)}

\text{(\textbar{PUTBASE} BASE OFFSET VALUE)}

These fetch and store, respectively, the 16-bit word (as a Lisp small positive integer) located at OFFSET words beyond BASE. \text{\textbar{PUTBASE} is really dangerous. E.g., (\text{\textbar{PUTBASE} NIL n}) for many small values of n will smash your system beyond repair. Not good for a residential environment where a smashed system can lose a lot of work.}

\text{(\textbar{GETBASEBYTE} BASE OFFSET)}

\text{(\textbar{PUTBASEBYTE} BASE OFFSET BYTE)}

Fetch and store 8-bit quanta. BASE is a word address, and OFFSET is a byte offset—counting the high byte of the base word as offset zero.

\text{(\textbar{GETBASEPTR} BASE OFFSET)}

Fetches a pointer at OFFSET from BASE. A pointer is a 24-bit quantity, which is stored right-justified in a 32-bit cell. Note, however, that BASE and OFFSET are both still in terms of 16-bit words.

\text{(\textbar{PUTBASEPTR} BASE OFFSET PTR)}

Stores pointer PTR at OFFSET from BASE. This is not a direct inverse of \text{\textbar{GETBASEPTR}}, because it stores a full 32 bits, never mind what used to be the high 8 bits originally stored there. \text{\textbar{PUTBASEPTR} does not do reference counting, so this can be especially dangerous if not used carefully. BASE is a word address, and OFFSET is in words, not cells! \textbar{RPLPTR} is similar to \textbar{PUTBASEPTR}, except that it does do reference counting.}

\text{(\textbar{RPLPTR} BASE OFFSET PTR)}

Stores a 24-bit pointer, similar to \text{\textbar{PUTBASEPTR}}, except that (a) it stores only 24 bits, preserving whatever used to be in the high 8 bits; and (b) it does reference-counting operations; decrements the count of the pointer being smashed and increments the count of
the pointer being put into the location. This is the proper way to smash a pointer field if you must. However, there is almost never any need for you to call this directly; the usual way to smash a pointer field is to use records.

Implementation notes: \getbasebyte and \putbasebyte compile directly into the corresponding opcodes, and execute entirely in microcode when the \offset and \value arguments are small positive integers. \getbase, \putbase, \getbaseptr, \putbaseptr, and \rplptr compile directly into the corresponding opcodes when the \offset argument is a constant less than 256; for other \offset arguments (variable quantities, larger integers), they require an \adddbase in addition.

\getbasefixp \base \offset
\putbasefixp \base \offset \value

These fetch and store 32-bit integers.

\getbasefloatp \base \offset
\putbasefloatp \base \offset \value

These fetch and store 32-bit floatps.

\getbasestring \base \offset \nchars

Creates a string \nchars characters long whose characters consist of the bytes located starting at \offset (a byte offset) from \base. Thus, the first character of the result is \getbasebyte \base \offset.

\putbasestring \base \offset \string

Stores the characters of \string as consecutive bytes starting at \offset (a byte offset) from \base.

\blt \dbase \sbase \nwords

Copies a sequence of \nwords words starting at \sbase to corresponding words starting at \dbase. This compiles directly into the \blt opcode. In the case where the source and destination ranges overlap, the behavior is well-defined: words are copied from the end of the range backwards to the beginning. Thus, this is equivalent to (for I from \nwords-1 to 0 by -1 do (\putbase \dbase (\getbase \sbase I))). Very fine point: this operation is defined to be completely uninterruptable if \nwords is less than 10; thus, you can use opcode to make small indivisible transfers.

\movewords \sbase \sbyteoffset \dbase \dbyteoffset \nwords

Obsolete predecessor of \blt.

\movebytes \sbase \sbyteoffset \dbase \dbyteoffset \ nbytes

Copies a sequence of \nbytes bytes starting at \sbyteoffset bytes beyond \sbase to \dbyteoffset bytes beyond \dbase. If the ranges overlap, the result is formally undefined.

\zerobytes \base \first \last

Stores zeroes into the bytes at offsets \first thru \last, inclusive, from \base. Thus, a total of \last-\first+1 bytes are cleared.

\zerowords \base \enbase
Stores zeroes into the words from BASE thru ENDBASE, inclusive. There are obscure reasons for the lack of symmetry among \ZEROWORDS, \ZEROBYTES, and \MOVEBYTES.
ABC, EXPORTS.ALL, &c:

Note that for Interlisp-D, LOAD(ABC) loads <LispCore>Library>EXPORTS.ALL.

(LOAD 'MAKE-EXPORTS.ALL) will connect to <LISPCORE>SOURCES> and gather all exports into the EXPORTS.ALL file.

“ABC” stands for “A Byte Compiler”—meaning the augmented environment required to compile Interlisp system code. The augmentation includes any of the definitions found under the EXPORT FILEPKG command. The variable EXPORTFILES, set up by loading the file FILESETS, contains the rootname of all system files which have any EXPORT commands. A file will generally export those items that other files need (e.g., records or macros) which are DONTCOPY, and thus not part of the user’s system.
SYSRECORDS [van Melle]:

In order for the inspector to be able to inspect an object of some user-declared datatype, it needs a declaration for it. The declarations for system datatypes are omitted from the loadup (by being marked DONTCOPY and being initialized with INITRECORDS). In order for their instances to be inspectable, they should be added to SYSTEMRECLST by the filepkg command SYSRECORDS, which is syntactically identical to RECORDS. The datatype declaration is actually stripped of comments, subrecords and initialization info before being put out.
Putting new DLion Microcode into a Sysout:

Load the file SPLICE.DCOM from <Lispcore>Sources>.

\begin{verbatim}
(NCLIP MICROCODEFILE SYSOUTFILE)

Copies the entire contents of MICROCODEFILE, a DLion .db file, into SYSOUTFILE, which must be a Lisp sysout. Both files must be random access.
\end{verbatim}
DTigerness vs. DLionness

How programs can tell if they're running on a DTiger

Programs can tell if they are running on a Dandetiger (1108 with CPE) by evaluating \( \text{AND} \ (\text{EQ} \ \MACHINETYPE \ \text{DANDELION}) \ (\text{ODDP} \ (\DEVICEINPUT 8)) \) - this will return T when run on a DTiger, NIL when run on anything else. \( \DEVICEINPUT 8 \) returns the microcode version number when run on an 1108; if the version is odd, you're running on a DTiger.
WHEREIS, and the WHEREIS database

The WHEREIS package is used to find where (which source package) an atom has come from.

The expanded WHEREIS package comes preloaded in FULL.SYSOUT, or can be loaded from \{ERIS\}<LISPCORE>LIBRARY>WHEREIS.DCOM. Normally WHEREIS only searches loaded files. If the function WHEREIS is called with a FILES argument of T it searches the list of hashfiles given in the global WHEREIS.HASH. These hashfiles may have names such as WHEREIS.HASH, LIBRARY.WHEREISHASH, SYSTEM.WHEREISHASH, etc., and may live in places like \{ERIS\}<LISP>INTERMEZZO>LIBRARY. Usage:

_(WHEREIS <foo> 'FNS T)

This definition also allows you to ask for MACROS, RECORDS, PROPS, and VARS in addition to FNS.

To make a new WHEREIS database use the function WHEREISNOTICE thus:

 WHEREISNOTICE(  
     (<LISPCORE>SOURCES <LISPCORE>LIBRARY> <LISPUSERS>)  
     T  
     <LISPCORE>SOURCES>SYSTEM.WHEREISHASH)

Note that it takes a long time to examine all the files. Best to leave this task to a lonely Dorado.
Installing New Opcodes [Masinter]:

[abstracted from messages to Jim desRivieres]

The various functions (CALLSCCODE, PRINTCODE, CHANGENAME) know about opcodes via the list \OPCODES. If you want to add some new opcodes, you can edit the list. The format of \OPCODES is documented, I think, in the function PRINTOPCODES, which is on the file ACODE. Note that if you install new opcodes on the fly you should then reset the variable \OPCODEARRAY to NIL.

You can tell if you have installed the opcodes by calling \FINDOP directly. (\FINDOP 'CAR) should return the opcode-description-record for CAR, while (\FINDOP 231Q) should look up opcode 231.

If you add opcodes, you should send a message to LispCore^ outlining what opcodes you want to reserve. The file OPCODES.TEDIT (on <LispCore>INTERNAL>DOC>) I think has a listing of opcodes too, and if you are reserving a range, that reservation should be documented there too.

Subject: adding UFNs

The UFN mechanism hasn't really been extended for simple experimentation but is workable with a little effort. Normally, UFN entries get set up at MAKEINIT time by a renamed version of a function, I think it is called \SETUPENTRY or some such. (LLCODE, LLBASIC, LLNEW or one of those). The entries in the OPCODES record is used to set up the ufns. Now, it is currently the case that UFN's can't do anything like push N things on the stack -- all they can do is pop N arguments (N>=0) and push 1 result.

Writing ufn's that do something other than that, e.g., that don't follow the normal function call paradigm, are a lot more work. Basically I think you have to get into the level of stack-hacking that is found inside LLSTK. For example, a UFN that wanted to push a bunch of NIL's would have to do something awful, like steal space out of its own basic frame to give it back to the caller. This kind of code is tricky to write and debug, especially because you can't do things like insert BREAKs.

Popping N off of course is easy since that is what function calls do.

In order to do a jump operation, doing something like (add (fetch PC of (\MYALINK)) 10) would do a relative jump to byte +10.

It may actually be necessary to extend the UFN mechanism to allow some of the extensions that you want. Why don't you figure out what you can do with the current mechanism, and come back with the ones that you can't figure out how to implement.
Adding new opcodes to the Interlisp-D system

Written by: Herb Jellinek
Revised: 14 June 1984

The process of adding new opcodes to the Interlisp-D system has long been a mysterious one. This document is an attempt to shed some light on these mysteries. The document covers: Creating new opcodes, Writing UFNs, and The OpcodeTool. Enjoy.

Creating new opcodes

There are a number of global objects and properties that one must know about in order to install new opcodes/UFNs. Here's a list of them:

\OPCODES

A list of the current opcodes, each of which is a record of type \OPCODE.

\OPCODEARRAY

An array-ified version of \OPCODES. If set to NIL it will be reinitialized from the contents of \OPCODES. \OPCODEARRAY is recreated when needed by the function \FINDOP.

DOPVAL

Information on how to emit code for a given function. There are two formats:

1. (nargs . opcode-sequence)
   If the number of arguments supplied matches nargs, compile into the sequence opcode-sequence.

2. ((nargs1 . opcode-sequence1)
   (nargs2 . opcode-sequence2) ...
   (nargsN . opcode-sequenceN). other-cases)
   If the number of arguments supplied matches nargs1, compile into opcode-sequence1, otherwise see if the number of arguments supplied matches nargs2, etc. One may also supply a function name as the tail of the list; the code generator will call that function if none of the other cases apply. The function \OPT.COMPILESERROR is typically used for this purpose; it is equivalent to HELP.

DOPCODE

The OPCODE record for a given atom.

OPCODE

A record describing the structure of the DOPCODE property and the elements of the list \OPCODES; it has the following fields:
UFNFN  name of the ufn. Actually read by MAKEINIT
LEVADJ  stack effect (+/-n) or token. Used by PRINTCODE. See code in PRINTCODE for details
OPPRINT used only by PRINTCODE.
OPNARGS number of extra bytes
OPCODENAME name of opcode
OP#  number of opcode, or range for opcode sequences

Herb will document OPPRINT.

**Writing UFNs**

UFNs are Lisp functions that either run in the place of unimplemented instructions or when the microcode detects a situation that is too complex for it to handle. (This is termed punting.) There are two cases involved in writing UFNs: those for single-byte opcodes, and those for multi-byte opcodes.

**UFNs for single-byte opcodes**

For example, assume we have a single-byte opcode called SQRT, which takes a FLOATP as operand and returns its square root. The instruction is designed to punt out to its UFN (named \SQRT) when its operand is of the wrong type, at which time the UFN can either attempt to coerce the operand to a FLOATP or signal an error. \SQRT need be no more than a function of a single argument.

**UFNs for multi-byte opcodes**

These UFNs are slightly more complicated, but not much. The difference between single-byte UFNs and multi-byte ones is in the handling of the "extra" (alpha, beta, gamma) byte or bytes. To wit: all multi-byte opcodes that begin with the same byte have the same UFN, and the extra bytes get passed to this UFN in the form of extra arguments. We might have a group of three bit-vector operators (we'll call them BITOP), that all begin with a bytecode of 72Q and vary from 0 to 2 in the second byte. The bytecodes each expect one argument on the stack. The UFN (\BITOP), would probably have the following form:

```
(DEFINEQ \BITOP
  (LAMBDA (BITVECTOR OP)
    (SELECTQ OP
      (0 (\BITOP.MASK BITVECTOR))
      (1 (\BITOP.SHIFT BITVECTOR))
      (2 (\BITOP.ROTATE BITVECTOR))
      (HELP "\BITOP - illegal operation" OP)))))
```

**The OpcodeTool**

[Imm: I changed the opcode format; I don't know if this works]
The OpcodeTool is a package that makes it easy to set up and test new opcodes in a running Lisp system. Do

   (LOAD '{Eris}<LispCore>Misc>OpcodeTool.dcom)

This package has one entry point, MAKEOPCODE, a function which takes 8 arguments:

- OPNAME   a litatom
- NUM       the opcode number
- OPNARGS   the number of extra bytes (alpha, beta, etc.)
- OPPRINT   usually T
- LEVADJ    the stack level adjustment for this opcode
- UFN       the UFN for this opcode
- UNIMPL    a list describing which machines have no microcode for this op
- DOPVAL    a (optional) DOPVAL prop for the litatom OPNAME

After you've run MAKEOPCODE, you can compile functions that use the new opcode and test them out.
Creating New Devices:

Section on making new file devices, How To.
VMEM.PURE.STATE [van Melle]

When preparing a demo, it is often nice to set things up in such a way that you can push the boot button at any time to instantly restart the sysout, rather than having to go back to some installation utility to reinstall the sysout. VMEM.PURE.STATE is a hack that lets you do this. Basically, while it is on, the page fault handler is altered to write dirty pages beyond the original end of the vmem, thus keeping the original vmem "pure".

\[(\text{VMEM}.\text{PURE}.\text{STATE} \ FLG)\]  

[Function]  

When \(FLG\) is true, enables "pure vmem" as of the next operation that writes out a consistent vmem, e.g., LOGOUT, SAVEVM, or SYSOUT. While in this state, as long as you do not perform another vmem-writing operation (LOGOUT, etc.), you can boot the machine (or slightly more cleanly, call (LOGOUT T)) and be back in the same state as the LOGOUT (or whatever) that initiated the pure image.

When \(FLG\) is NIL, returns to normal page fault operation. This is usually not too interesting, unless you really do want to LOGOUT, etc and forgo the "checkpoint" you set up. Note, however, that in either case, your virtual memory file is bloated by whatever pages had been written to the end of the vmem file instead of where they belonged.

There is a mode in which LOGOUT compresses the pages back to where they belong, but I never got it fully debugged.

There is a new MP error in this state: 9316. It means you wrote out so many dirty pages, you ran into the absolute end of the vmem file (8MB) even though you still have plenty of "virtual memory" left.

There are two typical modes of operation:

(1) Call \((\text{VMEM}.\text{PURE}.\text{STATE} \ T)\) before calling SYSOUT, thus making a sysout that has the pure feature turned on for anyone running it.

(2) Start up a sysout not so made, and then call

\[\text{PROGN} \ (\text{CLEARW} \ (\text{TTYDISPLAYSTREAM})) \ (\text{VMEM}.\text{PURE}.\text{STATE} \ T) \ (\text{LOGOUT})\]

\[\]

to turn the vmem into which this sysout was loaded one with the pure property.
Dorado Mufflers & Manifolds

Date: 23 Sep 84 19:29 PDT
From: JonL.pa
Subject: [JONL.PA: Mufflers and Manifolds]
To: Jellinek

A couple weeks ago I promised to send you "all my knowledge" about the alpha bytes of the MISC opcodes. Not much knowledge; don’t even know for sure why I picked "9", but possibly Bill will know of an "8" used for Dolphin-specific purposes.

-- JonL --

----- Begin Forwarded Messages -----

Date:  6 MAR 84 18:42 PST
From: JONL.PA
Subject: Mufflers and Manifolds
To:   vanMelle, Charnley
cc:   Purcell, JonL

Sorry I didn’t mention this before -- after talking with Bill and Don I decided to use opcode MISC1 with alphabyte of 9 to do the equivalent of Mesa’s ReadWriteMufflerManifold operation. No MISC opcodes at all were implemented on the Dorado (before now), and the set of alphabytes from 0 through 8 seem to be exhausted by the Dlion/Dolphin needs.

The interface to this operation is:

Input -- one 16-bit integer; low-order 12 bits are Muffler/Manifold address, bit 2^15 non-zero means to write manifold, zero means to read muffler.

Output -- for write operation: NIL. for read operation: one 16-bit integer whose low-order 15 bits are garbage and bit 2^15 is the 1-bit value of the muffler.

See the file <LispCore>Misc>MAKEDORADONSHOSTNUMBER for the code I’m about to install modulo the following: (1) SELECTQ on \MACHINETYPE, (2) don't do it if (MICROCODEVERSION) is less than 12004Q, (3) do "replaces" into (FFPAGE NSHost[i]) rather than cons up the NSHOSTNUMBER record.

----- End Forwarded Messages -----
This file is an attempt to explain the operation of the Dandelion rigid disk interface, the microcode, and how Lisp constructs and uses disk IOCBs to perform disk operations.

**DISK DRIVE INTERFACE**

The Dandelion’s central processor divides its time among the high speed I/O devices: the ethernet, the rigid disk, the I/O processor, and the display. The "I/O Page" is located in a well-known (to the microcode and Lisp) area of virtual memory, and it holds locations for communication between the different "micro-tasks."

Currently, the Dlion’s Disk IOCB is the second word on the I/O page (that is, \(\text{ADD} \text{BASE} \ \text{IOPAGE} \ 1\)). Memory locations placed on this page must be up to 16 bits long, which constrains the address to be within the first 256 pages.

The IOCB page is used to store parameters and other information that is picked up by the microcode. When one wants to initiate an I/O operation, it can be done by depositing the parameter block onto the IOCB page (somewhere) and then placing the location (16 bits) of the parameter block onto the device’s "mailbox" on the I/O page. When the device notices that something has been deposited onto its special I/O page location, it will read in the parameters, execute the operation, and reset the flag to zero to indicate that the operation is complete. (*Note: This is not completely true for the disk.*) So, device I/O in Lisp usually looks like the following:

\[
\text{\(\text{BLT} (\text{ADD} \text{BASE} \ \text{IOCBPAGE} \ \text{IOCBDisplacement}) \ \text{IOCB} \ \text{IOCBLen})\)}
\]

... or an alteration of an existing IOCB on the IOCB page ...

\[
\text{\(\text{PUT} \text{BASE} \ \text{IOPAGE} \ \text{DeviceCSBDisplacement}\)}
\]

\[
\text{\(\text{LOLOC} (\text{ADD} \text{BASE} \ \text{IOCBPAGE} \ \text{DeviceIOCBDisplacement}))\)}
\]

\[
\text{\(\text{until} \ \text{ZEROP} (\text{GET} \text{BASE} \ \text{IOPAGE} \ \text{DeviceCSBDisplacement})))\)}
\]

The \text{PUTBASEs} and \text{GETBASEs} usually come in the form of record package macros.

The reason why the disk does not follow the usual \text{IOPAGE} convention of resetting its CSB to zero is because the drivers were meant to cause interrupts when disk I/O is finished. Lisp does not currently utilize this feature, so to poll the IOCB to detect when it has been completed, the IOCB status is set with some unused bits activated, and when the IOCB completes, the disk microcode will fill in the status and wipe out those bits as a side effect.

**DISK IOCBs**

To make life easier on the Dandelion’s disk microcode, the implementors thought it to be a good idea to have the microcode emulate some kind of primitive "instruction set." So, when you want disk I/O, you have to write a little "program" in "IOCB Machine Language" to accomplish it.
Fortunately, these IOCBs are still around after booting, and Lisp leaves them in place but changes the fields to do more complicated operations.

The entire IOCB page is divided into three sections:

1. The Data Field:

This portion of the IOCB page contains mostly scratch space for the microcode and information for the programmer. Of particular interest here are the Header and Label "template" fields. For read operations, these fields are modified by the microcode, whereas on verify and write operations, they are just read.

The header field corresponds to the header records that were written on the disk when it was formatted. They contain identification information for the microcode - the sector's track, cylinder, and head numbers. These records are *never* written to. The usual operation on this field is verify, and it is primarily used to indicate to the microcode which sector is which on a given track, and to provide a security mechanism for the microcode. This template is also used to store the current cylinder number for the disk drive, and it is the place where the cylinder, track, and sector numbers are stored prior to a disk operation.

The label field is more general-purpose. In the pilot world, the ID number of a file and the page's relative location within the file are stored in the label field. For booting, a coded pointer is also stored here to lead the boot microcode from one sector to the next.

Note that the header and label fields *must* be in these locations on the IOCB page. (they may not be somewhere else in VM). The pointers to these fields from within the parameter blocks are only 16 bits long, so the headers and labels must be kept here.

2. The Parameter Area

The second portion of the IOCB page is the parameter areas for the IOCB programs. There are two of these IOCB parameter areas left over after booting, but Lisp only uses one of them. The information contained in the parameter block includes the run length, the type of operation to use (which operation, read/write/verify, to use on each field), the virtual page number of the disk buffer, and information on how to handle errors. They must be aligned on 16 word boundaries, due to the way that they are loaded into the micro-registers inside the CP.

3. The IOCBs

The third portion of the IOCB page contains the actual IOCBs themselves. There are two basic types of IOCBs:

1. Seek IOCB:

The Seek IOCB is complete as it stands. (it has no parameter areas to read in like the transfer IOCB has). The Lisp code fills in the fields for the number of cylinders and the direction to seek, and the IOCB’s code steps the drive head in the given direction for the given number of steps. There are no verify operations on seeks, so it is the programmer’s responsibility to remember which track number the head is currently positioned at. If a disk drive gets lost, a recalibrate operation is necessary. This can be accomplished by setting up an IOCB to step
out one track, and continually running it until the Track00 bit of the disk controller status register becomes T. This register can be read with the function (\DEVICE\INPUT 3) and the fields can be found in the record DL\DISK\STATUS on DISKDLION.

2. Transfer IOCB:

The Transfer IOCB reads in a parameter area of 17 words, executes the transfer operation, and exits.

**DISK IOCB MACHINE LANGUAGE**

As was mentioned before, the disk microcode emulates a very small instruction set (to keep the code size down and increase flexibility). This instruction set is as follows:

<table>
<thead>
<tr>
<th>Opcode</th>
<th>Operation</th>
</tr>
</thead>
<tbody>
<tr>
<td>8000 xx</td>
<td>Send word xx to disk controller register KCtl.</td>
</tr>
<tr>
<td>0007 ss</td>
<td>Set status bits from ss</td>
</tr>
<tr>
<td>0000 aa</td>
<td>Increment number in location aa, and skip if zero.</td>
</tr>
<tr>
<td>0002 aa</td>
<td>Unconditional jump to location aa.</td>
</tr>
<tr>
<td>0006</td>
<td>Finish up IOCB.</td>
</tr>
<tr>
<td>0400 aa</td>
<td>Write status to location aa.</td>
</tr>
<tr>
<td>0005 aa</td>
<td>Load parameter table from locations starting at aa.</td>
</tr>
<tr>
<td>0800</td>
<td>Transfer a run of pages, skip of no error</td>
</tr>
</tbody>
</table>

Some interesting "8000 xxxx" commands follow:

<table>
<thead>
<tr>
<th>Opcode</th>
<th>Operation</th>
</tr>
</thead>
<tbody>
<tr>
<td>8000 0422</td>
<td>Wait for pending seeks to complete. (InsureSeekComplete)</td>
</tr>
<tr>
<td>8000 0420</td>
<td>Seek step IN (positive direction)</td>
</tr>
<tr>
<td>8000 04A0</td>
<td>Seek step OUT (negative direction)</td>
</tr>
</tbody>
</table>

Inside the parameter areas, the following "code numbers" are important:

<table>
<thead>
<tr>
<th>Code</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>001E</td>
<td>Abort on NotReady, WriteFault, Overrun, or CRC errors</td>
</tr>
<tr>
<td>001C</td>
<td>Abort on NotReady, WriteFault, Overrun</td>
</tr>
<tr>
<td>001F</td>
<td>Abort on NotReady, WriteFault, Overrun, CRC, or Verify</td>
</tr>
</tbody>
</table>

**OTHER NOTES, RESTRICTIONS, ETC.**

To specify the length of the data field, "8100" is used instead of "0100". Setting the high bit of the data length field causes the microcode to increment the virtual page number after each page is transferred. This is used primarily for multiple page runs.
The length of the header and label fields must be decremented for verify operations.

It is impossible to follow a write operation with anything other than a write operation. That is, if you write the label field you must write the data field. Otherwise, the tail of the label write operation will trash the data field. (Something in the microcode or disk controller causes this, and it cannot be avoided!)

The files [Eris]<Lispcore>Dlion>DiskBootIOCBs.bravo and [Eris]<Lispcore>Dlion>DiskTest.dm contain many sample IOCBs. They are invaluable anyone tinkering with the Dlion disk system.

THE LISP DLION DISK HEAD

The heads for the D Lion disk are stored on the file DISKDLION in the sources directory. The following is a description of the functions in this file and their purposes:

`\DL.DISKINIT` [Function]

Determines the shape of the disk drive and sets up variables as follows:

<table>
<thead>
<tr>
<th>DISKTYPE:</th>
<th>One of \SA4000, \SA1000, \Q2040, \Q2080</th>
</tr>
</thead>
<tbody>
<tr>
<td>SEC/HD:</td>
<td>Sectors per head on this disk drive</td>
</tr>
<tr>
<td>SEC/CYL:</td>
<td>Sectors per cylinder on this disk drive</td>
</tr>
</tbody>
</table>

The data for each drive follows:

<table>
<thead>
<tr>
<th>Drive</th>
<th>Sec/Hd</th>
<th>Sec/Cyl</th>
<th>Heads</th>
</tr>
</thead>
<tbody>
<tr>
<td>SA4000</td>
<td>28</td>
<td>224</td>
<td>8</td>
</tr>
<tr>
<td>SA1000</td>
<td>16</td>
<td>64</td>
<td>4</td>
</tr>
<tr>
<td>Q2040</td>
<td>16</td>
<td>128</td>
<td>8</td>
</tr>
<tr>
<td>Q2080</td>
<td>16</td>
<td>112</td>
<td>7</td>
</tr>
</tbody>
</table>

`\DL.RECALIBRATE` [Function]

Attempts to find track zero of the disk drive by repeatedly stepping the drive out and checking the status word for Track00 indication. If more than 512 steps are made and Track00 still is not true, a call to RAID is made.

`\DL.DISKSEEK CYL` [Function]

Seeks disk drive to cylinder CYL, and updates information in the header template.

`\DL.TRANSFERPAGE DA BUFFER MODE LABEL RUNLENGTH NORAILDFLG` [Function]

"User" entry (that is, D Lion file system entry) to the disk head. DA is the disk address, which may be a fixp. The remaining args are the same as those for \DL.XFERDISK, as described below:
(
\DL.XFERDISK CYL HD SEC BUFFER MODE LABEL  [Function]
RUNLENGTH NORAILDFLAG
)

Starts a Disk I/O operation. The argument format is meant to be compatible with the old
\DL.XFERDISK. This minimizes the confusion with changing the swapper. New features
include the ability to work with labels and an error recovery mechanism. If a disk error occurs,
the \DL.XFERDISK function will retry the operation up to ten times. If it fails, it will do a
(\DL.RECALIBRATE) first and try ten more times before finally calling RAID. Arguments
are as follows:

CYL        Cylinder number of disk address
HD         Head number of disk address
SEC        Sector number of disk address

Note: These numbers will be normalized automatically. For example, it is
permissible to transfer Cylinder 0, Head 440, Sector 1215. \DL.XFERDISK
will change that into a meaningful value. This is how the swapper works - see
below.

BUFFER    A pointer to the first page that will be used in the disk operation. Note: The
page must be locked down, touched (referenced), and dirty, or else the swapper
will not perform properly!

MODE       One of the following:

    NIL   Read pages, read labels (VRR operation)
    T     Write pages, read labels (VRW operation)
    VRR   Read pages, read labels
    VVR   Read pages, verify labels
    VWW   Write pages, verify labels
    VW    Write pages, write labels
    VRW   Write pages, read labels (used by swapper)

LABEL     A pointer to the label record (10 words), or NIL if you don’t want to use a label
record. The label must be locked down to prevent page faults inside the
\DL.XFERDISK routine.

RUNLENGTH  The number of consecutive pages to transfer, or NIL for one. There are
restrictions on multiple page runs: To do a multiple page run, the virtual page
numbers of the buffer pages must be sequential, and the run may not cross
cylinder boundaries. (See function \CYLBOUNDCCROSSP below).

NORAIDFLG Normally, \DL.XFERDISK will bomb after failing to do an I/O operation
("failing" does not include verify errors). (It will call RAID). To supress this,
set NORAIDFLG to T and disk errors will be returned as status to the caller.
\( (\text{CYLBOUNDcROSSP DA1 DA2}) \)  

Predicate returns T if DA1 and DA2 are on different cylinders, NIL otherwise. Note: This function is not locked down.

\( (\text{DL.DISKOP IOCB}) \)  

Passes IOCB to the disk microcode (which starts the I/O operation), waits for it to complete, and returns the status.

\( (\text{D2V CYL HDSEC}) \)  

Returns the disk address of the page on cylinder CYL and with encoded head and sector information in HDSEC (left byte is head number, right byte is sector number)

\( (\text{V2HDSEC DA}) \)  

Returns encoded head and sector information from disk address.

\( (\text{V2CYL DA}) \)  

Returns cylinder number from disk address.

\( (\text{DL.ACTONVMEMPAGE FILEPAGE BUFFER WRITEFLG}) \)  

Performs a file operation on the virtual memory file. FILEPAGE is a file relative page number to transfer, BUFFER is the page number for the transfer, and WRITEFLG is passed to \( \text{DL.XFERDISK} \) as the MODE parameter. It is usually T or NIL. This function is implemented by figuring the starting address triple of the beginning of the VMEM file and computing the number of pages into the disk from there that the page is located (skipping bad pages), then supplying this information as the sector number to \( \text{DL.XFERDISK} \), which normalizes it internally to a real disk address.

\( (\text{DL.ACTONVMEMFILE FILEPG BUFFER NPGS WRITEFLG}) \)  

Performs multiple file operations on the virtual memory file. FILEPG is the starting file page number (relative to the start of the VMem file). BUFFER is a pointer to the first page in the group to be transferred. NPGS is the number of pages to transfer. WRITEFLG passed to \( \text{DL.ACTONVMEMPAGE} \) as the WRITEFLG parameter. This function will transfer a run of pages to or from the virtual memory file.

\( (\text{DLDISK.GETSTATUS}) \)  

Returns the status of the disk controller in a smallp. Use the record definition DLDISK.STATUS to understand its contents. This macro expands to \( (\text{DEVICE.INPUT 3}) \)
DLDISK.STATUS [Record Definition]

Record definition (access functions) for reading the result of (DLDISK.GETSTATUS).

Contains the following fields:

- **TRACK00**: True if on track zero
- **HEADSELECT**: Current head number
- **SA1000**: True if controller is in SA1000 mode
- **DRIVENOTREADY**: True if drive is not ready
- **WRITEFAULT**: True if last operation caused a write fault
- **OVERRUN**: True if last operation caused an overrun
- **CRCERR**: True if last operation caused a CRC error
- **VERIFYERR**: True if last operation caused a verify error

IOCBPAGE [Record Definition]

This record contains the layout of the IOCB page. The fields are as follows:

- **LASTIOCBSTATUS**: Last status reported while running IOCB
- **NEXTIOCG**: Short pointer to next IOCB in chained IOCBS. This is not currently used.
- **SEEKIOCBLOC**: Contains the location of the SEEK IOCB.
- **XFERIOCBLOC**: Contains the location of the TRANSFER IOCB
- **VRRIOCBLOC**: Contains the location of the VRR Parameter block
- **VVRIOCBLOC**: Contains the location of the VVR Parameter block
- **HCYLINDER**: Header Template: Contains current cylinder number. Changed in all operations.
- **HHEAD**: Header Template: Contains current head number. Changed in all operations.
- **HSECTOR**: Header Template: Contains current sector number. Changed in all operations.
- **LID**: Label Template: 5 words of ID number for the label.
- **LPAGELO**: Label Template: Low 16 bits of page-within-file information in the label.
- **LPAGEHI**: Label Template: High 7 bits of page number within file.
- **LFLAGS**: Label Template: Flag storage for boot code
- **LTYPE**: Label Template: Type of page (type of file in which the page is a part) (16 bits)
- **LBOOTLINKCHAIN1**: Label Template: Boot chain info
- **LBOOTLINKCHAIN2**: Label Template: Boot chain info
- **PRUNLENGTH**: Parameter Block: Run length (number of pages)
- **PLABELCMD**: Parameter Block: Code for operation on label field
- **PLABELLEN**: Parameter Block: Length of label field
- **PLABELABORT**: Parameter Block: Conditions for aborting transfer & error codes to scan for
- **PDATACMD**: Parameter Block: Code for operation on data field
- **PDATALLEN**: Parameter Block: Length of data field
- **PVPAGE**: Parameter Block: Virtual page number of memory buffer
DATAABORT  Parameter Block: Conditions for aborting transfer & error codes to scan for
PTERMCOND1  Code to halt hardware after transfer
PTERMCOND2  Code to halt hardware after transfer
SCYLINDERDISPLACEMENT  Seek IOCB: Number of cylinders to move in seek operation.
SSEEKCMD1  Seek IOCB: First part of seek command
SSEEKCMD2  Seek IOCB: Second part of seek command

**DISK IOCB PAGE**

This section contains the contents of the IOCB page.

Displacements are relative to the start of the IOCB page.

Lines with asterisks following the opcode indicate fields for the user to fill in.

**Interlisp-D AR Fields**

Interlisp-D software support and development uses an "Action Request" data base system for keeping track of bug reports and requests for features. We take feature requests as serious as bug reports -- don’t hesitate to ask. Users are encouraged to submit ARs, either via mail, electronic mail, or (for internal Xerox users) directly using the AREDIT facility within Interlisp-D. The following documents the fields we use in ARs and what they mean:

**AR identification**

**Number:** Every AR has a number, which increases by one for each AR submitted. AR numbers are *never* recycled, and ARs are *never* deleted. The AR number is automatically generated.

**Source:** This is an arbitrary string which should contain the name and electronic address of original customer or internal Xerox users reporting problem. Customers should be identified by "Liason (Customer name)", e.g., Raim.pasa (Bill White @ Teknowledge). This field is used in sending mail back to find out more technical details, or to notify people about the change in status. If multiple people report the same bug, each one should be included in the Source field.

**Problem Description**

**Subject:** A terse summary of problem, enough to identify it uniquely. "FOO doesn’t work" or "Floppy problem" is not good enough. Think of yourself as a newspaper headline writer: "Attempt to write file when Floppy door open causes awful noise". Implementors may change the Subject field as more details about the true nature of the problem becomes apparent. Feature requests generally start with "Want", e.g., "Want way to make windows triangular rather than square."

**Problem Type:** What kind of problem report or feature request?
- **Bug** The system does not work as documented.
- **Implementation** The system works, but the internal structure is wrong. (Generally submitted by other implementors or looking at the sources.)
- **Interface** The design of the user interface is wrong. Includes problems in the way in which things display, as well as program callable structures.
- **Feature Request** Request for a new feature or set of facilities
- **Documentation** The system works, but the documentation is wrong, unclear, or incomplete.
- **Performance** The system works, but it is too slow doing the described operation.

**Description:** This field should contain the complete description of problem or request, including any subsequent discussion. If bug reports come in via electronic mail, put the whole message in this field. Edit relevant info into the beginning of the Description, especially if it summarizes what the problem really is.

**Frequency:** How reproducible is the problem? Leave blank if irrelevant (e.g., feature request.) Generally only relevant for bug reports. One of:
- **Everytime** reproducible every time.
- **Intermittent** doesn’t always happen.
- **Once** saw it happen once.

**Impact:** How seriously does it affect your ability to get work done, value of Interlisp-D, etc. The names apply to bug reports, but feature requests should be rated along analogous lines.
- **Fatal** causes system crash, loss of work, etc. requirement for project completion.
- **Serious** can be worked around but seriously interferes with work, requires substantial reimplementation.
- **Moderate** tolerable, but clearly a problem, responsibility of Interlisp development.
Annoying annoying problem, minor request for new feature that "would be nice"
Minor may be some dispute about whether it is even a bug, very minor feature request.

**Test Case:** This field isn’t used for what the name might imply: it should be a list of the files needed to recreate problem. Recipe for reproducing the problem (which is what you might think a Test Case was for) should be in the Description.

**Lisp Version:** This should be either the release name (Fugue.1, Carol, Harmony) and MAKESYSDATE in which the problem occurs (or the feature doesn’t occur.) The Lisp AREDIT package attempts to fill this in; if you submit from a different system that you are running in, please change it. If its a documentation problem, include the date of the documentation.

**Machine:** What machine does problem occur on (one of 1108, 1132, 1100). Leave blank if *all*.

**Disk:** What kind of disk is on the machine? (only fill in if relevant to AR.) Constrained to have the known disk types for Machine.

**Microcode Version:** (automatically generated, delete if known to be irrelevant, e.g., for documentation problems.)

**Memory Size:** (automatically generated. Delete if known to be irrelevant.)

**File Server:** If problem deals with communication, what server are you talking to? (This field should really have "Server" on it, rather than File Server.) One of VAX/VMS, VAX/UNIX, 8037, etc.

**Server Software Version:** As appropriate for the server you’re talking to.

**System:** **Subsystem:** Category & sub-category of problem type. Subject to change. System includes: Lisp Software, System Software, Text and Graphics, Documentation, IO Architecture. Generally these are filled in by LispSupport, as it corresponds more to our own internal project structure.

### Problem disposition

**Workaround:** If relevant, this field can contain a known procedure to work around problem until it is fixed; generally a short recipe belongs here.

**Status:** Status of AR as it moves thru the system:

- **New** All ARs start out as New.
- **Open** Has been looked at by LispSupport; all fields are filled in & has been assigned.
- **Fixed** problem fixed, in LispCore loadup. The In/By: field is set to the next release name. The Assigned-to: field is set.
- **Closed** System with fix in it has been tested & released.
- **Declined** Request for feature officially *never* going to be implemented (e.g., we think its a bad idea). Bug report considered spurious (we don’t think it is a bug)
- **Superseded** Another AR includes the problem described in this one. In this case, the Subject of this AR should include the AR# of the one that supercedes it, and the superceding AR should contain the union of information in this one.
- **Obsolete** e.g., module in which problem reported is no longer supported.
- **Incomplete** The information submitted is not enough to take action -- not enough information to identify the bug, or the feature request doesn’t spell out in enough detail what is wanted. This is different from Declined in that the request is considered valid, but open for more detail.

**In/By:** What version of Interlisp-D has/will have this problem fixed? (E.g., Harmony, Intermezzo, Jazz, Fugue.6, etc.)
Disposition: Brief notes explaining changes to status, plus automatically generated description of who changed status when.

Difficulty: Rough estimate filled in by developer on scope of problem.
Easy < 1 week to fix
Moderate < 1 month to fix
Hard < 6 months to fix
Very Hard > 6 months to fix
Impossible can’t be fixed
Design requires a design

Priority: Development’s estimate of whether it will be in the “next” release. 
(Changes from release to release).
Absolutely Release will be held if not completed.
Hopefully Major release goal. Schedule slip admitted, but likely to get completed.
Perhaps Will get implemented if other revisions in same area are completed.
Unlikely Unlikely to be included in the next release.

Assigned To: The developer who ‘took care’ of this AR, either by fixing it or declining it. Currently only after AR is fixed.

Attn: The developer(s) who should look at this AR. We’re moving away from relying on this.

Submitter: The user name (and registry) of the person who actually did the Submit. Automatically generated by AR submit, not editable.

Date: The date the AR was originally submitted. Automatically generated by AR submit, not editable.

Edit-By: person who edit this AR last. Automatically generated by the Lisp AR edit tool. (The Disposition field contains more info about edits history.)

Edit-Date: date when this AR was last edited. Also automatically generated.
Maintenance Panel Error Code Summary for Xerox 1108 Interlisp-D

There are two types of maintenance panel codes: progress codes and error codes. Progress codes are placed in the Maintenance Panel at various stages of initialization. Error codes are traps which freeze or blink the error number in the maintenance panel. All errors except the 9000-range errors are fatal.

Summary of MP code ranges
0000-0499 boot-time diagnostics
0500-0699 IOP code
0700-0899 Pilot microcode
0900-0999 Pilot
1000-6999 tech-rep diagnostics
7000-8887 Star
8888-8888 MP lamp test
9000-9999 Lisp

Boot-time errors
0096 Insufficient real memory (<1MByte) for lisp
0149 Usually right after power-on. Disk not ready. Safe and effective to 0-boot from this state.

0200-0299 Booting phase 2 (Initial microcode)
0200 normal booting phase 2
0201 CP error in reading from boot device
0202 null Mesa germ installed in physical volume
0203 broken rigid disk boot chain (possibly intermittent)
0204 Illegal IOP port command
0205 CP Trap (CS parity or double-bit memory error)
0206 null diagnostic microcode in physical volume
0207 null Pilot/Mesa emulator microcode in physical volume
0208 null Mesa germ installed in physical volume
0217 Inconsistent Virtual Memory. Requires re-installation or try another partition.

0500-0502 Domino progress codes
0500 StartDomino Domino has started
0501 InitReadTOD Domino starting to read the TOD clock
0502 InitReadTODdone Reading of TOD clock completed (next MP number from Lisp)

0505-0599 Domino error codes
0505 CSParity CS parity error detected
0506 BurdockCPDisabled Burdock attempted to use EtherKludge
0507 CPBurdockDisabled CP attempted to use EtherKludge
0508 IOPBreak An IOP break with no IOP kernel
0509 IllegalIOPIntr Illegal IOP interrupt
0510 BadMapEntry Incorrect vm Map entry in IOP access.
0511 NoCPDmaComplete CP Dma operation failed to complete
0512 NoCPDmaChannel CP Dma channel not specified
0513 ReadCPPortDead CP not responding to Read CPPort
0514 WriteCPPortDead CP not responding to Write CPPort
0520 StackOverflow A task’s stack has overflowed
0565 InvToneCmd Invalid keyboard tone generator commd
0570 InvProcCmd Invalid cmd value in Processor CSB
0571 UnImplCmd Unimplemented cmd in Processor CSB
0572 SetTODError The Time-Of-Day could not be set
0576 LSEPctlOVR LSEP Control CSB overrun
0580 NoValidCommand Invalid floppy IOCB command
0581 UnImplFloppyCmd Unimplemented floppy IOCB cmd
0582 InvalidEscapeCmd Invalid Escape floppy cmd
0583 CommandTrack Floppy track register is not correct
0584  TrackToBig  Floppy track number is too large
0585  BadDmaChannel  Couldn’t program Floppy Dma
0586  NoDmaEndCount1  External Dma End Count not set
0587  NoDmaEndCount2  Internal Dma End Count not set

0900-0999 Pilot codes
0915  Pilot breakpoint
0937  Trying to find out the time and date. Will hang in this state if no time server is responding, and the time has not been set on the machine since power-up.
0981  Trying to discover Ethernet pup host number. Will hang in this state if non-Lisp code tries to perform Pup operations and no Pup ID Server responds.

9000-9299 DLion Interlisp-D microcode error detected

Most of these errors are indicative of some serious problem, probably hardware, and usually fatal (but try ^D if you can’t TeleRaid). The main exception is 9004—see description of code 9304.

9001  CSParErr  Control store parity error
9002  StackErr  hardware stack overflow
9003  IBEmptyErr  instruction fetch unit empty error
9004  VirtAddrErr  Attempt to reference virtual address >22 bits
9005  EmuMemErr  double bit memory error or non-existent memory
9009  CAR/CDR  bad pointer
9013  NegPcError  inconsistent PC at FnCall
9014  applyUfn  arg to apply not integer
9016  notFreeTrap  stack allocation error
9024  Page fault in the page fault handler.
9051  BadUfnTable
9120  MiscErr  opcode no such register
9121  MiscErr  opcode bad 2nd byte
9122  MiscErr  Input  opcode no such register
9126  PcNegError  inconsistent PC at Punt

9300-9399 Lisp system code error (call to \MP.ERROR)

These codes generally indicate an error state in Lisp system code that cannot be handled in the break package. Most are “should never happen” cases that indicate a serious error; but some (in particular, 9305 and 9318) may be much less serious. If possible, use TeleRaid to find out more information (press the Undo key to enter the TeleRaid server (cursor changes into “TeleRaid”), and run the TeleRaid user from another machine). Even if you can’t TeleRaid from another machine, several of these codes you can convert into a Lisp break if the world is still mostly consistent and the error occurred under user code (rather than, say, the garbage collector): type ^B to the TeleRaid server.

Summary of TeleRaid server commands:

^B  attempt to enter Break. If error is in a special system context, will change cursor to "CANT", indicating refusal to enter break. Warning: even if the system is willing to try to enter a break, it may fail, leaving your system unstartable. When in doubt, use ^D.

^D  perform Hard Reset--clear stack, flush all non-restartable processes.

^N  continue from error. Warning: You should not use this command except for the following errors: 9318 (when you believe it be be continuable, see below); 9915 error when caused by typing the Raid interrupt; 9325; 9326; 9329.

^P  display Pup host number (in decimal) in maintenance panel.

9302  Invalid Vmem: attempt to boot an image that is not a valid Lisp sysout, or which is inconsistent from having some, but not all, of its dirty pages written. Can happen if you boot instead of calling LOGOUT. Usually caught sooner as code 217.
9303  “No place for IOCB page at startup”—this usually only happens if your machine has insufficient memory.
9304  Obsolete [Map out of bounds].
9305  Invalid address: attempt to use a pointer that does not refer to an existing (allocated) part of virtual memory. Usually means garbage was fetched from somewhere that should have contained a pointer; a common source is code with type checking turned off attempting to fetch a datatype field from an object that is not a datatype, such as NIL or a small integer. This error can often be converted to a break with the ^B TeleRaid command if the Lisp image is otherwise in a good state.
9306  Obsolete [Invalid virtual page].
9307  "Unavailable page on real page chain"—inconsistent state in page fault handler.
9308  "Loop in SELECTREALPAGE"—inconsistent state in page fault handler.
9309  Attempt to allocate already existing page (from call to NEWPAGE).
9310  A 9309 error recursively inside the new page allocator.
9311  "Locked page occupies a file page needed to lock another"—bad state in virtual memory system.
9312  Arg to CLOCK0 not an integer box.
9313  Fault on resident page: processor took a page fault for a page that appears to be resident.
9314  PageFault on stack: shouldn’t happen, as stack is resident.
9315  Obsolete [Attempt to extend vmem beyond 8MB].
9316  "Attempt to write a locked page when not under FLUSHVM"—bad state in virtual memory system.
9317  Error in uninterruptible system code: an error that ordinarily would enter a break (e.g., a type test failure),
         but in a piece of code that should not be user-interruptable. This is generally a sign that some datum used
         by system code has been smashed, but this is not always fatal. Should you not be in a position to diagnose
         the error with TeleRaid, you can type ^N after entering the TeleRaid server; Lisp will proceed from the MP
         halt and attempt to enter a break anyway, from which (if it succeeds) you might be able to glean more
         information about the problem. Warning: continuing with ^N can be fatal if the error really was in a place
         where a break would not succeed.
9319  Stack full: hard stack overflow. A soft stack overflow (Lisp break "STACK FULL") occurs when the stack
         is mostly used up; if you proceed beyond that point without resetting you can completely fill the stack and
         get this MP code. Press STOP to perform a HARDRESET to clear the stack, or run TeleRaid to find out
         who was guilty of overflowing the stack.
9320  Storage is completely full. A continuable Lisp break "STORAGE FULL" occurs when the allocation space
         is nearly full.
9321  Unknown UFN: attempt to execute an unimplemented opcode. This usually means that the processor is
         trying to execute random memory, or took a wild jump somewhere. Often a microcode bug.
9322  Atoms full: the limit on number of litatoms (2^16) has been reached.
9323  Obsolete [Pnames full].
9324  Stack frame use count overflow: the program has attempted to create more than 200 references to the same
         stack frame.
9325  Storage nearly full: this is a warning that comes later than the "STORAGE FULL" break but before you
         completely run out (and get a 9320). You can continue from this error with ^N from TeleRaid.
9326  Bad MDS free list: the free list of recycled MDS pages got trashed. You can continue from this error with
         ^N from TeleRaid.
9327  Bad array block. The array allocator found a bad array block in its free list. Generally means some unsafe
         code trashed one or more locations in array space.
9328  A variation on 9327.
9329  The garbage collector attempted to reclaim an array block, but the block’s header was trashed. You can
         continue from this error with ^N from TeleRaid, but it is symptomatic of array trashing, and you should
         save your state as soon as possible and restart in a good sysout.
9330  Reference counting problem: an object marked as having a overflowed reference count (greater than 62) is
         not found in the overflow table.
9331  Reference counting problem: an object whose reference count just now overflowed was already in the
         overflow table.
9332  Reference counting problem: an attempt was made to decrement the reference count of an object whose
         reference count was already zero.
9333  One of a number of consistency checks in the process manager failed.
9334  The process manager needed to build a function frame for some operation, but failed. This normally should
         never happen, but could conceivably if you are about to completely fill up the stack (and thus would
         otherwise get a 9319 error).
9335  Occurs at boot time when the sysout you are trying to run uses the full 32MB virtual address space, but you
         are trying to run it on a machine that can only address 8MB. The function 32MBADDRESSABLE reports
         whether a machine has the hardware required to address 32MB.
9336  Somehow control was transferred to the T frame at the top of the world (effectively a (RETTO T), except
         that RETTO turns that case into a RESET), thereby evading the process world. This leaves the stack in an
         unresumable state.
9337  The process that is being scheduled to run next has had its stack released—invalid state in the process scheduler.

9393  (Koto Only) See 9341

---Post-Koto Error Codes---

9338-40 Error in locked page logic—not currently used.
9341  Hard disk error in the swapper—the swapper has tried several times to access a page of the virtual memory backing file and failed; page fault cannot proceed.
9342  Disk run table for the virtual memory backing file is malformed.

9400-9899 unassigned

9900-9924 Attempt to call Raid or 1132 Subr.

The only code normally seen in this range is 9915:

9915  Call to RAID. Note that if you have the Raid interrupt enabled (typically on ^C), you will get a 9915 error by typing that interrupt character, which you can continue by typing ^N from TeleRaid. Any other occurrence of 9915 generally signifies an error in system code that has not been explicitly assigned a code in the 9300 range.
If Mitch Model’s conjectures are true, then we have a few more good reasons to proceed with the extension to litatom capabilities in Interlisp-D. I have three main points to make, the second of which is rather lengthy, so I’ll warn you in advance:

1) How to find out how many litatoms your sysout has
2) The importance of swapping in the litatom-hash case
3) Performance tools: how to find out if you are being bitten by (2).

1) They think that they have about 30000 litatoms -- how do they know?
Currently, the value of the variable \AtomFrLst (minus about 1) will be the number of litatoms created in a given sysout. As we are all aware, Interlisp-D has no mechanism for reclamation of "dead" litatoms. If they are approaching this limit, then they will be the third *** major *** AI project which recently had to undertake a serious revision of implementation, due solely to the limit on litatoms (i.e., litatoms are the "natural" structure wanted, and the projects converted only after bumping into the hard limit).

2) They say that their subjective impression is that litatom hashing is slow. They could well be right. They should be pointed to ATOMHASH#PROBES, which is in the Lisp.sysout now (but may still be lacking in documentation?).

A good hashing algorithm, such as that in Knuth’s book on sorting and searching, will have a small average-number-of-probes and a fairly short "tail", even when the table is around 85% full; as I mentioned in a note to LispCore^ last week, Interlisp-D’s litom-hash algorithm produces a fairly small average-number-of-probes but an *** incredibly long "tail" ***. So the problem isn’t just that they have a lot of litatoms; rather, it’s that they are referencing ones that live on the tail (of course, the problem would be moot if there were enough real memory to hold the full virtual space).

The importance of knowing how many probes it will take to locate an atom can’t be overlooked. If found immediately, then the time will be bounded (at worst) by the time to swap in the relevant page of the litatom hasharray, the page of pname-pointer space, and the page of pname-character space; if we take 40ms as an average page-fault time, then MKATOM shouldn’t take longer than about 1/10 of a second. [on a Dorado, when no swapping is involved, litatom hashing takes about 110us plus 25us for each probe.] On the other hand, there are 256 pages of litatom hashtable, 256 pages of pname-pointer space, and at least as many of pname-character space; a "worst case" could take over 750 faults, with a time of about 30 seconds **** due entirely to a poorly-performing hash algorithm ****.

That is, we have three-orders-of-magnitude slowdown; and we can’t blame "pageing" in general, because a litom-hash should cause at most a couple of page faults -- not a couple hundred faults!

Is such a "worst case" realistic? Will it ever happen in any notable frequency? The answer, unfortunately, is yes. Litatoms created "last" have a higher probability of falling into the long "tail"; thus the ones of "your" application, which you use all the time, will likely be the ones to suffer the "whip of the tail".

Consider some statistics taken from the recent Full.sysout, with my working environment loaded:

2.9 is the expected number of probes, averaged over all atoms
75% of all atoms were found in 2 or fewer probes
95% of all atoms were found in 12 or fewer probes
Those statistics look "pretty good", but the remainder 5% were about equally distributed on the interval up to 207 probes. In fact, my favorite meta variable, FOO, is the one entry at 207! It took a long time to convince myself, let alone convince others, that the 10 second pause I experienced when typing

\begin{verbatim}
(SETOQ FOO 5)
\end{verbatim}

was due to litatom hashing, and not to DWIM, or GC or any of "the usual suspects". This is on a Dorado where, other things being equal, the average page-fault time is more like 25ms [I observed about 49ms for Dolphin and 37ms for DLion with 40MB Quantum disk. But remember, these are "one-shot" averages.]

Compare those 10 seconds with the usual few 10’s of milliseconds for this action!

3) There is a difficulty in even noticing that litatom hashing is the problem, because of the interaction with virtual memory problems; one has to have a "nose" for this sort of smelly problem.

I tried the usual metering tools on the forms (MKATOM "NIL"), which takes only one probe, (MKATOM "T") which takes 0 probes (single character litatoms are handled separately), and (MKATOM "FOO"), which takes 207 probes.

-- SPY’s output is useless; it merely said that 100% of the time was being spent in MKATOM.

-- DOSTATS, if it were working correctly, would be equally useless. It conveniently filters out the page swap time; only by a "bug" in the filtering did it leak out that 43% of the time went into \WRITEMAP (and as it happens, \WRITEMAP time seems to be less than 25% of time spent in swapping).

-- TIMEALL at least told me about the gross page faulting behaviour

Without suspecting pageing, one might be tempted to interpret the above results as saying that the probe comparison is poorly coded; yet more persistent analysis shows that it costs only about 61us per probe (on a DLion) when faulting isn’t involved -- so 207 probes on a DLion should cost at most 14ms, rather than 14+ seconds which does happen to me frequently.

By judicious use of /RELEASEWORKINGSET and a sub-piece of TIMEALL, I found that, in my environment, a "fresh" lookup of T takes 5 faults, NIL takes 8, and FOO takes 323.

The confounding thing is that in a Full.sysout, before I load my applications, there are 20800 litatoms, and the lookup of the worst-case litatom (again, FOO!) costs only 55 probes and 95 page faults. Why should loading a "small" application, with only about 5000 litatoms, blow the whole thing up? The answer must be that the hash algorithm begins to break down at an occupancy level of about 70%

So one can merely recommend that a user snoop around with ATOMHASH#PROBES to "indict" the lookup of some of his favorite atoms.

-- JonL --
LocalFile
1108 Local Hard Disk File System
Intermezzo Release

Introduction
The 1108 hard disk file system is designed to provide Interlisp-D users with a flexible mechanism for storing and accessing files. Like the file systems for the 1100 and 1132, the 1108 file system supports features like random access and version numbers on files. In addition the 1108 local file system supports a hierarchical naming structures for files.

Partitioning the Disk
The hard disk used with an 1108 may be partitioned into up to ten regions called logical volumes. Logical volumes are like directories on the disk device: they may be used to hold Interlisp virtual memories, Interlisp files, Mesa files, or Star files. You can partition the disk with the Installation Utility floppy or with Othello. Since partitioning the hard disk erases all its contents, you are advised to partition the disk appropriately before storing anything on it; otherwise, you will have to offload all files from the disk, repartition, and then copy the files back to the disk.

Although an Interlisp virtual memory file could coexist on a logical volume with other files, it is generally advisable to give each virtual memory file a logical volume which it does not share with anything else. Otherwise the resulting fragmentation would adversely affect swapping performance. A logical volume intended to contain an Interlisp virtual memory should be between 16,000 and 64,000 disk pages long.

The Intermezzo file system (unlike its predecessors) allows Interlisp user files to coexist on a logical volume that contains Mesa or Star files. So it is no longer necessary to have a special logical volume given over to Lisp user files, though you still can have one if you like. Note that to store Interlisp files on a logical volume, you must create a Lisp directory on that volume (see below for instructions).

File System Utility Functions
So long as there is a logical volume with a Lisp directory on it, you will have a local disk device called {DSK}. This device can be used from within Interlisp-D just like the {DSK} device on the 1100 and 1132, except that it supports a hierarchical naming structure for files.

If you do not have a logical volume with a Lisp directory on it, Interlisp will emulate the {DSK} device by a coredevice, which is fine except: (a) The coredevice provides limited scratch space for some system programs; (b) when running GREET, Interlisp will fail to find DSK.INIT.LISP and will have to prompt the user for an init file; and (c) since the coredevice is contained in virtual memory, it (and the files stored on it) can last only as long as you keep your virtual memory image.
To create a Lisp user file directory on a logical volume, call the function

(CREATEDSKDIRECTORY volumeName) [function]

CREATEDSKDIRECTORY affects only the specified volume, and (unlike previous versions of the file system) does not affect Mesa or Star files in the specified volume. CREATEDSKDIRECTORY returns the name of the directory created. Installing an Interlisp directory is something that should have to be done only the first time the logical volume is used. After that, the system will automatically recognize and open access to the logical volumes that have Interlisp directories on them.

Should you ever want to get rid of a Lisp directory (and all the files in it), call the function

(PURGEDSKDIRECTORY volumeName) [function]

PURGEDSKDIRECTORY affects only the Lisp files on the specified volume; it will not tamper with Mesa or Star files on the same volume. An alternative but cruder way to get rid of a Lisp directory is to use Othello or the Installation Utility to Erase the entire logical volume.

To find out if a particular logical volume already has a Lisp directory on it, call

(LISPDIRECTORYP volumeName) [function]

To find out what logical volumes you have on your local disk, call the function

(VOLUMES) [function]

To find out the total size of a logical volume in disk pages, call

(VOLUMESIZE volumeName) [function]

To find out the number of free pages left on a volume, call

(DISKFREEPAGES volumeName recompute) [function]

And to find out which logical volume contains the virtual memory you are currently running in, call the function

(DISKPARTITION) [function]

Finally, once an Interlisp directory has been installed on a logical volume, any program running in Lisp has access to the Lisp files on the the volume. Access is provided through the usual device independent file interface: CONN (to connect to any directory or subdirectory on the local disk), OPENSTREAM, CLOSEF, DELFILE, GETFILEINFO, SETFILEINFO, BIN, BOUT, LOAD, etc.

File Name Conventions

Each logical volume with a Lisp directory on it serves as a directory of the device {DSK}. Files are referred to as
Thus the file Init.lisp on the volume LispFiles would be called 
{DSK}<LISPFILES>INIT.LISP.

In addition, you can indicate subdirectories using the > character in file names to delimit subdirectory names. Subdirectories allow users to group files to a finer degree of granularity. Files with subdirectories are written

{DSK}<logical-volume-name>subdir1>...>subdirN>file-name

For example, suppose you had a file LRdesign.tedit on the subdirectory ParserGenerator on the subdirectory Compiler on the directory (logical volume) LispFiles of the hard disk device; its name would be written 
{DSK}<LISPFILES>COMPILER>PARSERGENERATOR>LRDESIGN.TEDIT.

You can default directory names for the 1108 hard disk in an unusual but simple way. That is: if the file does not have a subdirectory and you leave out the directory (logical volume) name, the directory will default to the next logical volume which has a Lisp directory on it including or after the volume containing the currently-running virtual memory. Thus if your disk has logical volumes Lisp, Tajo, and LispFiles, and the Lisp volume contains the running virtual memory, and only the LispFiles volume has a Lisp directory on it, then {DSK}INIT.LISP will refer to the file 
{DSK}<LISPFILES>INIT.LISP. All the utility functions presented above default logical volume names in a similar way, except for those that can’t, such as CREATEDSKDIRECTORY. If you want to find out what the default Lisp directory is, call

(DIRECTORYNAME '{DSK})

This defaulting convention is necessitated by several parts of the Interlisp system which create scratch files on the device {DSK} without specifying a directory (logical volume).

Displaying File System State

DSKDISPLAY is a library package which provides a display window for 1108 local file system. The window keeps track of what logical volumes you have on your local disk, which ones have valid Lisp directories on them, and how much space is left on each volume.

The file system display can be in one of three states: ON, OFF, or CLOSED. ON means the display window is updated whenever the file system state changes. (This continuous updating can slow down the file system significantly.) OFF means that the display window is open, but updated only when the user left-buttons it with the mouse. CLOSED means that the display window is closed and never updated. When the DSKDISPLAY package is loaded, the display mode is set to CLOSED.

The functional interface to the file system display is provided by

(DSKDISPLAY newState) [function]
DSKDISPLAY returns the old state of the file system display, and if newState is one of the litatoms ON, OFF, or CLOSED, then the display state will be changed to newState.

The mouse interface to the file system display is as follows: left-buttoning the display window will update it, and middle-buttoning the window will bring up a menu which allows you to change the display state.

Scavenging

Unlike previous releases, Intermezzo provides full disk scavenging service to guard against the unlikely event of file system failure. There are two classes of file system failure: Lisp directory failure, or lower-level (Pilot) failure. Scavenging service for Lisp directories is provided by the library package SCAVENGEDSKDIRECTORY; scavenging for Pilot is provided by either Othello or the Installation Utility.

Pilot failures manifest themselves as a "HARD DISK ERROR" break within Lisp. To fix such a failure, return to top level, log out of Lisp, get into either Othello or the Installation Utility, use the Scavenge option on the logical volume in question, and then reboot Lisp.

Lisp directory failures show up as infinite looping or other aberrant behavior while doing a directory search or enumeration. To repair the directory, return to top level, load the package SCAVENGEDSKDIRECTORY, and call

(SCAVENGEDSKDIRECTORY volumeName) [function]

Should you have any doubt which logical volumes to scavenge, scavenge them all. Should you not be sure which scavenger to use on a volume, use them both, Pilot first, then Lisp directory. Neither scavenger will harm an intact volume.
LocalFile Implementor’s Guide
Filed as [eris]<lispcore>internal>doc>localFileImpl.tedit
Written by Tayloe Stansbury 18-Feb-85
Modified by Tayloe Stansbury 15-Aug-85 12:27:46

The Dandelion/Dove local file system is implemented in two files: LocalFile and DskDisplay. User-level documentation for the file system can be found in the 1108 User’s Guide or on [eris]<lispcore>doc>localfile.tedit.

The Dandelion/Dove local file system has two layers: the Pilot layer and the Lisp streams layer. The Pilot layer emulates a subset of the Pilot file system, as described in the Pilot Programmer’s Manual. The Lisp streams layer implements the Lisp streams specification laid out in [eris]<lispcore>internal>doc>streams.tedit.

The Pilot layer is implemented by three modules in the file LocalFile:

1.  LFALLOCATIONMAPCOMMS, which keeps track of which pages have been allocated and which are free. LFAllocationMap provides the functionality of [idun]<apilot>11.0>pilot>private>volallocmapimpl.mesa, though its implementation is only very loosely based on that file.

2.  LFFILEMAPCOMMS, which keeps track of the mapping between file ID numbers and runs of disk pages. This mapping is stored in a specialized B-tree. LFFileMap provides the functionality of [idun]<apilot>11.0>pilot>private>volfilemapimpl.mesa, though its implementation was based more on [idun]<apilot100>pilot>private>volfilemapimpl.mesa, and later updated to be compatible with the Mesa 11.0 release of Pilot.

3.  LFPILOTFILECOMMS, which has a primitive notion of file, as embodied in its datatype FileDescriptor. LFPilotFile handles things like creating, extending, shrinking, and deleting files; reading and writing file pages; labels; and volume root directories (which map file types onto higher level directories -- e.g. Lisp file type -> Lisp directory ID, Mesa file type -> MFile directory ID, etc.). LFPilotFile does not emulate any particular Mesa file, but rather grew up as the gray area between the two layers became more well-defined during the evolution of the Lisp local file system.

The Lisp stream layer is defined by three more modules in the file LocalFile:

1.  LFDIRECTORYCOMMS, which implements the Lisp directory. The Lisp directory maps symbolic Lisp file names onto Pilot file ID numbers, and handles directory search and directory enumeration.

2.  SCAVENGEDSKDIRECTORYCOMMS, which implements a scavenger for the Lisp directory. It works by purging the old Lisp directory, creating a new one, using the BTree to figure out what Lisp files there are on the volume, using the leader page of each Lisp file to figure out what its name is, and then inserting an entry in the new directory for each Lisp file. There is no Pilot-level scavenger implemented in Lisp; for that we rely on the Othello Scavenge Logical Volume command.

3.  LFCOMMS, which implements all other operations of the local disk file device. LocalFile uses Pilot files as backing files for Lisp streams: page 0 of the Pilot file becomes the stream’s leader page (containing stuff GETFILEINFO and the scavenger will be interested in), page 1 of the Pilot file becomes page 0 of the stream, etc. Pilot backing files may be longer than the Lisp stream they hold.

In addition, the file DskDisplay provides a window which displays file system status. This file is separate because it relies on the window system and therefore must be loaded considerably later in the loadup process than LocalFile need be.
Some future projects for the file system (apart from fighting off the stream of ARs):

1. Modify the READPAGES and WRITEPAGES methods to transfer contiguous pages all at once, and set the MULTIBUFFERHINT to be T.

2. Rewrite DiskDlion (which implements the Dandelion/Dove disk head) so that disk requests that cross cylinder boundaries are handled in runs rather than a page at a time (for both the Dandelion and Dove). Without this, large disk requests (which happen especially during deleting) can tie up the system for quite a while.

3. Modify DiskDlion to do a process switch while waiting for the disk. Currently it busy waits.

4. Currently too much of the file system is uninterruptable. Unfortunately, the primitive UNINTERRUPTABLY now prevents process switch in addition to preventing keyboard interrupts. What we really need is a construct that will do the latter but not the former. (There is now an AR for such a beast.) Given that, we should remove as many calls to UNINTERRUPTABLY as possible.

5. Currently files are allocated 20 pages at a time, regardless of whether the openfile request came with a size hint. This was originally because allocating long files sometimes took long enough that NS connections got dropped. Once #2 is accomplished, long allocations should be quite a bit faster though; and #s 3 and 4 will make it possible for other processes to sneak in while allocations are going on. Then it would make sense to change the file system to allocate files all at once when a hint is provided.

6. Currently, allocation map buffers and file map buffers are written out only once per stream creation or deletion. Without automatic built-in scavenging, that strikes me as a bit unsafe (although it does speed things up some). It would probably be better to write them out once every allocation or deallocation (and the performance penalty for doing so will not be too great if allocation requests are larger as a result of #5).

7. Longer term: rewrite the directory so that it uses some form of tree search. The linear search currently used gets unacceptably slow for large directories.

Should you have any questions, do not hesitate to contact me. My mail address is Stansbury.pa, and my extension is 4330. Good luck!
Making a Patch for Distribution

(1) Fix the Ar(s) in <Lispcore>Sources>, <Lispcore>Library>, the microcode, or the emulator, whichever is appropriate.

For Library-file patches:
(2) Move the entire LCOM/DFASL file(s) onto <Lispcore>Patches>.
(3) In the Workaround section of each AR you've fixed, note the name of the file(s) you moved onto the patch directory, and the date/time you moved them.

For Lisp system-code patches:
(2) Decide which functions, variables, etc. are needed for the patch file. Determine what pre-requisite patches (if any) need to be applied before this one makes sense.
(3) Make sure you have the latest RELEASETOOLS loaded (the Medley sysout as Cheryl made it doesn't).
(4) Use the "Patch" command to build a patch-file template:
    patch ar1 ar2 ...
    where ar1, ar2, etc. are the AR numbers of the ARs this patch will fix.
    Patch will create the COMS for a file named AR-ar1-PATCH, and will bring them up in an SEdit window for you to edit.
(5) Edit the COMS for the patch file to include all the functions, variables, etc. that are needed.
(6) Connect to {Eris}<Lispcore>Patches>.
(7) MAKEFILE and compile the patch file there.
(8) In the Workaround field for each Ar you fixed in this patch, note the name of the patch file and the date & time you made it.

For microcode patches:

For emulator patches:
Hardware:
Bigger Disks
Faster local IFSs
Color display
Sell better peripherals
   Laser writer
   better file server
   SCSI
Labelless Disks
Streaming Tape

Documentation:
Updated and online doc
Improved documents
Consistent paradigm for writing documents (IM formatting replacement)
Make system easy to learn

Window system / User interface:
   Interruptable pop-up Menus
   TIP tables
   Remote Windows
   Faster text display
   Imager
   Image Streams
      clean up code
      collapse common code
      add clipping
   Rethink & overhaul Image Objects
   Loopsified window system
   Consistent look & feel (window UI and commands)
      User interface as consistent as Viewpoint or Macintosh
      Same keying or mousing gets same op everywhere
   Cheap, Pervasive Text (TTYIN replacement)
   Symbol ESC completion on type-in

Programming Environment:
   Same machine low-level debugger
   Source level debugger
   Good stepper
   NS based Teleraid
   Teleraid and CL stack ops
      revert
      return from
   Teleraid Inspect
   Interactive Interface to File manager
   Better File Browser
   Definition groups
   Extensible SEdit
   Programmers Interface to SEdit
   More Common Lisp integration

Higher level language features:
   Unification
   Single, Common prettyprinter
   Fast prettyprinter
   Path name cleanup
      use pathnames all the way down
      get SAME object always for same file
   Single Compiler
   Decouple DWIM - CLISP
   Fast sequence functions
   Ropes
System building and installation:
Non-Dorado loadups
FASL in the init
Packages in the init
Common Lisp primacy, eg in the init
State saving smaller than sysout-sized
Revamp software Installation process
better user interface
written in Lisp, not Mesa
FAST
include error Recovery

Language kernel:
Big Reference counts w/microcode support
Full GC (circular objects)
Get arith to IEEE compliance
GCable Symbols
Unboxed floating point compler
Finalization of GCed objects
Smaller base sysout
More Common Lisp microcode, eg EVAL
Common Loops IN the system

Operating system:
Pre-emptive scheduler
Non-consing Synchronizers (monitorlocks)

Device drivers:
SNA networking
Floppy speed
Improve local disk speed
Real Subdirectories
Support File Cacher
Reliable TCP & RS232
Run in XNS only world
Run in Stand Alone World
Sun NFS support
XNS over phone lines

Applications:
Video Image Manipulation
Bitmap Editor as good as MacPaint
Mail support for
     X.400
     SMTP
Release Lafite
Lisp based File Server
3270 terminal emulator
Good 3rd party software development path
Database
Spreadsheet
AR category clean up
Programming system Management Tools
Adobe Tools
Notecards
TEdit

Footnotes
Index
toc
egns
styles
LPT output
change masks
better than Tex
WYSIWG Page mode
DES/DIS/DIF/VP convert
Easier Landscape Printing
YACC and such
C, Fortran, Pascal, Cobol

Work environment:
Work at Home
Better design process
NS Character Set Issues:
Greg Nuyens, Aug 16, 1984

This note describes a proposal for incorporating the NS character set standard into Interlisp-D. This proposal will encompass the following areas:

--implementation of a "long" character data type

It specifically omits the following:

--external file representations. **

--the reworks necessary to fonts, etc. to attain DIG, though this proposal is made with these issues in mind.

Definitions

The following terms are defined for use in the remainder of the document.

character: an instance of the "long" character data type.
byte: an 8 bit unsigned integer corresponding to the current Interlisp-D character.
character set: the (conceptual) array of 256 characters into which all the representable distinct characters have been separated. An example is character set 0 which contains most but not all of the characters currently used in Interlisp. For instance an umlaut is not included in character set 0.
font: A style in which characters are rendered. A font includes (conceptually) an image for every representable character (2^16 - 256). A font is a member of the cross product of Family, Weight, Slope, Face, Nominal Size, Rotation, and Expansion. An example is TimesRoman 12 Bold Italic Regular Compressed with 90 degree rotation. To contrast character set and font, note that only one character set (0 ??) contains the greek letter alpha, but every font contains a rendering for that character. In practice few (no?) fonts will contain all the images of all the characters.

Overview

Before discussing how these functions will change, an overview of the scheme for the internal functions:

Unknown IMAGEOBJ type
GETFN: SKIO.GETFN

There will be two types of character data, the previously described long and short characters. However, any single string will consist of only one type of character. Thus strings as currently represented, (effectively byte arrays) will continue to exist. However, there will also be arrays of long characters. Any functions which receive arguments of mixed type (e.g. RPLCHAR given an string of short chars and a long char to replace with) will produce results composed of long chars only.

Thus, the current implementation of substrings (as "tails" of strings) will not suffice, since the original string may be coerced upward to a long char string by an operation occurring after a substring has been returned. The plan is to use forwarding pointers in string space and store substrings as <header,offset,length> triplets. Thus when a short char string is coerced upward into a long char string, the original header will have a pointer to the new location. Any substrings returned previous to the coercion will still be valid, since they reference the (now indirect) original header. The offsets will always be scaled by a bytes-per-character value implicit in the type of string (1 for short strings, 2 for long strings).

This scheme guarantees the advertised property of substrings that they are indeed shared tails. That is, a destructive change to a substring will affect the string. This will be true regardless of any coercion of the string that occurs.
Also recognize that any coercions performed on substrings will change the representation of the whole string.

Changes to Interlisp Functions
In previous discussions the two following lists of functions affected by this proposal were identified:
First the functions which deal with the internal representation of character data:

RPLSTRING(X N Y)
this function must change so that if either argument is "long", both are coerced to long. For the character argument, this is simply to add the default character set. For the string however, it will be necessary to copy the string coercing each character by appending the default character set.

RPLCHARCODE(X N CHARCODE)
must now take long or short charcodes, handling them as will RPLSTRING.

GNC{CODE}(X)
will always return an atom representing a long character (Does this mean having all the single character atoms? NO--they can be MKATOMed on the fly.) {or for GNCCODE, a long charcode}

GLC{CODE}(X)
as above

NCHAR{CODE}(X N FLG RDTBL)
will always return an atom representing a long character.

NCHARS(X FLG RDTBL)
Returns number of characters independent of representation. When FLG is T the prin-2 length (as yet unspecified for long chars) will be used.

STRPOS{L}(PAT STRING START SKIP ANCHOR TAIL) (and MAKEBITTABLE)
If either PAT or STRING is constructed of long chars, then the comparison will take place as though both were long. However, no destructive changes will be made.

CHARACTER(N)
Always produces an atom whose printname is the long character whose representation is N.

CHCON(X FLG RDTBL)
Still produces a list of charcodes. These may be short or long charcodes

SUBSTRING(X N M OLDPTR)
Performs the substring operation, guaranteeing the EQ invariant for substrings. The internal rep'n will be the header together with the offset and length, so that if upward conversion later happens, shared tails remain.

ALLOCSTRING(N INITCHAR OLD)
As before except, that if INITCHAR > 255 then the resulting string will be a long string. (Coercing the OLD string's char array as needed.)
MKSTRING(X FLG RDTBL)
   As before, except the PName may be long.
CONCAT{LIST}(U ...) \{L*\}
   If any of the arguments are long strings, the result is a long string.
STREQUAL
   This will be true when the characters are the same, regardless of
   the representation.

...and the following functions which must know the external representation of
character data

FILEPOS
SETFILEPTR
BIN
READC
\INCHAR
\OUTCHAR
COPYBYTES
COPYCHARS

Efficiency Concerns
   the common case of bytes stays fast (though some penalty)
   readc is already coercing bytes upward into smallp's why not into long chars?
   will it be necessary to have all 2^16 - 256 unit length pname atoms exist.
   (what does readc currently return)?
   The intention is that the common case of short char arguments will retain
   their current efficiency.
For Immediate Action:
---------------------

The following opcodes are not emitted, have no microcode, and can be immediately recycled: (Someone should volunteer to do this and announce to xclispcore)

<table>
<thead>
<tr>
<th>Opcode# (octal)</th>
<th>Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>007</td>
<td>CDDR</td>
</tr>
<tr>
<td>036</td>
<td>PUTHASH</td>
</tr>
<tr>
<td>041</td>
<td>BOUT</td>
</tr>
<tr>
<td>043</td>
<td>LIST1</td>
</tr>
<tr>
<td>044</td>
<td>DOCOLLECT</td>
</tr>
<tr>
<td>177</td>
<td>AUDIO</td>
</tr>
<tr>
<td>374</td>
<td>RESERVED for Dolphin</td>
</tr>
</tbody>
</table>

The following opcodes are emitted, but have no microcode -- and may be recycled after recompilation of all sources. (Someone should volunteer to remove all optimizers -- Macros, Dopvals, Dopcodes, etc. -- associated with these opcodes and announce to xclispcore)

<table>
<thead>
<tr>
<th>Opcode# (octal)</th>
<th>Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>033</td>
<td>GETPROP (?)</td>
</tr>
<tr>
<td>035</td>
<td>GETHASH</td>
</tr>
<tr>
<td>050</td>
<td>ELT</td>
</tr>
<tr>
<td>051</td>
<td>NTHCHC</td>
</tr>
<tr>
<td>052</td>
<td>SETA</td>
</tr>
<tr>
<td>053</td>
<td>RPLCHARCODE</td>
</tr>
<tr>
<td>055</td>
<td>EVALV</td>
</tr>
<tr>
<td>160</td>
<td>ATOMNUMBER</td>
</tr>
<tr>
<td>313</td>
<td>GETBASEFIXP</td>
</tr>
<tr>
<td>314</td>
<td>PUTBASEFIXP</td>
</tr>
</tbody>
</table>

Recycling these opcodes demands recompilation, but this might be an additional reason for declaring .DCOM files not readable in Lute.

For Discussion and Design:
--------------------------

Uncoordinated changes:
(that is, changes which do not alternate the meaning of existing constructs)

(Order of tasks is random -- not priority order)

<table>
<thead>
<tr>
<th>Approx. time</th>
<th>Task</th>
</tr>
</thead>
<tbody>
<tr>
<td>Day</td>
<td>Add opcode for Read-Char (like NTHCHC, BIN) convert (byte/word) to (Characterp/Smallp)</td>
</tr>
<tr>
<td>Day</td>
<td>Add opcode for = Compare two numbers for equality -- does coercions</td>
</tr>
<tr>
<td>Day</td>
<td>Add opcode for ASH (arithmetic shift) Arithmeticly shift integer X bits to left</td>
</tr>
</tbody>
</table>
if X pos. or X bits to right if X neg.

Day
Port LISTGET to 1186 8K microcode

Day
CL versions for ASSOC, FMEMB, EQUAL, (MEMBER)
Differ from IL versions in that EQL is used
rather than EQ --- microcode may only do EQ
test on Symbols and punt otherwise

Day
Debug EQL, ARG0 -- insure correct and efficient
algorithm

Week
Complete port of unboxed scalar F.P. opcodes
to 1186 (includes basic arith., and comparison)

Week
Microcode more cases for RECLAIMCELL
RECLAIMCELL currently only reclaims Cons's
-- should be extended to FIXP and Floatp boxes.

Month
Microcode additional CL arith. operators
(Truncate and friends)
Spec. here not yet clear -- will appear after
benchmarking

?  CL:EVAL (like EVAL but for commonlisp)

?  REF

Month
Finish array microcode

Coordinated changes:
(that is, changes which require changes both to lisp and microcode)

(Order of tasks is random -- not priority order)

Approx. time    Task
--------- -------
Week            CREATECELL countdown
                Modify GC so reclaim occurs after
countdown to zero from some settable start
                - Important for tighter control over GC -

Month          GC hash algorithm changes
                Address issues of GC hash table overflow
                - Important for Cons'y benchmarks -

Week           Subtyping in TYPEP
                Make TYPEP more useful
                May render TYPEMASK.N redundant

Week           Replace DTEST and TYPECHECK to be more
                TYPEP like (two type bytes rather than one?)

Month +        FN call changes for &optional, &key, &rest,
closures and arg # checking, field descriptors,
multiple values, discriminators
                (Larry, Bill and Pavel have volunteered to work
on this)
UFNs—Handling undefined op-codes

When the microcode (or C emulator) doesn't handle an opcode, it "punts" to the UFN for that opcode: a Lisp function that does what the opcode should do.

To find out what function to call, the microcode looks at a 256-cell block of storage called the "UFN table" (pointed to in Lisp by \UFNTable). The UFN table contains, for each opcode

(FNINDEX WORD) Atom number (really “definition index”) of the function to be called.
(NEXTRA BYTE) # of extra bytes to be pushed as argument to the UFN (either 0, 1, or 2).
(NARGS BYTE) # of arguments to call the UFN function with.

The Op-code descriptions

In multibyte opcodes (len-1>0), alpha is byte 1, beta is byte 2, and gamma is byte 3.
TOS refers to the argument on the top of the stack; TOS-1 is arg one back, etc.
@[x] is the contents of the word pointed to by x.

<table>

TAKE CDR Twice [not currently used or implemented or emitted.]}
REPLACED BY :

7 UNWIND    ?   ?    \UNWIND.UFN

(N is the alpha byte, KEEP is the beta byte) Unwinds the dynamic stack of the current frame to absolute stack depth N, performing any unbinding indicated by bind marks found along the way. If KEEP is 0, the original top of stack is discarded, otherwise it ispushed after unwinding everything else. This opcode is essentially the same as UNBIND or DUNBIND, except that you stop when the stack depth is N, rather than stopping as soon as you have processed the first bind mark.)
The stack depth $N$ is measured in cells (doublewords) starting at the base of the pvar region. $N=0$ means the stack is utterly empty (including the pvar region; i.e., the end of stack pointer (pointer to next stack block) would be the same as PV). Of course, $N=0$ cannot be used at all in the present architecture, since there is always at least a quadword pad between the frame header and the start of the dynamic stack. If we get rid of that quadword, then $N=0$ could have meaning in a frame that had an empty pvar region, though that is not true of any closure target, the current sole user of this opcode.

Note that taking the stack depth as alpha byte means this opcode cannot unwind to any deeper than depth 255. For sake of reference, the largest pvar region in Full.sysout is for the function \CURVE, whose pvar region is 92 cells long (59 locals and 32 fvars), which means it could still achieve a dynamic depth of an additional 173 cells before UNWIND would care (it actually never exceeds a depth of 30).

\{let SP be the stack pointer; i.e., TOS = @SP\}

\begin{verbatim}
TOP _ loc[pvar0]-2 + 2*N
if KEEP neq 0
then TEMP _ TOS
until (SP _ SP - 2) = TOP
  do if @SP is bind mark
     then perform its unbinding
  if KEEP neq 0
  then push TEMP
\end{verbatim}

call fn (alpha,beta) with N args \[required\]

\begin{verbatim}
# name len-1 stk level effect UFN table entry
10 FN0 2 1 
11 FN1 2 0 
12 FN2 2 -1 
13 FN3 2 -2 
14 FN4 2 -3
\end{verbatim}

call fn (beta,gamma) with alpha args \[required\]

call fn (tos) with (tos-1) args after popping tos & tos-1 \[required. Right now, it goes to \INTERPRETER if TOS isn't a litatom. May add requirement that will work with code blocks.\]

\begin{verbatim}
# name len-1 stk level effect UFN table entry
15 PNX 3 PNX
\end{verbatim}

call fn (tos) with (tos-1) args after popping tos & tos-1 \[required. Right now, it goes to \INTERPRETER if TOS isn't a litatom. May add requirement that will work with code blocks.\]

\begin{verbatim}
# name len-1 stk level effect UFN table entry
16 APPLYFN 0 -1
\end{verbatim}

call fn (tos) with (tos-1) args after popping tos & tos-1 \[required. Right now, it goes to \INTERPRETER if TOS isn't a litatom. May add requirement that will work with code blocks.\]

\begin{verbatim}
# name len-1 stk level effect UFN table entry
17 CHECKAPPLY* 0 0 \CHECKAPPLY*
\end{verbatim}

If TOS is a literal atom whose definition cell has CCODEP on and ARGTYPE=0 or 2, return it, otherwise call UFN. Note that CHECKAPPLY* is always immediately followed by an APPLYFN. If it would save some time, you might be able to immediately jump to the APPLYFN code. (note: definition cell: bit 0 is CCODEP, bit 1 is "fast" \[this fn has empty nametable\], bits 2-3 are ARGTYPE) \[not required; implemented on Dorado\]

\begin{verbatim}
# name len-1 stk level effect UFN table entry
20 RETURN 0 0 \HARDRETURN
\end{verbatim}

do return except when:
  slow bit in returner is on
  and
returnee usecount not 0
or
returners BF usecount is not 0
or
returnee not immediately followed by
a free block
or
the basic frame of the returner.

In any of those conditions, call UFN or context switch to hardreturn context (which?). [required]

<table>
<thead>
<tr>
<th>#</th>

<th>stk level effect</th>
<th>UFN table entry</th>
</tr>
</thead>
<tbody>
<tr>
<td>21</td>
<td>BIND</td>
<td>2</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

push binding mark, bind variables, popping values of stack. [required]

alpha byte is [#NILS <<4 + #BINDS].

beta byte is [FirstPVAR], which is 1-origin (i.e., 0 is PVAR1?? it looks like --J DS)

BIND takes #BINDS values off the top of stack and binds FirstPVAR and successive PVARs to those values. It then sets the #NILS PVARs beyond that to NIL.

Finally, a "binding mark" is pushed on the top of the stack:

```
+-+-+-*+---++---+-*+---++---+-*+---++---+-*+---++---+-*+---++---+-*+---++---+-*+---++---+-*+---++---+-*+---++---+-*+---++---+-*
|       ~(#NILS + #BINDS)       |         FirstPVAR << 1        |
```

Binding marks are identified on the stack because they're negative: The high bit is guaranteed to be 1.

    (this punts on cases where RPLACD must allocate space) [not required; in Dorado, 12K]

# name len-1 stk level effect UFN table entry
32 CONS 0 -1 CONS

Cons pages start with two word header:
word 0: [cnt, nxtcell] (two 8-bit fields: count of available cells
on this page, and word# of next free cell
on this page)
word 1: nextpage (page# of next cons page)

DTDs (data type descriptors) have (ucode relevant fields in caps)
word 0: NAME
word 1: SIZE
words 2,3: FREE
words 4,5: descrs
words 6,7: tyspecs
words 10,11: POINTERS
words 12,13: oldcnt
word 14: COUNTER
word 15: NEXTPAGE
\CDR.NIL= 200q

LISTPDTD is the DTD for type LISTP, i.e., at DTDbase + (LLSH 5 4)

Subroutine MAKECONSCELL[page](given page, return new cell from it):
new cell is at page + page:nxtcell
new CNT is old CNT - 1; punt if CNT was zero
new NXTCELL is new cell’s cdr code

Subroutine NEXTCONSPAGE:
if LISTPDTD:NEXTPAGE # 0 then return it, else punt
(lisp code scans for page with cnt>1)

CONS(X Y) // note: this may not be right. Check sources for truth
If Y is NIL:
get NEXTCONSPAGE
MAKECONSCELL on it
store new cell with \CDR.NIL in cdrcode (hi byte)
X in rest of cell
Elseif Y is a listp and the CNT in Y’s page > 0, then
MAKECONSCELL[Y’s page]
store X as CAR, CDR code = ([(LOLOC Y) and 377q] rsh 1) + 200q
Else:
get NEXTCONSPAGE
MAKECONSCELL on it
store Y in new cell (hi byte 0)
(remember this as Z)
MAKECONSCELL on same page
store X in new cell, with hi byte= [(LOLOC Z) and 377q] rsh 1
ADDREF X
ADDREF Y
increment LISTPDTD:COUNTER
DELREF result

If TOS is not of type STREAM (13q) then PUNT

Format of stream is (only some fields are used by microcode):
word 0: COFFSET ; a byte offset from BUFFER
word 1: CBUPSIZE ; size of input buffer in bytes
word 2&3: flags [byte] = READABLE (bit 0), WRITABLE (bit 1),
          EXTENDABLE (bit 2), DIRTY (bit 3),
          PEEKEDCHARP (bit 4), ACCESSBITS (bit 5-7)
BUFFER [24 bits] ; pointer to data
word 4: BYTESIZE
CHARSET ; 8 bits each
word 5: PEEKEDCHAR ; valid when PEEKEDCHARP true
word 6: CHARPOSITION
word 7: CBUFFMAXSIZE ; maximum size of output buffer

If COFFSET >= CBUFFSIZE then PUNT [buffer overflow]
If READABLE is off then PUNT
Fetch and remember the byte at BUFFER + COFFSET[byte offset]
  Note that this address is guaranteed to be valid at this point,
  but it could pagefault.
Update the stream:
  store COFFSET _ COFFSET + 1
Return the remembered byte as a small positive number.

[not required; in Dorado, 12K]

    ELSEIF overflow entries then GCHANDLEOVERFLOW
    ELSE NEXTOPCODE
Miscellaneous opcode for opcodes needing n args from the stack. The alpha byte contains the sub-opcode number and the beta byte contains the number of arguments on the stack. This opcode was added specifically for bytecode emulated implementations, where the opcodes could be written in C. This opcode provides the same functionality of the SUBRCALL opcode, except it has the added flexibility of having the opcodes UFN (on both Suns & D-Machines). The UFN vectoring routine is written to adjust the stack according to the number of arguments stated in the beta byte, and there is a UFN handler for each sub-opcode. The opcode is generated using the (MISCN NAME &REST ARGS) macro & optimizer defined in LLSUBRS. The NAME parameter must be registered in \MISCN-TABLE-LIST list, which is of the form (name index ufn-name). The \INIT-MISCN-TABLE function initializes the MISCN's sub-opcode UFN vector.

The predefined MISCN sub-opcodes are as follows:

<table>
<thead>
<tr>
<th>index</th>
<th>name</th>
<th>function</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>USER-SUBR</td>
<td>This is for the user-supplied subr C coded subrs. It contains its own sub-opcode division based on the 1st argument on the stack. Like MISCN, USER-SUBR requires that the user-subrs be registered with the variable \USER-SUBR-LIST (name index ufn) by calling the \INIT-USER-SUBR-TABLE function. Thus user-defined subrs can each have their own ufn handler which will be indexed through the MISCN &amp; USER-SUBR UFN mechanism. This opcode can be generated using the (USER-SUBR NAME &amp;REST ARGS) macro found in LLSUBRS.</td>
</tr>
<tr>

<tr>
<td>5</td>
<td>STRING-EQUAL-HASHBITS</td>
<td>IL hash-bits function for String-EQUAL harrayp's</td>
</tr>
<tr>
<td>6</td>
<td>CL:VALUES-LIST</td>
<td>Return a list of multiple values</td>
</tr>
</tbody>
</table>

To reserve new MISCN & USER-SUBR entries, you should set the global values for \MISCN-TABLE-LIST and \USER-SUBR-LIST in the LLSUBRS file & re-write the file to insure that you will have unique numbers. The function WRITECALLSUBRS should also be called to generate a new subsrs.h file, which contains the C constant definitions for the proper indexes in the C code.

The args to the MISCN UFN routines consist of (INDEX ARG-COUNT ARG-PTR), where INDEX is your sub-opocode number, ARG-COUNT is the number of args to be found on the stack, and ARG-PTR is a pointer to the 1st arg found on the stack. The rest of the args can be found by using (\ADDBASE ARG-PTR (LLSH n 1)) for the n-1th arg.

USER-SUBR UFNs have similar args of (USER-SUBR-INDEX ARG-COUNT ARG-PTR), where USER-SUBR-INDEX is the user-subr sub-opcode index, and ARG-COUNT & ARG-PTR are the same as in MISCN UFNs.

CAUTION: Since the stack affect is variable, thus not known to the compiler, the optimizer may do something funny to the stack args around your call. You should check the emitted code to be sure that things compiled correctly. Putting your calls in small functions will help.

TOS is VAR.
If TOS is not litatom, punt.
Returns 24 bit pointer to cell where VAR is bound.
Note: must check VAR=NIL, and return pointer to NIL's value cell. (Free variable lookup algorithm fails if given NIL, at least on Dorado.)
If variable was bound on stack, the value returned will be a pointer into stack space. If variable is not bound, value will be pointer to top level value cell.
[not required; in Dorado (I think), not in DLion? In Maiko emulator]

<table>

</table>

same as SICX. Different opcode for benefit of code walkers.

TOS is a virtual page# as a smallposp

TOS is a virtual memory flags of that page, as a smallposp

Flags are:
  bit 0: referenced
  bit 2: write-protect
  bit 3: dirty

Vacant is denoted write-protect + dirty

[This is the same as XNovaOp ReadFlags, with AC0 -> loloc[TOS]]

TOS is a virtual page# as a smallposp

TOS is the corresponding real page, as a smallposp

[This is the same as XNovaOp ReadRP, with AC0 -> loloc[TOS]]

TOS-2 is a virtual page# as a smallposp

TOS-1 is a real page as a smallposp

TOS is a word of flags as a smallposp

Make the indicated virtual page# be associated with the given real page, with status flags. Real page is immaterial if flags = VACANT

Return the virtual page #

[This is the same as XNovaOp SetFlags, with AC0 -> loloc[TOS-2], AC1 -> loloc[TOS-1], AC2 -> loloc[TOS]]

[not yet in Dorado]

TOS is current value from printer port, as a smallposp

Ufn if machine cannot do this.
[not in 4k]
### RCLK

Store into words pointed to by TOS the processor clock [up to 32 bits, left justified].

### MISC1

These are miscellaneous opcodes that dispatch on alpha to provide infrequent and/or machine-specific operations. To save microcode space (currently), the two opcodes share the same dispatch table, i.e., the alpha's do not overlap. There are two opcodes principally so that there can be a reasonable ufn handler: MISC1 takes 1 arg, MISC2 takes 2.

**Current values for alpha:**

- **STARTIO** [bits]
  - 0: Currently only for Dolphin ethernet. Perform the "StartIO" function with bits given as smallp TOS. (Resets Ethernet to known quiet state).
  - 1: INPUT [devreg]

**DLion codes:**

- For INPUT {alpha = 1 mod 4}
  - TOS = 00 mod 16, EIOData
  - TOS = 01 mod 16, EStatus
  - TOS = 02 mod 16, KIOData
  - TOS = 03 mod 16, KStatus
  - TOS = 04 mod 16, uSTATE
  - TOS = 05 mod 16, MStatus
  - TOS = 06 mod 16, uTest
  - TOS = 07 mod 16, MP code 9122
  - TOS = 08 mod 16, Version
  - TOS = 09 mod 16, <12K>_BusExt L <4K>_MP code 9122
  - TOS = 10 mod 16, <12K>_BusExt M <4K>_MP code 9122
  - TOS = 11 mod 16, <12K>_uFLmode <4K>_MP code 9122
  - TOS = 12 mod 16, MP code 9122
  - TOS = 13 mod 16, MP code 9122
  - TOS = 14 mod 16, MP code 9122
  - TOS = 15 mod 16, MP code 9122

- For OUTPUT {alpha = 2 mod 4}

**Dorado only, RWMUFMAN**
Check type of TOS; let DTD be pointer to DTD of this type
If not LISTP then punt
Reclaim list:

```plaintext
code_PTR: cdr code
if (code and 200q) = 0 then punt [or optional: if code = 0 then punt]
FreeListCell(PTR)
val_deletedef(PTR: carfield) * deletef CAR
if code # cdr.NIL
then PTR_PTR: pagebase + (code lsh 1) * point to cdr or lv cdr
   [if (code and 200q) = 0 * optional
      then FreeListCell(PTR) * cdr indirect--free cell
   PTR_GetBasePtr(PTR)]
   if deletef(PTR) * deletef CDR
      then val_PTR
return val
FreeListCell(PTR):
     PAGE address of PTR's page
     if PAGE:Nextpage < 0 then punt [only when page was full
     PTR: cdr code = PAGE:next cell
     PAGE:next cell word# of PTR
     PAGE: count = PAGE: count + 1

How to reclaim other types, roughly (needs type table change):
if Type bit "ok to reclaim" is off, call UFN
store DTD:FREELST in first two words of DATUM
store DATUM in DTD:FREELST
[not required; implemented for Listp on D0, non-listp on Dorado?, ? for 12K]
```

```plaintext
# name len-1 stk level effect UFN table entry
173   GCSCAN1   0       0       0       GCSCAN1
scan HTMAIN from (TOS)-1 to 0 for a cell with
collision bit on or else stack bit & reference cnt both are 0
if none found, return NIL
else return new index.
   note: design allows NWWInterrupts to be processed
   note: can actually perform GCRECLAIMCELL on the
   cell indicated if stack bit off and ref cnt=0)
[not required; in all]
```

```plaintext
# name len-1 stk level effect UFN table entry
174   GCSCAN2   0       0       0       GCSCAN2
similar to GCSCAN1, but scan for word
with collision bit on or stack bit on.
Note: can optionally turn stack bit off, check if
count is 1 and zero entry, continue scanning
Note: design allows NWWInterrupts to be processed
[not required; in all]
```

```plaintext
# name len-1 stk level effect UFN table entry
175   SUBRCALL   2       0       0       SUBRCALL
Call Bcpl subr number alpha with beta arguments.
The following have some microcode on the DLion:
17'b  Raid
15'b  Logout
06'b  BackGround
11'b  DspBout
20'b  Pup
22'b  SETSCREENCOLOR
23'b  ShowDisplay
```
# name     len-1 stk level effect   UFN table entry
176  CONTEXT    0    0                  CONTEXTSWITCH
switch to context (TOS).

# name     len-1 stk level effect   UFN table entry
177  (was audio) [not required; not currently implemented]

# name     len-1 stk level effect   UFN table entry
200-217 JUMP    0    JUMP
220-237 FJUMP   0    CJUMP
240-257 TJUMP   0    CJUMP
260  JUMPX     1    JUMP
261  JUMPXX    2    JUMP
262  FJUMPX    1    CJUMP
263  TJUMPX    1    CJUMP
264  NFJUMPX   1    NCJUMP
265  NTJUMPX   1    NCJUMP

Assorted jumps. The offset of the jump is given in the succeeding bytes, sign-extended to the left in the case of the single-byte offsets. The offset is relative to the start of the instruction. The opcodes with implicit offset run from +2 thru +21q.
JUMP* are unconditional.
FJUMP* and TJUMP* perform the jump only if TOS is NIL or non-NIL, respectively.
NFJUMPX and NTJUMPX perform the jump only if TOS is NIL or non-NIL, respectively.
Additionally, they pop the stack only if the jump is not taken.

# name     len-1 stk level effect   UFN table entry
266  AREF1     0    -1                 %AREF1
Perform a one-dimensional array access:

(AREF1 array index)
1.) Check that array is a oned-array -- if not punt
2.) Check that 0 <= index < total size for array
3.) Compute (index + offset for array)
4.) Extract base, and type number -- and pass base, type number, index + offset to array-read subroutine and return result on top of stack.

# name     len-1 stk level effect   UFN table entry
267  ASET1     0    -2                 %ASET1
Perform a one-dimensional array set:

(ASET1 new-value array index)
1.) Check that array is a oned-array -- if not punt
2.) Check that 0 <= index < total size for array
3.) Compute (index + offset for array)
4.) Check array not read-only
5.) Extract base, and type number -- and pass newvalue, base, type number, index + offset to array-write subroutine and return newvalue on top of stack.

311  GETBASEPTR.N  

TOS _24-bit pointer @(TOS+alpha).

# name          len-1 stk level effect      UFN table entry
312  GETBITS.N.FD  

Takes 1 arg on stack (PTR) and 2 bytes (n, fd). fetches the "field" fd from the word PTR +n. fd is a
mesa field descriptor: the left 4 bits is the number of the "first" bit of the field, while the right 4 bits
is the width of the field-1. E.g., 0:17 is the full word, 0:0 is the leftmost bit.

# name          len-1 stk level effect      UFN table entry
313  Unused  

# name          len-1 stk level effect      UFN table entry
314  CMLEQUAL    0    -1                 CL:EQUAL

Takes two arguments off the stack and performs some cases of the
c:equal predicate. Punts if either argument is a not an immediate
datum or a number.  [not required, not implemented on 4K and Dorado]

# name          len-1 stk level effect      UFN table entry
315  PUTBASE.N   1    -1                 

Store TOS as word at location (TOS-1)+alpha
Pop (Return TOS-1).
Punt if TOS not smallposp. Note that UFN will specify extra byte for punt.

# name          len-1 stk level effect      UFN table entry
316  PUTBASEPTR.N  

Takes (PTR, NEWVAL) on stack, leaves PTR on stack, stores
NEWVAL at PTR+N. (note: no punt case)

# name          len-1 stk level effect      UFN table entry
317  PUTBITS.N.FD  

Takes (PTR, NEWVAL) on stack, stores bits of NEWVAL at
FD field of PTR+N. Returns PTR.
Punt (UFN) if NEWVAL is not smallposp.

# name          len-1 stk level effect      UFN table entry
320  ADDBASE     0    -1                 ADDBASE
321  VAG2        0    -1                 VAG2
322  HILOC       0    0                   
323  LOLOC       0    0                   

as before

# name          len-1 stk level effect      UFN table entry
324  PLUS2       0    -1                 PLUS
```
DIFFERENCE 0  -1  DIFFERENCE
TIMES2 0  -1  TIMES
QUOTIENT 0  -1  QUOTIENT

(same as I- versions, except UFN different. Optionally perform as F- opcode if one of arguments is floating.)

<table>

unbox TOS & TOS-1
(if SmallPos then 0,,loloc, if SmallNeg then -1,,loloc,
tyepetest if FIXP then fetch 32 bit quantity)
perform 32x32 operation, and then
if overflow occurs, punt
[used to say: call OFLOWMAKENUMBER (atom ???)
   with result mod 2^32 as two 16 bit smallposps.
   This can't work; what did we mean?]
If no overflow:
if hi part 0, return SmallPosHi,,lo
if hi part -1, return SmallNegHi,,lo
else need to return large integer. Two choices:
1) set up as if in call to MAKENUMBER (atom ???) with 2 args being
   Hi and Lo part of result, as smallposps; or
2) Perform CREATECELL of type FIXP, and then store results
   in generated box; return new box
   [only smallpos x smallpos required on IPLUS, IDIFFERENCE;]
   Current implementation status:
   Only smallpos x smallpos on ITIMES in both microcodes
   only smallpos/smallpos for REMAINDER, QUOTIENT in Dorado]

<th>len-1</th>
<th>stk level</th>
<th>effect</th>
<th>UFN table entry</th>
</tr>
</thead>
<tbody>
<tr>
<td>354</td>
<td>UBFLOAT2</td>
<td>1</td>
<td>-1</td>
<td></td>
<td>UNBOXFLOAT2</td>
</tr>
</tbody>
</table>

alpha bytes:
0 ADD x+y
1 SUB x-y
2 ISUB y-x (currently unused)
3 MULT x*y
4 DIV x/y
5 GREAT x>y (returns T/NIL rather than unboxed floating)
6 MAX (max x y) currently unused
7 MIN (min x y) currently unused
8 REM (x remainder y), i.e. x-(floor x/y)*y
9 (UBAREF A I)
Same as AREF1, except that this one returns an unboxed number
implementations: Dorado has GREAT only 12K has all but REM

<table>
<thead>
<tr>
<th>#</th>
<th>name</th>
<th>len-1</th>
<th>stk level</th>
<th>effect</th>
<th>UFN table entry</th>
</tr>
</thead>
<tbody>
<tr>

<td>1</td>
<td>0</td>
<td></td>
<td>UNBOXFLOAT1</td>
</tr>
</tbody>
</table>

alpha byte:
0 BOX (tos -> floating box (tos))
1 UNBOX (tos -> floating unbox (tos), float if FIXP)
2 ABS (currently unused)
3 NEGATE (currently unused)
implemented all on 12K

<table>
<thead>
<tr>
<th>#</th>
<th>name</th>
<th>len-1</th>
<th>stk level</th>
<th>effect</th>
<th>UFN table entry</th>
</tr>
</thead>
<tbody>
<tr>
<td>356</td>
<td>AREF2</td>
<td>0</td>
<td>-2</td>
<td></td>
<td>%AREF2</td>
</tr>
</tbody>
</table>

Perform a two-dimensional array access:

(AREF2 array i j)
1.) Check that array is a twod-array -- if not punt
2.) Check that 0 <= i < bound0
3.) Check that 0 <= j < bound1
4.) Compute (j + i * bound1)
5.) Extract base, and type number -- and pass base, type number, (j + i * bound1) to array-read subroutine and return result on top of stack
Perform a two-dimensional array set:
(ASET2 newvalue array i j)
1.) Check that array is a twod-array -- if not punt
2.) Check that 0 <= i < bound0
3.) Check that 0 <= j < bound1
4.) Compute (j + i * bound1)
5.) Check array not read-only
6.) Extract base, and type number -- and pass base, type number, (j + i * bound1) to array-write subroutine and return newvalue on top of stack.

# name len-1 stk level effect UFN table entry
357  ASET2  0  -3  %ASET2

---

[IGREATERP required; FGREATERP not implemented]

### GREATERP

Same as IGREATERP (see PLUS, etc)
[not required]

### EQUAL

If args are EQ, return T
If either arg is litatom, return NIL
else call UFN
[not required; not implemented]

### BOXIPLUS

Same as IPLUS2, IDIFFERENCE, except store result @TOS -- first arg is number box (for which optionally check) -- and no overflow check.
Miscellaneous floating point array ops; will eventually be renamed MISC5. Provides access to just about everything the Weitek FP chip does. Operates on two arrays; puts results in a third.  

args: (BASE1, BASE2, DEST, N).

Alpha bytes:

0 FLOATWRAP
1 FLOATUNWRAP
2 FLOAT
3 FIX
4 FPLUS
5 FDIFFERENCE
6 FDIFFERENCE
7 (FPLUS (ABS source1) (ABS source2))
8 (ABS (FDIFFERENCE source1 source2))
9 (ABS (FPLUS source1 source2))
10 FTIMES

[not required; implemented on 1108X only]

Takes FFTTABLE as TOS; performs one FFT step thereupon.  
[not required; implemented on 1108X only]

Miscellaneous 3-arg opcode.

Alpha bytes:

0 EXPONENT(source dest n)
   source is vector of floatps, dest is vector of words
   store exponent of source for n in dest
1 MAGNITUDE
   source is a vector of complex, dest is a vector of float
   store magnitude of source in dest
2 FLOAT
   source is a vector of word, dest is a vector of float
   float source & store in dest
3 COMP
   source is a vector of float, dest is a vector of complex
   spread source into dest, storing 0's.
4 BLKFMAX
5 BLKFMIN
6 BLKFABSMAX
7 BLKFABSMIN
8 FLOATTOBYTE
   source is vector of float (must have even number of elements), dest is vector of words
   store source into dest, storing 0's.
9 ARRAYREAD (base typenumber index)
   Dispatch on typenumber and perform a typed get.  
[not required; implemented on 1108X only]

Miscellaneous 4-arg opcode.

Alpha bytes:

0 TIMES
1 PERM
2 PLUS
3 DIFF
4 SEP
6 \ BITMAPBIT bitmap x y newvalue (optional)
7 ARRAYWRITE (newvalue base typenumber index)
   Dispatch on typenumber and perform a typed put
[some confusion on how 0,2,3 different from corresponding TIMES, PLUS, DIF [not required; implemented on 1108X only]]

Floating Point Array ops: EXP, MAG, FLOAT, COMPLEX, BLKMAX, BLKMIN, BLKABSMAX, BLKABSMIN, FLOATTOBYTE
DIFFERENCE, MAGIC, BITMAPBIT
{reserved for DOLPHIN}

374 - - ? - X - -
375 X X X X X X X X SWAP
376 X X X X X X X X NOP
377 - - - - - - - - {unused}

notes:
4K microcode:
PLUS2, DIFFERENCE, TIMES2, QUOTIENT will ufn if args not INTEGERS
IPLUS2, IDIFFERENCE will accept FIXP’s as arguments, but will ufn if result is
not a smallp or smallneg
ITIMES2, IQUOTIENT, IREMAINDER will ufn if both args are not smallp

12K microcode:
PLUS2, DIFFERENCE, TIMES2, QUOTIENT will try floating point if args not
INTEGERS
IPLUS2, IDIFFERENCE will accept FIXP’s as arguments, and box the result if it
is not a smallp or smallneg
ITIMES2, IQUOTIENT, IREMAINDER will ufn if both args are not smallp
edits are in bold. We should meet to review what’s in microcode and what the priority list should be. I suggest we do this at the end of the Common Lisp status meeting... does anyone have any objection to discussing it then?

OPCODES IMPLEMENTED IN MICROCODE BY MACHINE

Jan Pedersen

Key: '09 = 12K Dandetiger
'08 = 4K Dandelion
'00 = Dolphin
'32 = Dorado (as reported by Gwan)
'32L = Dorado (as reported by Larry)
'86-4 = 4K Daybreak
'86-8 = 8K Daybreak
X = Has microcode
P = Prolog microcode set
- = Doesn’t have microcode
? = Don’t know

notes:

4K microcode:
PLUS2, DIFFERENCE, TIMES2, QUOTIENT will ufn if args not INTEGERS
IPLUS2, IDIFFERENCE will accept FIXP’s as arguments, but will ufn if result is not a smallp or smallneg
ITIMES2, IQUOTIENT, IREMAINDER will ufn if both args are not smallp

12K microcode:
PLUS2, DIFFERENCE, TIMES2, QUOTIENT will try floating point if args not INTEGERS
IPLUS2, IDIFFERENCE will accept FIXP’s as arguments, and box the result if it is not a smallp or smallneg
ITIMES2, IQUOTIENT, IREMAINDER will ufn if both args are not smallp

—End of message—
Fields in the context:

**CurrentNode**
The node whose linear form is currently being computed.

**LinearPointer**
Points to the "next" item in the linear form. This is the item with which the next generated item will be compared, and the item before which it will be inserted if it doesn’t match.

**LinearPrev**
If LinearPrev is a cons, (CDR LinearPrev) is LinearPointer (LinearPrev is one behind LinearPointer in the linear form). Otherwise, it’s a node, and (fetch LinearForm of LinearPrev) is LinearPointer. Used to fixup linear form.

**CurrentLine**
The LineStart most recently generated in the linear form.

**CurrentX**
The X coordinate at which the next linear item will be displayed.

**RightMargin**
The right margin for generating the linear form.

**CurrentBlock**
The LineBlock describing the most recently generated linear items on this line. Reset to FirstBlock at the end of each line displayed.

**FirstBlock**
The beginning of the LineBlock list. The LineBlocks from FirstBlock to CurrentBlock describe the segment of the linear form between CurrentLine and LinearPointer, indicating which parts are already available in the window for BITBLTing and which will have to be repainted.

**Matching?**
Means something like: the linear form we’re generating has been matching the linear form that was already there (at least since the beginning of CurrentNode)

**Below?**
T if the linear form we’re generating is definitely off the bottom of the screen. NIL if it might have to be displayed. ’new if we’re redisplaying from scratch (nothing to BLT).

**Visible?**
T if we’re matching and the bits we’re matching are actually on the screen.

**RelinearizationTimeStamp**
NIL if we’re prettyprinting, otherwise incremented by 1 each time we relinearize from the top. Used to determine the validity of cached info in LineStarts

**RepaintStart**
**RepaintLine**
**RepaintX**
If there are no bits to be reused at the end of a line, we postpone displaying it until we find something that needs to be moved (or we get to the end of the window). This can go on for many lines. during this time, RepaintStart records where the painting needs to start from, RepaintLine has the y information, and RepaintX records where the painting will start from. It may always be the case that

RepaintLine = (CAR RepaintStart)
RepaintX = (fetch Indent of RepaintLine)

Fields in EditNodes:
StartX
The X coordinate at the time this node was linearized. not sure what 0 means (something magic). \\reuse.linear.form seems to think this means that the node is atomic and hasn’t been displayed before.

The coordinate system:
The top left corner is (1,-1) (or maybe (0,0)?). Therefore everything’s displayed with positive x and negative y (bottom right quadrant).
List Formats

SEdit allows one to specify how a class of forms are to be pretty printed. This is done by defining a list format on a symbol. This causes all forms whose car is this symbol to be displayed with the specified format.

List formats for most Common LISP and Interlisp special forms are provided with SEdit. The source code for these definitions can be found on the Lisp Library Floppy #XXX.

```lisp
(def-list-format name (doc-string) (format-name | &key :args :sublists :inline :miser :last :indent) ) [Definer]
```

Tells SEdit how to prettyprint forms whose CAR is NAME.

Short form

If FORMAT-NAME is provided then NAME is defined to be formatted just like FORMAT-NAME. If, for example one had defined a list format for `dotimes` one could then define `dolist` to be formatted the same way with:

```lisp
(def-list-format dotimes dolist)
```

Long Form

The keyword arguments have the following meanings:

- **:ARGS** -- value should be a list of names of list formats. These formats are assigned to the elements of the list in order starting with the first element (which will be NAME). Note that these formats override any formats that would normally be assigned to the elements of the list (based on their first elements). NIL is allowed in the :ARGS list, and means do not override the format of this element; that is, allow it to be formatted normally. Also, a symbol S is allowed in the :ARGS list if S has earlier been assigned a format; this means to assign S's format to this element. There are also two special keywords allowed as entries in the :ARGS list: :KEYWORD and :RECURSIVE. :KEYWORD means that if the element assigned this format is a symbol then treat it like a keyword, i.e., put it in bold face. (This list uses the convention that all symbols which allow declarations in their body [such as DO and LET] are formatted as keywords.) :RECURSIVE means to assign this element the same format as is being defined; that is, the entire top level format is assigned recursively to this element. This is very useful for formats like :DATA format (see below). If L has more elements than there are entries in the :ARGS list, the last entry in the :ARGS list is repeated for all the extra elements of L. Hint: most :ARGS entries have NIL as their last element. If no :ARGS list is specified, the elements of L get their natural formatting.

- **:SUBLISTS** -- value should be a list of element positions (counting from 1) or T. T means all of the arguments should be parsed as lists even if they are NIL (so NIL will display as () rather than NIL). A list of element position means those element positions will be parsed as lists. For example LET has :SUBLISTS (2) meaning the second element of a form whose first element is LET is a list (i.e., the binding list). DO has :SUBLISTS (2 3), DEFUN has :SUBLISTS (3) and COND has :SUBLISTS T. Default is :SUBLISTS NIL meaning print all NIL args as NIL not ().

- **:INLINE** -- value can be T or NIL (default NIL). If T, the form will go all on one line if it fits. If NIL, the form will be broken across lines at arg boundaries even if it would all fit on one line. For example, OR has :INLINE T and LET has :INLINE NIL.

- **:MISER** -- value can be :ALWAYS, :NEVER, or :TOFIT (default :TOFIT). Specifies when to use miser indentation. The default means use miser indentation if non-miser indentation would force the arguments into miser indentation. [need to explain what miser mode is]

- **:LAST** -- value should be a format specification like those in the :ARGS list. This format specification will be applied to the last element of L but only if doing so would supercede the last entry in the :ARGS list. In other words, if the last element of L would receive the repeated format from the :ARGS list, it gets the :LAST format instead. This option is really only useful for pathologically formatted forms like Interlisp's SELECTQ.

- **:indent** -- An indentation specification is either a symbol (normally a keyword) or a list. If it's a symbol, it's looked up on the SEDIT::*INDENT-ALIST* (which see) and the SEdit-internal indent specification found
there is used. If it’s a list, it consists of some optional keywords (described below) followed by argument
group specifications. Each argument group specification is either a number or a list containing a single
number. In both formats, the number indicates that that many arguments should be grouped together at
a single indentation level. The simple number format means that each of those arguments should go on
its own line (they will line up vertically with each other), while the number-in-a-list format means that the
arguments in the group can go together on a single line if they fit. The indentation level for each
argument group is determined by how many groups follow it in the indentation list. Each group is
indented 1 level further in than the group which follows it; thus, the first argument group is indented most,
the next one next most, and so on until the last one, which is always indented one step in from lambda-
body level.

This is best explained with examples. A simple example is LET, whose indentation specification is (1).
This means that LET will be followed by a single distinguished argument group consisting of one element
(the binding list) which will be indented one step in from the let body. Another simple example is DO,
whose indentation specification is (2). This means that DO will be followed by a single distinguished
argument group consisting of two elements (the binding list and the termination clause) which will be
indented one step in from the do body. It also means that the bindings and the termination will be
required to go on separate lines. Contrast DO with DEFUN, whose indentation specification is ((2)). Like
DO’s spec, DEFUN’s spec says there is one group with two members (the name and the lambda-list), but
unlike DO’s spec, DEFUN’s spec says that the first two args can go on the same line if they fit there.
Finally, consider a possible spec for MULTIPLE-VALUE-BIND of (1 1) which says that the first group
consists of one arg (the variable list) and the second group consists of one arg (the form to eval). The
form to eval will be indented one step in from the body, and the list of variables will be indented one step
in from there.

Note that a group specification of 0 (zero) is allowed: this occupies an indentation step but does not put
any arguments at that level. But we do not allow (0) as a group specification since this would not be any
different than plain 0 and probably means that the specification is confused in some way.

The keywords allowed at the beginning of an indent specification are:

: BREAK or : NOBREAK or : FIT -- These specify placement of the first argument in the first group.
Default is :FIT, which means put this arg on the same line as the CAR of the form if it fits there in
preferred mode, otherwise put it on the next line. Note that if the first arg goes on the same line as the
CAR, its placement specifies the indentation level for the entire first group. That way long CARs will
move the first group over to the right. (This makes the binding and termination of both DO and DO* line
up, for example.) Specifying : NOBREAK means the first arg is forced to go on the same line as the CAR.
Specifying : BREAK means the first arg is forced to go on the next line (and thus at the indentation level
derived from the number of groups). UNWIND-PROTECT is a good example of using :BREAK to force
the first arg onto its own line. Note that you can only specify one of : NOBREAK, : BREAK, or : FIT.

: TAGBODY -- Normally all forms in the body (whether atomic or not) go at the same indent level.
Specifying : TAGBODY indicates that atomic body elements (not atomic elements of the argument groups)
should be exdented to line up with the CAR of the entire list (such as PROG or TAGBODY, which see for
examples).

: STEP -- This can be specified as many times as desired and each time increases the indentation of the
body (and thus all the argument groups) by one step. If you just want to move some of the groups in but
not all of them (and not the body) then use 0 groups at the appropriate place instead of using :STEP at
the beginning. :STEP is very useful with : TAGBODY.

By the way, the normal body indentation is taken from the INDENT-BASE field of the LISP edit
environment, which is initialized to the width of a capital ‘M’ in the SEdit default font. The normal
indentation step is taken from the INDENT-STEP field of the LISP edit environment, which is initialized to
twice the width of a capital ‘M’ (that is, twice INDENT-BASE). These defaults are chosen so that, in a
fixed-width font, the body of a form lines up two characters in from the ‘(’ of the form, and each argument
group line up two characters in from the next one (or the body). If you want non-standard values for
either of these parameters, you can change the values in the LISP edit environment and then reinitialize
your SEdit formats. Also, if you change font profiles, reinitializing SEdit will fix up the indents appropriately.
The formatting methods for lists

The assign-format, compute-format-values, and linearize methods of lists are now driven by tables encapsulated in list-format objects, allowing easy special formatting for particular lisp forms. This note primarily documents the format of list-format objects, and along the way mentions how they are used to implement those three methods. (note that dot-lists currently aren't handled by this mechanism)

Finding the right list-format

assign-format-list finds an appropriate list-format to control the list’s formatting, using one of four options:

- if the list is assigned a format which is a list-format object, use that;
- else if the car of the list can be found in a list-formats table, use the associated object from that table;
- else if the car of the list has a known clispword property, use the clisp list-format;
- else use the default list-format

since the same list-format object will be needed for computing width estimates and and linearization, assign-format caches it in the unassigned file. there are two types of list-formats; standard and non-standard. standard list-formats contain information to control the standard list formatting methods. nonstandard list-formats are an escape mechanism for situations where the required formatting is too hairy for the standard methods; they simply provide replacements for the assign-format, compute-format-value, and linearize methods. this is implemented by all list-formats having a non-standard? field, and list-formats whose non-standard? field is t having 3 additional fields: set-format-list, cfv-list, and linearize-list. there’s not much else to say about non-standard list-formats, except that at present the only one is the format for clisp. for the rest of this document we’ll talk about standard list-formats.

A general rule

several list-format fields contain lists of entries which correspond to the list node’s subnodes. these lists all have roughly the same form:

\[(last \ first \ second \ ... \ nth)\]

where \(first\) is the information to be used for the formatting the first subnode, \(second\) the information for the second, ..., \(nth\) the information for the nth and all subsequent nodes, except that \(last\) is the information to be used for the last (some forms (e.g. il:selectq) have special formatting for the very last item). \(n\) depends on how many of the nodes need special formatting. lambda, for instance, uses lists of the form \((a \ b \ c \ a)\) — thus the first element is formatted using \(b\), the second with \(c\), and all subsequent ones with \(a\). the default list format uses lists of the format \((a)\), since all subnodes are formatted similarly. il:selectq uses lists of the form \((a \ b \ c \ d)\) — so \(b\) applies to the il:selectq atom, \(c\) to the evaluated expression, \(d\) to each clause, and \(a\) to the final otherwise clause.

the other important fact about these lists is that they’re blind to comments; comment subnodes are ignored when figuring out which information goes to which subnode, and the comments themselves are formatted by hardwired rules.

Assigning formats

assign-format-list uses the list-formats field of the list-object, which is a list in the format described above. each element of the list is the format to assign to the corresponding subnode (nil, :keyword, or a list-format object — or :recursive, which means to assign this node’s list-format to its subnode).
Linearizing

each list-format contains descriptions of two possible presentations of that list — a “preferred” format and a “miser” format, in the list-pformat and list-mformat fields of the list-format. linearization decides which presentation is appropriate, based on the width estimates of this node (see below for a description of where they come from) and the horizontal space available.

the list linearization will always have the form "(" subnode <space> subnode <space> ... subnode ")", where <space> is either a one-space-wide horizontal movement, or a line break (with some indentation) (we assume the list contains no comments for now). thus, the problem of formatting the list reduces to specifying, for each element after the first, whether to space or break, and if you break, how much to indent. using a list in the above format, a specification is given for each subnode after the first as to how this decision is to be made.

these spacing specifications are expressions in a simple language. each expression must at a minimum specify the indentation if a line break is made here. the simplest expressions are just that — an integer, giving the indentation (in pixels) from the opening "(". this expression won’t break unless it has to, but if it does it will use that indentation. to force a break, an expression of the form (break . exp) is used (where exp is a nested expression). to line up the presentation of subnodes, spacing specifications can set a tab stop and then later position relative to it. (set-indent . exp) works just like exp, except that after it has been determined where this subnode is to be positioned, the tab stop is set at that point. a later spacing specification of (from-indent . exp) means that if we break at this point, the indentation is to be taken relative to the tab stop. note that the order of parts in an expression isn’t important; (break from-indent . 3) has the same effect as (from-indent break . 3).

the remaining types of expressions allow the formatting to depend on a variety of conditions, such as whether the previous node’s presentation fit on one line, or whether this node is atomic. they all have the form (condition exp1 . exp2), where condition is one of the atoms below, exp1 is the spacing specification to be used if the condition holds, and exp2 is the spacing specification to be used if it doesn’t. (remember that a spacing specification is interpreted to determine the space preceding a subnode; in the list below, "previous node" is the node before the one whose placement is being determined, and "next node" is the node whose placement is being determined).

prev-inline: did the previous subnode’s presentation fit on one line?
next-inline: does the next subnode’s width estimate indicate that it will fit on this line?
next-preferred: does the next subnode’s width estimate indicate that it will fit in preferred format?
prev-atom, next-atom: is the previous/next node atomic (i.e. has no subnodes)?
prev-keyword, next-keyword: is the previous/next node an atom in the keyword package?
prev-lambdaword, next-lambdaword: is the previous/next node a lambda keyword (&aux, &rest, etc)?
whole-inline: do the width estimates of the node being formatted indicate that it will fit on one line?

Formatting comments

the preceding discussion assumed that the list being formatted contained no comments. the formatting of comments is completely automatic (i.e. out of the control of the list-format), primarily to simplify list-formats. they are formatted like other subnodes, except that they don’t use the spacing specifications. single-semi comments are positioned at a fixed horizontal position (at the end of the current line if it isn’t too long, otherwise on a new line). triple-semi comments always start on a new line, at the left margin. double-semi comments are a little trickier; they start at the current tab stop, after the spacing specification for the next node has been interpreted. this requires looking ahead in these cases, and determining what the result of interpreting the space specification will be. it would probably be worth figuring out simpler ways to do this.
subnodes following comments always start on a new line (i.e. their spacing specifications are interpreted as if they began \texttt{break . ...}).

**Computing width estimates**

cfv-list must compute two values: the width of this node if its presentation can fit on one line (or nil if it can’t), and the width of this node in its "preferred" presentation. The second of these is computed by simulating the linearization process using the preferred spacing specifications, and always assuming the worst when evaluating the prev-inline, next-inline, next-preferred, and whole-inline conditions. The inline width is determined by an even simpler scheme: if all of the subnodes can go inline, and the list-inline? field of the list-format isn’t nil, the list can go inline with width equal to the sum of its subnode’s inline widths, plus the appropriate blanks and parens.
Node Types and Node Type Methods in SEdit

All SEdit editing operations and presentations are controlled by methods associated with classes of nodes in the edit tree. By defining a new class of nodes with appropriate methods, or modifying an existing class, SEdit may be configured for a wide range of editing tasks. This document describes the programming involved in defining such a class, using the basic Interlisp-D type definitions as examples.

Node Types and the Edit Tree

The edit tree is a data structure maintained by SEdit as a representation of the structure being edited. The tree is initially constructed by parsing the data structure to be edited as a hierarchical data structure. Each node in the tree corresponds to a part of the edited structure, either an instance of a lisp datatype or a combination of several data structures. For instance, atoms and strings are usually represented by separate nodes in the tree, but a sequence of several cons cells may be represented by a single list node. Instances of a single data type may be represented by a variety of node types, depending on the context in which they appear. All editing operations are defined in terms of these nodes. The definitions for editing Interlisp code define ten node types:

1. atoms (actually litatoms and numbers)
2. strings
3. lists (NIL-terminated sequences of cons cells)
4. dotted lists (sequences of cons cells terminated by something other than NIL)
5. CLisp expressions (if, fetch, iteration, etc.)
6. forms (lisp function calls)
7. LAMBDA expressions (also includes LETs, PROGs, etc.)
8. quoted structures (i.e. two element lists whose first element is the atom QUOTE)
9. unknown (any data type other than litatom, number, string, or cons)
10. root (a special node type for the root of the edit tree)

Node types 5 through 8 are special cases of type 3, which are recognized in some contexts.

Creating the Edit Tree

To create the edit tree, SEdit conducts a preorder traversal of the given data structure. At each step, it dispatches on the datatype of the structure and calls the corresponding function, which is responsible for building the rest of the tree by making a call to \create.node and recursive calls to the parser (\parse). Each node built will record (among other things)

- the node type (chosen by the parse function)
- the node's super node
- the node's subnodes (one for each recursive call to \parse)
- the node's depth in the tree
- the structure which was parsed to create this node

Because the correct parsing of a node often depends on contextual information, the parser allows each parse method to pass an argument to its subnodes. For no particularly good reason this argument is called the parse mode. The interpretation of the parse mode is up to the individual parse methods. The default mode is NIL; most parse methods ignore any unrecognized mode. In addition to the default mode, the Interlisp code definitions use a couple of other modes (the atoms Binding, BindingList, and KeyWord).
Edit Node Types

The type information SEedit associates with each node is actually a set of methods, i.e. functions to perform various actions on nodes of that class. Each node type must provide methods to perform seventeen different actions. This is, of course, poor man’s object oriented programming. One day in the grand and glorious future Interlisp-D will metamorphose into something which properly supports object oriented programming, whereupon SEedit will be rewritten. In the meantime, this works well enough.

The methods for node types fall into four groups:

- those used to generate the presentation of a node (2 methods)
- those used to place selections and points (6 methods)
- those used to effect editing commands (5 methods)
- those which perform various housekeeping functions (4 methods)

We'll consider each of these groups in turn, specifying in detail how the methods are invoked and what they are expected to do.

Presentations and the Linear Form

The visual presentation of the data structures is represented in SEedit by a structure called the linear form. The linear form is a sequence of presentation commands which produce the desired presentation. Presentation commands are very simple, and there are only four of them:

- insert a string of characters in a given font
- insert horizontal space
- insert a given bitmap
- start a new line, with a given indentation and vertical separation from the previous line

The Linearize method for a node type must construct the sequence of presentation commands for a node of that type, by inserting the appropriate commands in the correct order. It may call the Linearize method of each of its subnodes. For instance, a very simple algorithm for linearizing lists might be:

```plaintext
output "(" in the default font
for each subnode
  if this isn’t the first subnode, output some space
  linearize the subnode
output ")" in the default font
```

The actual algorithm used by SEedit is somewhat more complicated; for instance, lists usually don’t fit all on one line, so it inserts line breaks at appropriate points.

To format structures such as lists properly, it’s important to know how much space the presentation of each subnode will occupy. This is a problem, since the amount of space the presentation of a structure occupies often depends on the amount of space available when it is presented. SEedit deals with this by computing width estimates for each node. These are five values computed by each node for use by its super node:

a) if the node can be presented on a single line, the width of that presentation
b) the width of the most readable presentation of this node (its preferred presentation)
c) the width of the narrowest possible presentation of this node
d) the length of the last line of the preferred presentation of this node
e) the length of the last line of the narrowest possible presentation of this node
These width values allow the super node to make reasonable decisions on indentation and line breaks. The last line lengths are important because the super node may append additional material to the last line of a subnode's presentation, and would like to know how long the resulting line would be. These five values are stored as extra fields in each node, and referred to as the InlineWidth (NIL if the node can't be presented inline), PreferredWidth, MinWidth, PreferredLLength, and MinLLength, respectively.

In much of the program these width estimates are called format values. I've started calling them width estimates as a reminder that they are not required to be accurate, but should be quick to compute. It is important that a node's width estimates not indicate that it can be presented inline when it actually requires several lines, but other width values can be incorrect without breaking the program. On the other hand, incorrect width estimates will often lead to less than optimal presentations. The width estimates computed by the Interlisp code definitions are always correct (at least, that was the author's intention).

Each node type defines a method called ComputeFormatValues which will fill in the width estimates of a given node. To do so it may examine the structure the node represents and the format values of its subnodes. For instance, the ComputeFormatValues method for type list looks approximately like this:

```
InlineWidth is
  if all of the subnodes can be presented inline
    the sum of the InlineWidths of the subnodes,
    plus the width of two parentheses,
    plus the width of n-1 blanks
  else
    NIL

PreferredLLength is
  the PreferredLLength of the last subnode,
  plus the preferred indentation,
  plus the width of one parenthesis

MinLLength is
  the MinLLength of the last subnode,
  plus the width of two parentheses

PreferredWidth is
  the largest of
    the PreferredWidth of the first subnode,
    plus the width of one parenthesis
    the maximum PreferredWidth of the other subnodes,
    plus the preferred indentation
    the PreferredLLength of this node

MinWidth is
  the largest of
    the maximum MinWidth of any subnode,
    plus the width of one parenthesis
    the MinLLength of this node
```

Note that these calculations assume the node has at least two subnodes — special case rules are needed for fewer. Also, the formatting rules assumed are that

- the inline presentation of a list is an left parenthesis, followed by the subnodes separated by blanks, followed by a right parenthesis; all of the subnodes must present inline
- the preferred presentation of a list is an left parenthesis, followed by the subnodes, where each subnode after the first is on a new line indented by the preferred indentation; the final subnodes is followed by a right parenthesis
- the minimum presentation is similar to the preferred presentation, except that subnodes are indented only by the width of the left parenthesis

(Indentations are always non-negative, and specified relative to the horizontal position of the start of the node's presentation; thus the presentation of a node always occupies the quadrant to the right and below the point at which its presentation starts.)
The linearization method is given two arguments in addition to the node to be linearized and the usual context information. The first is a right margin, which it should try to keep its presentation within (if possible). This value is actually stored as another field in the node. The second argument is an index. In some situations, SEdit may request that the linear form of a node be recomputed starting part way through. In this case, the index given will be the index of a subnode, and the method should output just that part of the node's linear form which follows the presentation of that subnode.

Linearization methods are permitted to call five lisp functions to create the node's linear form:

\(\text{\textbackslash output.string} \ \text{context} \ \text{string} \ \text{prin2?} \ \text{font}\)

Insert string in the specified font at this point in the linear form. context is the usual context encapsulation. string may be any Interlisp object; its standard printed representation will be used. if prin2? is true, the PRIN2 representation of string will be used instead.

\(\text{\textbackslash output.space} \ \text{context} \ \text{width}\)

Insert a horizontal space of the specified width at this point in the linear form.

\(\text{\textbackslash output.bitmap} \ \text{context} \ \text{bitmap}\)

Insert a bitmap at this point in the linear form. It will be aligned with the line's baseline.

\(\text{\textbackslash output.cr} \ \text{context} \ \text{indentation} \ \text{lineskip}\)

Start a new line, with the specified indentation (relative to the start of this node's presentation) and separation from the previous line.

\(\text{\textbackslash linearize} \ \text{subnode} \ \text{context} \ \text{right.margin}\)

Insert the linear form of a subnode at this point in the linear form. Its linear form should not extend beyond right.margin (if right.margin is not specified, it will default to this node's right margin).

**Pointing and Selecting**

When the user uses the mouse to place the caret point and/or select part of the edited structure, SEdit is faced with the task of mapping the mouse's (x,y) coordinates to the appropriate structure description. These descriptions take the form of datatypes called EditPoints and EditSelections. An EditPoint records

- the node which owns this point (i.e. the one which will be informed if something is inserted here)
- an index, which the owning node may use to record arbitrary information about the point's location
- a type, one of Structure, Atom, or String, indicating how characters typed here will be interpreted
- a line (in the linear form) and x offset within that line, indicating where the caret should be positioned in the window if this point is displayed

EditSelections are similar, except that they have two indices (since selections may cover a sequence of substructures), and describe two positions (bounding the part of the linear form which should be underlined to display this selection).

The responsibility for translating mouse positions to points and selections is shared between the kernel and the type methods. The kernel determines which part of the linear form is being pointed at, and then asks the node which produced that part of the linear form to determine the point or selection. Sometimes the node will decide that in fact its super node or one of its subnodes should really be responsible, and if so it may pass on the request to them. For instance, if the user tries to insert characters at the beginning of an atom, they may actually point to the space between that atom and a preceding structure. The node which output that space was the atom's super node, i.e. the enclosing list. When it receives a request to position a character point in the space between two
subnodes, it should realize that this was likely an attempt to actually edit one of the subnodes, and
pass the opportunity to them.

The first method in this group is SetPoint. It is called with (among other things) the context (all
methods are passed the edit context; from now on we'll stop mentioning it), the node, the index of
the linear form item in which the mouse is positioned, the x offset within that item, and the type of
point requested (i.e. the choice of mouse button used to place the point). It must fill in the fields of
the point, or call some other node's SetPoint method to do it. It can call \set.point.nowhere to
indicate that no point is near this mouse position, and thus the point returned should not allow
input.

There are two other calling sequences a SetPoint method may be invoked with, to allow SetPoint
requests to be readily passed between nodes. A subnode may pass a SetPoint request to its super
node, indicating that the point is to be placed either immediately before or immediately after itself.
For instance, this is what atomic structures do when asked to insert structure. To do this, the
subnode calls \punt.set.point, passing a flag to indicate whether the point should be before or after
this node. Conversely, a node may pass the SetPoint request to one of its subnodes, indicating that
the point is to be placed at the beginning or end of that subnode (as in the example with left-clicking
the space in a list, above). The SetPoint method can determine which case it is being asked to
handle by examining its arguments.

SetPoint methods usually calculate the position of the point when they set it. If the linear form
changes, or the point is set by some other means, it becomes necessary to recompute the position of
the point so that the caret may be displayed. The ComputePointPosition method of the node
owning the point is responsible for filling in the line and x offset values on request.

Similarly, the SetSelection method and ComputeSelectionPosition methods determine the
current selection, given the mouse position. These are very similar to the corresponding methods for
points, and may call \set.selection.nowhere or \punt.set.selection. \set.selection.me is a useful
default SetSelection method; it simply sets the current selection to this node.

There are two additional methods related to selections. GrowSelection is called when the user
uses multiple mouse clicks to select structures. If the mouse handler detects a multi-click sequence,
it calls the SetSelection method for the first click, and GrowSelection for each subsequent click.
The GrowSelection method of the owner of the current selection is responsible for enlarging the
selection to include the next enclosing level of structure. \grow.selection.default is the
GrowSelection method for most types; it simply calls \punt.set.selection, causing the super node to
become the new selection owner.

The SelectSegment method handles right-button mouse actions, which extend the current selection
to include the item pointed to. If the mouse is pointing at part of the linear form of the owner of the
current selection, the SelectSegment method of that node will be called to fix up the selection.
Otherwise, the deepest common super node of the node selected and the node pointed to will be
asked to determine the new selection, given which of its subnodes the selection and mouse are in.

Editing Operations

When an editing operation (such as the deletion or insertion of material) is performed, an
appropriate method is called for the affected node, and this method is expected to fix up both the tree
and the actual structure being edited. These operations are all defined in terms of points and
selections, and the method invoked is that of the owner of the point or selection.

The Insert method takes a previously created point owned by this node and either a string of
characters or a list of nodes which are to become subnodes. The appropriate changes are to be made
to the tree and structure, and the point should either be adjusted to be after the inserted material or
cancelled, as appropriate. Some appropriate functions to call are:

  (\\note.change node context)
  This node has changed in some way which affects its presentation. Its width
  estimates should be recomputed, and the linear form update appropriately.
If the structure resulting from an editing operation is no longer EQ to the original, \subnode.changed will inform the node's super node that it must make the appropriate updates. For instance, if a character is inserted into a litatom it actually becomes a new litatom. No change actually takes place in either atom, but the structure which contained the original atom must change to refer to the new one.

The Delete method takes a previously created selection and deletes the selected material. It returns a flag indicating whether in fact the material can be deleted; many data structures do not allow material to be deleted. It may also be asked to set the caret point so that inserted material will replace that which has just been deleted.

The Replace method replaces the selected material with either a string of characters or a list of nodes (depending on the type of selection). \replace.default is a default implementation of this method, which does a deletion followed by an insertion. This is satisfactory for many data structures, but fails for those which do not allow deletions (e.g. quoted structures).

The Split method is only required for those types which allow character points (i.e. atoms and strings). When a delimiter (e.g. blank or cr for atoms, double quote for strings) is inserted at such a point, the node's Split method will be called. The usual behavior is to change the caret point to a structure point, and to separate the structure into two if the point was not at the beginning or end of the structure.

The BackSpace method implements the action of the backspace key. Given the caret point, the method is expected to make the appropriate deletion and adjust the point accordingly. Sometimes only the latter is necessary; for instance, if the point is positioned immediately after a list, backspace merely moves the point so that it is after the last element of the list (this corresponds to the action of the right parenthesis moving the point to after the parenthesis).

Miscellaneous Methods

There are four other methods for node types to implement, which are invoked by SEdit when the effects of some editing command might be important to a node other than that directly affected. The first of these, SubNodeChanged, was mentioned above; when the structure associated with a subnode is replaced with one which is not EQ to the original one, the super node's SubNodeChanged method will be invoked so that it can fix up its structure appropriately.

Two other methods are used to implement copying and moving structures. When a move or copy selection is made, the CopySelection method of the node owning the selection will be invoked, and passed the selection, a flag indicating what type of selection was made, and a description of the destination. The destination will be either the context of this or another SEdit process, or NIL, indicating that the copy or move is being made to a non-SEdit process, so the material should just be BKSYSBUFed. The default method \copy.selection.default provides an implementation of this method suitable for most applications. If this is used, the CopyStructure method must be defined. CopyStructure is called with a node which has been constructed as a copy of an existing node. Because the copy operation should create new structure rather than just creating another pointer to the same structure, the CopyStructure method must fill in the Structure field of the node with the appropriate newly created structure. The Structure fields of its subnodes will already be copies of their structures, so all that is usually required is to create a new data structure out of these.

When material is moved or copied to other parts of the structure, the position at which it is inserted may imply a different parsing of the structure than that from which it is taken, since the parsing is context dependent (remember the parse mode?). In such a case, the new super node may ask the node to reparse itself, using the ReParse method. This usually involves minor adjustments to presentation, although in the worst case it may involve completely parsing the structure again from scratch.
Editing Interlisp Code with SEdit

The Interlisp editing definitions configure SEdit as an editor for programs written in Interlisp-D, and are ultimately intended as a replacement for DEdit, the system display editor. Although the current system is still missing many convenience features, it currently provides a workable alternative to DEdit. This document provides detailed information on using SEdit as a code editor. It is assumed that the reader has read the introduction to SEdit, and is familiar with the Interlisp-D programming environment. This part of SEdit is under active development; this document will be changed as improvements are made.

Running SEdit

After loading SEdit, the function SEdit allows it to be installed and de-installed as the default system display editor. Executing (EDITMODE 'SEDIT) will cause future edit requests (from functions such as DF, from Masterscope, and from inspectors and browsers) to use SEdit instead of DEdit; executing (EDITMODE 'DEDIT) will revert to using DEdit. The function will return the previous editor state (SEDIT or DEDIT).

Unlike DEdit, SEdit does not run in the process which invokes it. This has some important effects:

a) SEdit processes can be started and stopped in any order. The windows may be shrunked and kept around indefinitely if desired.

b) Calls to editing functions such as DF return as soon as the process is started, rather than waiting for the editing to be completed (however, when SEdit is invoked from Masterscope, it forces Masterscope to wait until the user indicates that they are done editing (by closing or shrinking the window); this is simply a convenience to avoid Edit where any commands from immediately covering the screen in hundreds of edit windows).

c) As a consequence of (b), some functions normally performed by DF (such as informing the file package that the function has been changed and needs to be saved, unsaving the definition of a compiled function, or updating the “last edited” date) are instead performed by SEdit, and often at different times (since SEdit can’t wait until the user is “done editing”).

Commands

At present, SEdit has no attached menu of commands. Many of the commands in DEdit’s menu (such as Before, After and Replace) are completely unnecessary in SEdit (because of its more uniform interface). Some of them (such as Delete, and soon ()in and ()out) are provided by keyboard commands. A menu may be added in the future with the introduction of more obscure commands.

Pointing and Selecting

Like TEdit, SEdit maintains a current insertion point at which typed, copied, or moved material will be inserted. The point is set by moving the mouse to the desired position and clicking a mouse button, and is indicated by a flashing caret. Unlike TEdit, SEdit has two types of points: structure points and character points. Structure points are allowed within non-atomic structures which have a variable number of components (i.e. lists); they indicate that another Lisp structure can be inserted at the indicated position. In normal (NIL-terminated) lists, structure points can be placed before the first element, after the last element, or between any two adjacent elements; in a non-NIL terminated (dotted) list, points may not be placed anywhere after the dot. Character points are positions at which individual characters may be inserted (rather than whole Lisp structures), and are allowed in atoms and strings. The caret changes to reflect the type of point: structure points look like '▲', and character points look like ‘A’.

Similarly, both structures and individual characters can be selected. A selection may be

- one of the characters in the pname of an atom or string
• a sequence of consecutive characters in the pnam of an atom or string
• a lisp structure presented as an entity (e.g. an entire list, string, atom, quoted structure, etc.)
• a sequence of such structures appearing consecutively in a list

Note that not all lisp structures are presented as distinct entities, and so not all will be selectable. For instance, the individual cons cells comprising a list are usually not separately selectable. Also, extra characters added to the presentation as punctuation are not individually selectable; you can’t select the left parenthesis of a list, or the closing quotation mark of a string.

The type of selection and point made depends on the mouse button used. The left button selects characters and places character points; the middle button selects structures and places structure points (this is supposed to be reminiscent of TEdit). The right button extends the current selection to the smallest selection which covers the current mouse position. As an added convenience, clicking with the left or middle button more than once in the same spot will enlarge the current selection one step, through enclosing layers of structure.

Inserting and Replacing

To insert characters in an atom or string, use a mouse button to place a character point at the desired location and just type the characters. As each character is typed, it will be inserted and the caret point will be moved after it. The Backspace key deletes the character to the left of the caret.

To insert new structures in lists, place a structure point at the desired location and type one of

• a left parenthesis to insert a new list
• a double quotation mark (") to insert a new string
• a normal character (i.e. one with syntax class OTHER) to insert an atom beginning with that character

In the first case, an empty list will be inserted and the caret will be moved inside it. In the second, an empty string will be inserted and the caret will become a character point inside the string. In the third case, a new atom will be inserted, and the caret will become a character point to allow appending more characters to the atom’s name.

There are a few other characters which are recognized specially:

• a right parenthesis places the caret point immediately after the list immediately enclosing it
• a double quotation mark, while inserting characters in a string, places the caret point immediately after the string (if it was after the last character in the string) or splits the string into two strings (if it was between two characters)
• a blank or carriage return, while inserting characters in an atom, places the caret point immediately after the atom (if it was after the last character) or splits the atom into two atoms (if it was between two characters)

These characters all leave the caret point ready to read another structure. The rules may sound a little bizarre, but they work out to give just the right behavior — typing in the printed representation of a lisp structure will give you that structure. (At present, this only works for (undotted) lists, string, litatoms, and numbers; soon dotted lists and quoted structures will also be implemented).

Special characters, such as parentheses, spaces, and double quotation marks, can be inserted in atoms by preceding them with the escape character (a percent sign).

To replace structure, it is selected “pending delete”. Pending deletion selections are made whenever the current selection is extended using the right mouse button (as in TEdit). To distinguish them from normal selections they are displayed by outlining the selected material, rather than underlining it. When structures or characters have been selected pending delete, typing anything will cause them to be replaced with the new material.
Copying, Moving, and Deleting

Structures or characters may be copied or moved from one part of an SEEdited structure to another, between two SEEdited structures, or between an SEEdited structure and any other Interlisp process which will accept or produce character string representations of lisp structures. To copy material, place a point of the appropriate type at the desired destination, and then select the desired material while depressing the Copy key (Shift on the Dorado keyboard). Selections made with the Copy key depressed will be displayed by a gray underline. As soon as the Copy key is released, a copy of the current selection is inserted at the point. If the TTY process is a non-SEdit process, a printed representation of the selected material will be BKSYSBUFed for it to read.

Moving material is done in a similar fashion, except that the Move key is depressed while making the selection. Move selections are displayed by a gray outline. As soon as the Move key is released, the selected material will be inserted at the current caret point and deleted from its original position. On the Dorado keyboard, Move selections are indicated by depressing both the Shift and Control keys.

Material may also be deleted in this fashion. Depressing the Control key while making a selection will cause the selected material to be deleted as soon as the Control key is released. Delete selections are displayed by inverting the selected material (displaying it white-on-black instead of black-on-white).

Whenever selections are being made, the selection is considered complete only when the mouse buttons and any modifier keys (Copy, Move, etc.) have been released. Thus, selections requiring more than one mouse click (e.g. sequence selections) can be made by keeping the modifier key depressed throughout the process. Alternatively, if the wrong modifier key is initially depressed, it can be released and another depressed as long as a mouse button is held down during this time. To completely abort the selection, click a mouse button outside the window before releasing the modifier key.

There are two other ways of deleting material. The Backspace key, as was previously mentioned, deletes the character to the left of the caret (this strictly true only when the caret is a character point in an atom or string; at other times it does other, reasonable things — you'll have to try it out to find out exactly what). The Delete key deletes the current selection. (Note that this is different from the Control key, which is a selection modifier; with Delete a normal selection is made and then the Delete key is depressed, while the Control key is depressed while the selection is actually being made — the choice of which is to use is a matter of personal taste.)

Formatting

SEdit attempts to display the structure being edited in as readable a fashion as possible, while keeping within the width of the display window. It uses fairly conventional rules for pretty-printing lisp, augmented with some special formatting rules for Interlisp special forms (e.g. LAMBDA expressions and CLisp). The components of these special forms are given indentation based on their function within the form, and special keywords are displayed in bold face to improve readability. Some effort is made to propagate the width constraint information so that relatively uniform indentation is used, rather than having complex nested expressions end up mashed against the right edge of the window. In extreme cases SEdit will extend the presentation past the right edge of the window rather than produce too ugly a presentation. If this happens, a horizontal scroll bar will be added to the window to allow editing the whole presentation.

SEdit Windows

The windows SEdit creates behave like all good Interlisp windows. They may be moved, reshaped, and scrolled. If they are reshaped to a different width, the formatting is recomputed to make the best use of the available space. The may be shrunk, producing a relatively unexciting icon adorned with the name of the variable or function being edited. When they are shrunk, the process reading commands from the keyboard is deleted (to save stack space, and allow keeping a large number of SEdit windows around), but it is automatically recreated as soon as the window is expanded again, so this should be effectively invisible. Closing an SEdit window or icon terminates the editing and releases the data structures used.
Unlike DEdit, it is not clear when to consider an SEdit editing session complete. The user may start an edit process, do some editing, shrink the window, expand it again later, etc. For some purposes it is important to have such a notion. For instance, the file package must be informed when a function is edited, so that the new definition can be saved to the appropriate file. If a function has been compiled, and the source is then edited, the compiled code should be discarded. If the editor is invoked on a sequence of structures by Masterscope or EDITFNS, it must know when it is time to go on to the next structure. When a function has been edited, a new comment should be added recording the time and date and the initials of the programmer. All of these cases require some way of indicating that this set of editing operations is completed, even if the editing process is not to be terminated. At present, SEdit handles this by assuming that editing is complete when the window is closed or shrunk.

Confusing SEdit

SEdit currently assumes that no changes will be made to the structure being edited during an edit session, other than those made by SEdit itself. Of course, since SEdit exists in a lisp environment replete with shared structures and destructive functions, there is no way to enforce this. For instance, while editing a variable whose value is a list you could (from an executive window) run a function to destructively change that list. There is no way for SEdit to notice the change as it happens, and at present it will not recover gracefully if it encounters the inconsistency later on.

To avoid causing these problems to itself, SEdit automatically avoids starting two edit processes on the same variable or function. This is only a partial solution, however, and the user is advised to watch out for this problem. If you suspect that a structure being edited has been changed by some other process, simply close the window and start another edit process. This will force SEdit to reexamine the structure.

In the immediate future SEdit will be fixed to detect the most common case of such changes, namely corrections made by DWIM. It is also planned to make SEdit much more robust in the face of other changes it may detect (in the not quite as immediate future).
How SEdit Works

SEdit incorporates a variety of complex algorithms and data structures. Although the code is commented, there is no logical place within it to properly describe the use of these. Therefore this document provides an overview of the most interesting and tricky parts of the program. If you want to understand exactly what the code does, this isn't a replacement for actually reading it. This is, however, a highly recommended introduction to the code; it's probably not worth trying to understand the code if you haven't read this first.

The Code

The code for SEdit currently resides in five files, named SEdit, TopLevel, SEditWindow, Linear, and IntrLsp. The first four of these comprise the SEdit kernel and its interface to the rest of Interlisp-D; the last is the definitions which configure SEdit as an editor for Interlisp code. The approximate division of labor is:

**SEdit**
- process initialization, keyboard command loop, top-level method invocation, building and manipulating the edit tree

**TopLevel**
- interface to Interlisp-D editing functions and file system, starting and managing SEdit processes

**SEditWindow**
- window system interface, mouse selection and pointing, scrolling

**Linear**
- building and manipulating the linear form, optimized screen updating

**IntrLsp**
- methods for the standard Interlisp types

Included with the code listings is a directory of SEdit function names, identifying the file within which they occur. Within each file listing the functions are sorted into alphabetical order. SEdit currently uses the convention of preceding its function names by a pair of backslashes, to clearly distinguish them from other parts of the Interlisp system. At some point a more conventional prefix will be chosen.

Control Flow

SEdit sessions are started via the system function EDITL, which originally invoked the TTY structure editor. When SEdit is enabled, EDITL is modified to call SEdit. SEdit first attempts to find an active SEdit already editing the same function or variable. If one is found, SEdit makes sure that the edit window is expanded and not buried on the screen, and then returns. In this way it avoids starting several SEdit processes on the same structure, which could lead to major confusion. If no active SEdit is found, it will start a new one. It places a window, either by asking the user where the window should be or by using the window position of a previous SEdit (to avoid prompting the user over and over again). Once it has a window, SEdit starts a new process running the keyboard processing loop, and waits for it to signal that it has initialized.

A further complication is that EDITL may be invoked with a sequence of TTY editor commands which are to be performed. Rather than attempt to implement the large and baroque command set of the TTY editor, SEdit simply calls the TTY editor to execute the command sequence, but with the constraint that should the command sequence involve a pause for user editing (i.e. the TTY: command), the TTY editor will call SEdit back. This mechanism is used heavily by Masterscope, which usually passes a sequence of editor commands which search for particular parts of the function and then allow the user to edit them.

If EDITL is invoked without any commands, it returns as soon as the command loop signals that initialization is under way. The editing will be handled by the new process, and whoever invoked SEdit can now go on with other things. Alternatively, if a command sequence is given, SEdit will
wait until the command process signals that the user has indicated editing is complete before returning. This is quite important; if EDITL doesn't wait under these conditions programs like Masterscope may try to start dozens of SEdit procedures, without giving the user time to actually do any editing.

The command loop which is executed by the SEdit process ($\texttt{sedit}$) first checks to see if this is a new SEdit context or an old one. If it's new, the structure must be parsed to generate the edit tree and linear form, window parameters must be initialized, and the initial presentation must be displayed. If this is a continuation of an old edit session, any pending adjustments to the presentation are completed, and the current selection is redisplayed. Either way, $\texttt{sedit}$ then enters a loop reading single characters and executing the appropriate action.

**Keyboard Input**

The interpretation of characters typed from the keyboard is determined by an Interlisp readable, which maps characters to syntax classes. The syntax classes understood by SEdit are:

- **STRINGDELIM**: this is the delimiter for strings (i.e. double quote)
- **SEPRCHAR**: white space, e.g. blank and carriage return
- **ESCAPE**: when preceded by this character, other characters should be treated as syntax
  - **OTHER**: (the usual escape character is %)
- **OTHER**: a "normal character", suitable for inclusion in the pname of a litatom

(type where when function): a read macro. function is the function to be invoked when this character is typed. type determines what information will be passed to the function, and how its result will be interpreted; at present the only legal value is INFIX, indicating that the function will be passed the complete edit context, and is free to make any changes whatsoever. where and when control under what conditions the function will be invoked; the valid combinations are:

- (ALWAYS IMMEDIATE) the function will be invoked whenever the character is input (e.g. Delete)
- (ALWAYS NONIMMEDIATE) the function be invoked except when the character is typed as part of a string (e.g. left parenthesis)
- (FIRST NONIMMEDIATE) the function will only be invoked when this character is typed at a structure point, i.e. as an atom on its own (e.g. period)

Note that these are not exactly the conventional interpretation of readable entries, but have been adapted to SEdit's needs.

The action produced by a character depends on both the syntax class of the character and the type of the current point (string, atom, or structure). For instance, a SEPRCHAR typed to a string point will insert that character in the string, typed to an atom point will split the atom, and typed to a structure point will simply be ignored. An OTHER character typed to a string or atom point will be inserted, but typed to a structure point will cause a new node, representing the single character atom, to be created and inserted.

**Mouse Actions**

In the Interlisp-D window system the effects of mouse movement and buttons are determined by a special mouse process, which invokes functions attached to the windows. The effect of this is that activities like selecting and pointing are actually run under the mouse process, rather than under the SEdit process. This has several ramifications. First, the mouse process must be able to easily access the state of the editing process, so that it has the necessary information available to carry out the actions. For this and other reasons the entire state of the SEdit process is encapsulated in a single data structure, called an EditContext, which is then attached as a property of the window.
Second, access to the editor’s data must be controlled, so that multiple processes don’t interfere with each other. This is achieved through a monitor lock on the EditContext (called the ContextLock).

The Linear Form

The data structure used to encode the linear form must satisfy several constraints. First, as its name suggests, it is treated as a sequence of items. The window is repeatedly being redrawn from the linear form, and usually the segment which is redrawn cuts across the tree structure. This requires being able to start iterating through the linear form from any point, and continue until some other arbitrary point, preferably without having to maintain a stack. On the other hand, it is generated and modified hierarchically; the kernel must be able to quickly extract and replace the linear form for any node in the tree, without affecting the nodes above or (in some cases) below it. To achieve this, the linear form for each node is stored as a list pointed to by the node, which ends with a pointer back to the node. This list may contain linear items and subnodes of the node, indicating that their linear forms are to be inserted at that point. Finally, each node contains a pointer (called the LinearThread) which points to the position in its supernode’s linear form at which it appears. This threading allows any part of the tree structured linear form to be easily and efficiently traversed.

One complication to this scheme is that because of the reference counting garbage collector in Interlisp-D, we don’t actually make the tail of the linear form point back to the node directly. This would introduce a circular chain of pointers, preventing these structures from ever being garbage collected. Instead, we use a data structure called a WeakLink, which contains one non-reference counted pointer field. Of course, the use of such pointers can make debugging hazardous; unfortunately, they are pretty much unavoidable in memory management scheme such as Interlisp-D’s, and SEdit uses them in a number of places.

Most of the items which can appear in the linear form are relatively simple, but LineStarts are the exception. LineStarts are inserted by the linearization procedures to indicate that a new line is to be started, but are used by the kernel a lot of extra information. First, each LineStart is linked to the LineStart before and after it, allowing efficient access to sequential lines of the linear form. Second, each LineStart records the maximum ascent and descent of the items which appear on that line, since these determine the amount of vertical space required to determine the line. Since lines can contain arbitrary combinations of text in different fonts and sizes, as well as bitmaps of arbitrary size, each line’s ascent and descent must be separately computed, and may change with any change to the nodes appearing on that line. Third, each LineStart has a pointer to the node in whose linear form it appears; although this could be determined by scanning along the linear form, it’s used often enough that we cache it. Fourth, each LineStart stores the y coordinate of that line’s baseline. This is a function of that y coordinate of the preceding line, the line ascents and descents, and the separation between the lines.

Thus, the algorithm for updating the window from the linear form is something like this:

```lisp
(* pointer is the current position in the linear form)
while pointer is not NIL do
  if pointer is a list, then
    let item be the first element of the list
    if item is a number (* horizontal space), then
      increment current x by item
    elseif item is a LineStart, then
      set x to the indentation of item
      set y to the baseline of item
    elseif item is a bitmap or string item, then
      paint this item and increment x by its width
    else item is a subnode
      set pointer to the linear form of item
    elseif pointer is a WeakLink
      set pointer to the CDR of the linear thread of
      the node pointed to by this WeakLink
```

Incremental Relinearization

When the node structure is changed, SEdit is faced with the task of updating the screen as efficiently as possible. This is actually treated as two problems: first, the new linear form must be computed as efficiently as possible, and second, given the changes that occurred in the linear form, we wish to make the corresponding adjustments to the window, with a minimum of repainting.

The first problem is dealt with using a number of tricks. First, as changes are made to the tree no attempt is made to update the linear form immediately; all that is done is to keep a list of those nodes which have been changed and thus need their linear forms recomputed (this is the purpose of `\note.change`). This list is kept sorted by depth, and duplicates are discarded. Once SEdit decides that it's time to update the window, it finds a minimal set of nodes to relinearize, such that all of the changed nodes are contained directly or indirectly (as subnodes of an included node), and the width estimates of these nodes have not been changed by the editing (hence the linear form of their super nodes won't have changed). The linear form of each of these nodes is recomputed. Second, during this relinearization, subnodes of a relinearized node will not be relinearized if their structure hasn't changed, and SEdit is able to determine that their resulting linear form won't have changed (e.g. their margins haven't changed). In practice, this typically results in a major decrease in the amount of relinearization involved.

The second problem is more difficult. The idea is that we want to reuse as much of the existing window display as possible. If part of the linear form is already displayed in the correct place, no changes should be made to it. If part of it is already displayed, but in the wrong place, SEdit tries to use a bitblt call to copy those bits to the correct location rather than reconstructing them. This is complicated by the fact that material copied may be less than one line or span several lines. The line its moved to may have greater or less ascent and descent than the one it came from; in fact, the ascent and descent of the destination line won't be known until it's completed. To deal with this, SEdit builds a second description of the line, in parallel with the construction of the linear form. This structure describes the line as a sequence of blocks, each of which represents a subsequence of the linear form. Each block may also already appear in the window, in which case the coordinates from which it can be retrieved are also recorded. At the end of each line, SEdit examines the sequence of blocks, determines which ones actually represent useable blocks of bits, copies them, and repaints any gaps. To avoid overwriting bits which it may later want to use, SEdit will sometimes shift whole parts of the screen out of the way; this introduces additional complications, since coordinate transformations are now required to determine the actual location of the desired bits.

A Word About Lines and LineStarts

SEdit defines a LineStart data type to record information about a line in the linear form. The LineStart does not record the actual linear items which appear on that line; that information is implicitly recorded in the linear form itself. The linear form is an list of linear items, and LineStarts are items. Thus, the items on a line are those which follow it in this list (until the next LineStart). Since this information is often needed, many of the places where one might expect a pointer to a LineStart actually contain a pointer to the linear form which start at that LineStart, i.e. a list, the first element of which is the LineStart. This is referred to as a Line.

Pretty Printing

The code listings at the end of this document were generated by SEdit's formatting routines. This seemed like an obvious thing to do, but a couple of caveats are in order. First, the formatting rules are still incomplete; in particular, they do a miserable job on `create` expressions (which have a very non-LISP like syntax). Second, quite little modification was required to add this capability to SEdit, but the result isn't an ideal pretty printer. It does a good job (better than Interlisp's pretty printer), and hopefully will soon do an even better job, but it's a very expensive way to do it. Constructing the complete edit tree for a one-shot linearization consumes excessive memory and time, and consequently printing large files of functions requires considerable patience.

Contexts, in detail

(an annotated description of the Context data structure definition)
Environment: an `EditEnv`
The Environment provides a number of parameters controlling the editing process. The idea is that different environments are built to describe different editing tasks (editing different languages, or just different edit styles), and then shared between all edit contexts of that type.

DisplayWindow: a `WINDOW`
This is the primary window, in which the edited structure is displayed.

EditType: probably a `litatom`
Doesn’t affect the editing, but used (in conjunction with `IconTitle`) to help identify the source of the structure being edited. One of `VARS`, `FNS`, `PROP`, etc.

IconTitle: a string or `litatom`
The name of the structure being edited, used to title the window and icon. Also, in conjunction with `EditType`, used to determine whether an existing SEdit session is already editing a structure the user has asked to SEdit.

ContextLock: a `MONITORLOCK`
The monitor lock used to control access to this Context.

CompletionEvent: an `EVENT`
SEdit will signal this event when the user shrinks or closes the window, or otherwise indicates that they have done enough editing. When called under the TTY editor, the process which spawns the SEdit command loop will wait for this event.

WindowLeft, WindowRight, WindowBottom, WindowTop: integers
During screen update processes, SEdit caches information about the window dimensions here, since they’re used so frequently.

CurrentX: an integer
CurrentLine: a `Line`
While generating the linear form, SEdit uses these to record the start of the current line and the horizontal position within that line.

LinearPointer: a position within the linear form
This is the current position within the linear form, for purposes of comparison and insertion.

LinearPrev: a position within the linear form
This is one step behind the LinearPointer, to allow fixing up pointers when an item is inserted. If `LinearPointer` points to the first item within the linear form of a node, `LinearPrev` will point to that node.

Root: an `EditNode`
Points to the root node in the edit tree.

LastLinearizedSubNodeIndex: an integer
During linearization, this field is used to record the last subnode linearized of the current node (as a consistency check).

ChangedNodes: a list of `EditNodes`
This list records which nodes in the tree have had their structure changed and hence require relinearization. It’s headed with a dummy item (NIL) to simplify insertion, and sorted by decreasing depth. Most of the time, this list should contain exactly those items whose `Changed?` field is T.

CaretPoint: an `EditPoint`
Records the current insertion point.

Selection: an `EditSelection`
Records the current selection.
Caret: a CURSOR
This is the mark to be displayed at the current caret point (hollow or solid, depending on the type of point).

SelectionDisplayed?: a boolean
Records whether the current selection has been underlined, outlined, or whatever.

LastMouseX, LastMouseY: integers
LastMouseType: one of (Atom, Structure)
Records the position of the last mouse click, and the button used, to detect multi-click sequences.

\X, YT: integers
These slots in the EditContext are used at one point in the program to return multiple values from a function; too bad there’s no better way.

FirstBlock: a LineBlock
The first in the sequence of blocks constructed to describe the current line.

CurrentBlock: a LineBlock
The last (so far) in the sequence of blocks being constructed to describe the current line.

Matching?, Below?, Visible?: booleans
These are used while constructing the block sequence to keep track of our current state.

RepaintStart: a position within the linear form
RepaintLine: a LineStart
RepaintX: an integer
Also used to keep track of state while constructing the block sequence.

ShiftY, ShiftDown, ShiftRight: integers
When the block shifter moves the rest of the window contents out of the way, these variables record what has been done to allow translating coordinates. Everything below ShiftY has been shifted down by ShiftDown; everything on the current line past the current position has been shifted right by ShiftRight.

RelinearizationTimeStamp: an integer
During relinearization, the position of a line may move. However, the old position of that line may be later needed to locate useful bits. When the position or dimensions of a possibly useful line are changed, the old values are cached. Since the values are only good for the current relinearization, they are marked with this time stamp, and each relinearization its value is increased.

Environments, in detail
(an annotated description of the Environment data structure definition)

ParseInfo: a PLIST
This PLIST maps TYPENAMEs of edited data structures to the functions which can parse them.

ParseInfoUnknown: a function name
This is the function called to parse any data structure whose TYPENAME doesn’t appear in ParseInfo.

DefaultFont, ItalicFont, KeywordFont: font descriptors
These are the fonts to be used when formatting.

DefaultLineSkip: an integer
If the linearization procedure doesn't specify the vertical spacing between lines this value will be used.

**ReadTable**: a READTABLE
This is the table used to determine the syntax of keyboard input and the interpretation of command characters.

**SpaceWidth**: an integer
This is the default space to leave between adjacent items in lists, etc.

**DefaultIndent, MinIndent, MaxIndent, MaxWidth**: integers
These values control the formatting of list structures.

**LParenString, RParenString, DotString, QuoteString**: StringItems
To prevent repeatedly constructing StringItems for the standard punctuation symbols, they're cached in the environment and shared. These must be reconstructed if the fonts are changed.

### EditNodes, in detail

(an annotated description of the EditNode data structure definition)

**NodeType**: an EditNodeType
The type of this node, providing the set of methods.

**ParseMode**: a litatom
The parse mode in which this node was parsed.

**SuperNode**: an EditNode
This node's super node; NIL if this is the root.

**Depth**: an integer
The depth of this node within the tree; the root has depth 0.

**SelfLink**: a WeakLink
To avoid building uncollectable circular structures, the linear form ends with WeakLink back to the node. To avoid consing WeakLinks, we cons one and cache it here.

**SubNodeIndex**: an integer
This is the index of this node within its super node's subnodes.

**Structure**: anything
This is the structure this node actually represents.

**Changed?**: a boolean
True if this node has been changed and will require relinearization. Most of the time, true iff this node is on the context's list of changed nodes.

**InlineWidth, PreferredWidth, PreferredLLLength, MinWidth, MinLLength**: integers
The width estimates computed by this node's ComputeFormatValues method.

**SubNodes**: a list of EditNodes
The subnodes of this node.

**LinearForm**: a list of linear items
The linear form of this node, terminating in a WeakLink back to the node.

**LinearThread**: a list of linear items
The position of this node within its super node's linear form (hence a list whose CAR is this node)
Unassigned: anything
   Available for use by this node's methods to cache any additional information they wish
to record.

StartX: an integer
   The horizontal position at which the linear form of this node begins.

RightMargin: an integer
   The right margin used when formatting this node.

ActualWidth: an integer
   The maximum horizontal offset of any part of the presentation of this node from the
starting position.

ActualLength: an integer
   The offset of the end of the last line of this node's presentation from the node's starting
position.

FirstLineLinear, LastLineLinear: Lines
   The line on which this node's linear form begins, and the line on which it ends.

Inline?: a boolean (computed)
   True iff FirstLineLinear and LastLineLinear are the same.

FirstLine, LastLine: LineStarts (computed)
   The CARS of FirstLineLinear and LastLineLinear.

**EditNodeTypes, in detail**

(an annotated description of the EditNodeType data structure definition)

Name: a string or litatom
   This is not used by SEdit, but provides a handy point of reference when debugging.

ComputeFormatValues, Linearize, ReParse, SubNodeChanged, SetPoint,
ComputePointPosition, ComputeSelectionPosition, SetSelection, GrowSelection,
SelectSegment, Insert, Split, Delete, Replace, CopyStructure, CopySelection,
BackSpace : function names
   These are the methods of this node type.

**LineStarts, in detail**

(an annotated description of the LineStart data structure definition)

NextLine, PrevLine: Lines
   These lines immediately before and after this one in the linear form.

Node: an EditNode
   This is the node in whose linear form this LineStart was generated.

LineAscent, LineDescent: integers
   The maximum ascent and descent of any item on this line, and hence the dimensions
   of the line.

LineSkip: an integer
   The vertical separation of this line from the line preceding it.

Indent: an integer
   The amount by which this line is horizontally indented.

LineLength: an integer
   The total length of this line (including indentation).
YCoord: an integer
   The vertical position of the top of this line (including the LineSkip). Since we set up
   the window's coordinate system with (0,0) in the top left corner, YCoords are always
   negative or zero.

CachedY, CachedAscent, CachedDescent: integers
   During relinearization, we may need to determine what the position and dimensions of
   a line were after we've changed them. When this is a possibility the old values are
   saved here.

CacheTime: an integer
   When the old position and dimensions are cached, the current value of the context's
   RelinearizationTimeStamp is recorded here, so that we can quickly determine when the
   cached values are out of date.

LineHeight: an integer (computed)
   The sum of LineSkip, LineAscent, and LineDescent.

BaseLineY: an integer (computed)
   YCoord minus the sum of LineSkip and LineAscent.

NextLineY: an integer (computed)
   YCoord minus LineHeight; should be equal to the YCoord of NextLine.

OldTop, OldBottom: an integer (computed)
   If the cache values are up to date (comparing their time stamp with that of the
   context) use them; otherwise use the current values.

StringItems, in detail
   (an annotated description of the StringItem data structure definition)

   String: a litatom or string
      The text to be displayed.

   Font: a font descriptor
      The font in which the text should be displayed.

   PRIN2?: a boolean
      True if the PRIN2-name of String should be used, rather than the pname (i.e. string
      delimiters will be displayed, command characters will be escaped).

   Width: an integer
      The width of this item when displayed.

EditPoints, in detail
   (an annotated description of the EditPoint data structure definition)

   PointNode: an EditNode
      The owner of this point, i.e. the node in which insertion will take place.

   PointIndex: an integer
      Used by the PointNode to record the point's position within the node.

   PointType: one of (Structure, Atom, String)
      Determines how characters typed at this point are to be interpreted.

   PointLine: a LineStart
   PointX: an integer
      The position in the window at which the flashing caret should be displayed while
      waiting for keyboard input.
EditSelections, in detail
(an annotated description of the EditSelection data structure definition)

SelectNode: an EditSelection
   The owner of this selection.

SelectStart, SelectEnd: integers
   Used by the SelectNode to record the selection’s boundaries within the node.

SelectType: one of (Structure, Atom, String)
   If typed input replaces this selection, this determines how it will be interpreted.

SelectStartLine, SelectEndLine: LineStarts
SelectStartX, SelectEndX: integers
   The boundaries of the area to be highlighted when this selection is displayed.

DeleteOK?, ReplaceOK?: booleans
   The use of these flags is not completely implemented yet.

LineBlocks, in detail
(an annotated description of the LineBlock data structure definition)

BlockStart: a position within the linear form
   The start of the segment of linear form this block represents (the end is determined by
   the start of the next block).

BlockNewX: an integer
   The horizontal position at which this block will be displayed.

BlockWidth: an integer
   The width of this block when displayed.

NextBlock: a LineBlock
   The next block in the sequence.

Bits?: a boolean
   True if the segment of linear form represented by this block is already displayed on
   the screen.

BlockX, BlockBaseLine, BlockAscent, BlockDescent: integers
   If Bits? is true, these fields give the current position of the block’s presentation.
An Extensible Structured Data Editor for Interlisp-D

Lisp environments are populated by a variety of complex linked data structures, particularly linguistic structures (such as programs written in Lisp and other languages). These are often designed with visual representations (e.g., the pretty-printed form of Lisp code). Through such features as read macros and print definitions, the data structures may be converted to or from a textual representation. In many cases, the only convenient way to edit the structure may be to edit the textual representation and then re-interpret it. This approach suffers from several difficulties:

- writing the structure out and reading it back in will generally create an entirely new structure; this may be a problem if the structure is shared or part of a larger structure
- the requirement that enough information be written out to reconstruct the data when it is read back may conflict with the desire that the presentation be convenient to understand and change
- if the text editor is to provide any assistance (syntax checking, semantic checking, etc.) it must be integrated with the Lisp environment, and continually translating structures to and from their textual representation
- no allowance is made for nontextual graphic presentations

SEdit provides a different approach. Data structures are edited directly, with visual presentations provided as a means of communication. Like WYSIWYG text editors, the editing window contains a continuously updated presentation of the data structure, and editing operations are input in terms of this presentation. Presentation and editing rules are defined for each data type, and a kernel program uses these rules to perform the editing.

A set of such rules have been written to configure the editor as a tool for editing Interlisp programs. Interlisp code is pretty-printed in the window, and editing operations use a simple "point and type" user interface. This provides a more convenient way of editing Interlisp than previously existing tools, and furthermore will allow the simple construction of editors for other languages implemented in the Interlisp environment (Prolog, CommonLisp, 3-Lisp, Loops, etc.).

A Sample Session

Before discussing the structure and implementation of SEdit, we will try to give a feel for what it does by a brief description of some simple editing. Of course, it is a little hard to convey the flavour of as interactive a process as editing with just a few words and pictures. This discussion assumes some familiarity with the uniform editing interface which many Interlisp-D programs (and in fact most Xerox software) supports, since that was the model for SEdit's interface. The basic principles are that

- there can be a current insertion point, usually indicated by some sort of caret, at which inserted material appears
- there can be a current selection, usually indicated by underlining or other highlighting, which indicates the material to be affected by a following command (commands may change the selected material, change some aspect of it (such as font or formatting), delete it, etc.)
- the point and selection are usually placed by positioning the mouse and pressing a button; the left or middle button places the point near the cursor and selects the indicated material, while the right button extends a previously made selection to include the indicated material
- material may be selected while holding down a modifier key; instead of becoming the current selection, an action is performed as soon as the key is released. The standard modifiers are `Copy`, which inserts a copy of the selected material at a previously
chosen insertion point; Delete, which deletes the selected material; and Move, which copies the selected material and then deletes it.

To SEdit an Interlisp function after SEdit has been loaded, use the usual (DF function). This creates an edit window for the function. Unlike the older display editor (DEdit), DF will return immediately, since the editing is done in a separate process. The function body will be pretty-printed in the window:

```
SEdit fibonacci

(LAMBDA (n)
  (* mdd " 3-May-86 18:26")
  (if (LEQ n 1)
      then n
    else (PLUS (fibonacci (SUB1 n))
             (fibonacci (DIFFERENCE n 2)))))
```

Since SEdit knows that this is Interlisp code, it uses some formatting rules specific to Lisp as well as its general rules for formatting lists, atoms, and strings. Formatting rules specify visual presentations as the positioning of text strings (in any font) and arbitrary bitmaps.

SEdit allows operations both on complete Lisp objects (such as lists and atoms) and on parts of objects, such as the individual characters in an atom's name. To do this conveniently, it uses the convention that the left mouse button is used to point to parts of structures, while the middle mouse button always points to whole Lisp structures. Thus, left-clicking the \( \text{Q} \) in \( \text{LEQ} \) selects that character, but middle-clicking there will select the whole atom (this convention matches TEdit's character/word selection convention). Furthermore, the same convention applies to insertion; a left click between the \( \text{E} \) and \( \text{Q} \) will allow inserting more characters, but a middle click will allow inserting a new structure (after the \( \text{LEQ} \), since the mouse was closer to the end of the atom than the beginning). SEdit indicates the type of insertion expected by changing the caret, to '\( \text{\text{A}} \) for a substructure and to '\( \text{\text{A}} \) for a structure. Thus, left-clicking the right side of the \( \text{Q} \) in the above window produces:

```
SEdit fibonacci

(LAMBDA (n)
  (* mdd " 3-May-86 18:26")
  (if (LEQ n 1)
      then n
    else (PLUS (fibonacci (SUB1 n))
             (fibonacci (DIFFERENCE n 2)))))
```

and any characters now typed would be appended to the atom \( \text{LEQ} \). On the other hand, middle-clicking in the same place produces:
and if characters were inserted they would form a new atom.

Enclosing structures are selected by multiple clicks. In the previous example, if the middle button were clicked twice, the list \((\text{LEQ} \ldots)\) would be selected; if it were clicked thrice, the \((\text{if} \ldots)\) would be selected, etc. Sequences of structures or substructures are selected by extending the current selection with the right mouse button. If the atom \(\text{LEQ}\) has been selected, right-dicking the 1 would select the sequence of three structures \(\text{LEQ}, n, \text{and } 1\) (this is not the same as selecting the list which contains these structures). Similarly, the \(\text{onacc}\) in the middle of \(\text{fibonacci}\) could be selected by left-dicking at one end of the sequence and right-dicking at the other end.

Some characters activate SEdit commands. For instance, typing a left parenthesis inserts an empty list at the current insertion point and positions the point inside it. Typing a right parenthesis positions the point just after the list immediately enclosing the current point. Typing a blank when inserting within an atom splits the atom at the point (unless the point is at one end of the atom) and switches to structure insertion. This allows Lisp list structures to be typed in as usual. For instance if we continue the above example by typing \"(a b \" the window will now appear like this:

\[
\text{SEdit fibonacci}
\]

\[
(\text{LAMBDA } (n)
  (* mdd "3-May-86 18:26")
  \text{(if } (\text{LEQ} \ (a \ b) \ n) \text{ then } n
  \text{ else } (\text{PLUS} \ (\text{fibonacci} \ (\text{SUBL} \ n))
    \ (\text{fibonacci} \ (\text{DIFFERENCE} \ n \ 2)))))
\]

(Note that the matching right parenthesis appears as soon as the left parenthesis is typed; this is an immediate consequence of having the window always be a pretty-printed presentation of the underlying list structure. Double quotes work the same way for strings.)

Modified selections allow the easy rearrangement of existing structures. For instance, to switch the order of the two arguments to \(\text{PLUS}\), simply

a) middle-click after \(\text{PLUS}\) (sets the insertion point)
b) hold down the \(\text{Move}\) key (we are going to move part of the structure to the current insertion point)
c) middle-click on the second \(\text{fibonacci}\) twice (selects the whole function call)
d) release the \(\text{Move}\) key (to indicate the selection is completed)

Just before the \(\text{Move}\) key is released, the window looks like this:
The selection is highlighted by a dotted outline to indicate that this is a **Move** selection (Copy selections have a dotted underline, pending-replace selections have a solid outline, and Delete selections are inverted). As soon as the change is made, the window is updated to show the resulting structure (SEdit determines what changes to the presentation result from the editing, and repaints as little of the presentation as possible).

An Overview of the Control Structure

The operations demonstrated above are actually performed by the cooperation of three separate pieces of code: the SEdit kernel, the SEdit user interface, and a set of methods defining the datatypes to be edited. By factoring the control this way, SEdit can be customized to edit new datatypes or provide different commands without having to modify or understand the complexities of the kernel (this is fortunate, since the kernel is quite complicated). The kernel invokes the datatype methods at appropriate times, manages the global sequencing of operations, and handles the optimization and caching necessary to update the screen efficiently. The datatype methods fall into three classes:

- methods for effecting and responding to changes in the structure being edited
- methods for positioning the point and selection appropriately
- methods for generating the visual presentation of the structure

The user interface translates mouse and keyboard events into appropriate calls on the SEdit kernel operations. It is not as modular as I would like; the keyboard event interpreter is table driven and readily extensible, but the mouse event interpreter is not extensible at present.

Each instance of SEdit has a *context*, which includes the structure being edited and the window in which the editing is being done. Editing operations are performed by calling kernel procedures and passing the context. The context is monitor locked, so operations may be invoked from several processes. Normally, each context has an associated keyboard process which reads keyboard commands and performs them. No editing state is maintained by the keyboard process; it can be deleted and recreated as convenient (but SEdit ensures that there is never more than one keyboard process per context).

SEdit is installed by calling the function `(EDITMODE 'SEDIT)`, whereupon it becomes the system display editor and will be used whenever the user asks to display edit a structure (through edit commands, Masterscope searches, inspectors, browsers, or whatever). The context remains active until the edit window is closed (although the keyboard process disappears while the window is shrunk).

An Overview of the Data Structures

The SEdit user is aware of two data structures: the structure being edited, and the window in which it is presented. Internally, SEdit maintains two additional data structures: the tree, which is a representation of the structure being edited, and the linear form, which is a representation of the visual presentation appearing in the window. The tree provides a common representation for the underlying structures. This allows SEdit to implement a small number of simple editing operations uniformly described as tree mutations, while the type-specific methods map these into the actual changes required. It also caches various bits of information computed by SEdit. The linear form is a
sequence of strings, atoms, and bitmaps to be displayed, intermixed with horizontal and vertical positioning information.

These four data structures are all representations of the same data. The constraints between them are maintained as follows:

As an example, consider editing the list structure `(if (NULL a) then (QUOTE Done))`. The underlying structure is composed of cons cells and atoms:

SEdit's tree will look like this:

Note that each node in the tree has a type, indicating the type of the structure, and a field containing the structure itself. Note also that the types need not correspond directly with Interlisp's type
structure: in this example, many cons cells are grouped together as one node in the tree, and may be marked as type list, CLisp (a class of special form), form, quote, binding, etc. depending on the components of the structure and its position in the surrounding structure. Thus, the list (QUOTE Done) is classified as type quote above (and has one subnode), but would have been type binding (with two subnodes) had it appeared in a list as the second element of a form identified as a LET or PROG.

The linear form will be something like:

```
"("), default font
  "if", keyword font
skip 7 points
  "("), default font
    "NULL", default font
skip 7 points
    "a", default font
  ")", default font
new line, indent 20 points
  "then", keyword font
skip 7 points
    """, default font
    "Done", default font
  ")", default font
```

Note that although the linear form is a sequence (hence its name), it reflects the structure of the tree from which it was generated. Finally, the window will show some or all of the presentation described by the linear form:

```
(if (NULL a)
  then 'Done)
```

SEdit has two other important data structures. The context was mentioned before; it includes the data structures mentioned above, information such as the current selection and current insertion point, and all the other little bits of state SEEdit needs to keep track of what is going on. The environment contains all of the customization information which controls SEEdit's behaviour: the tables which drive the generation of the tree from the original data structure, the table for interpreting keyboard events, parameters such as default spacing and fonts, etc. At present, there is just one environment defined — the one which configures SEEdit specifically for editing Interlisp code, but by creating new environments the user could have SEEdit contexts for editing Prolog, CommonLoops, etc., all coexisting.

(Actually, there is a second environment defined, which tricks SEEdit into pretty-printing Interlisp code into a TEDit document (to produce the listings later in this document), but it hardly qualifies as an edit environment.)
Documentation

The rest of the documentation for SEedit is in five sections:

- a more detailed account of how to use SEedit to edit Interlisp code
- a description of how SEedit is configured for editing a new type
- a detailed description of SEedit's internals
- an annotated listing of the code which implements the basic Interlisp types
- an annotated listing of SEedit's kernel

The first of these is independent of the others, but the second should be read before attempting to understand any of the following sections. If you are planning to extend SEedit to edit your own language (or change the way it currently edits one), you should also look at the third of these — a few good examples are sure to convey what the specifications missed.

Other Comments

The formatting and incremental reformatting algorithms, the incremental window update algorithms, and the various data structures were all developed by the author, so there are no references for them. Although there are several extensible prettyprinters for Lisp environments (notably Waters’ GPRINT), some do not allow a sufficiently general class of presentations, most only deal with formatting lines of fixed width characters, and none deal with the (crucial) problem of incremental reformatting.

At present, SEedit is usable but far from polished. There is still room for improvement in the screen updating, and many rather desirable commands are still missing (notably undo and redo). Extra formatting rules for CommonLoops are a high priority, as is completing the interface to other Interlisp tools (e.g. the file package). Finally, the author hates the name SEedit, and promises three free features of their choice to the first person who comes up with one he likes better.
How SEdit Formats LISP Forms

If you have a list format associated with the car of a lisp form, SEdit will use the information in that list format to prettyprint the form. The details of internal list format structure are documented elsewhere; this note describes an easy-to-use interface to these internal structures.

Getting and Setting Formats

Formats are associated with the cars of lists. To find out what format is associated with a particular function name, say FOO, you say (GET-FORMAT 'FOO). This returns three values: (1) The external form of the format spec for FOO (described in the next section), (2) the internal form of the format spec for FOO (described elsewhere), and (3) one of the symbols :EXTERNAL (meaning FOO had both an external and an internal format), :INTERNAL (meaning FOO had an internal format but no external one), or NIL (meaning FOO has no associated format). To associate a format with FOO, you say (SETF (GET-FORMAT 'FOO) FSPEC), where FSPEC is an external format spec (as described below). If you want to give FOO the same format as BAR, you can (of course) say (SETF (GET-FORMAT 'FOO) (GET-FORMAT 'BAR)), as in (SETF (GET-FORMAT 'DO*) (GET-FORMAT 'DO).

SEdit’s initial formatting information is broken into two parts: those formats which only exist in internal form and those which exist in both internal and external form. The internal-only formats are not of concern to us here (they really exist only for special interlisp constructs like CLISP). The external formats are all gotten by looking at entries on the *LISP-FORMAT-ALIST*, which we describe below. The function (RESET-FORMATS) resets SEdit’s formatting info to its initial state, and RESET-FORMATS is called as part of the initialization sequence. The function INSTALL-FORMAT-ALIST takes an alist with entries like those on the *LISP-FORMAT-ALIST* and installs the specified formatting information. INSTALL-FORMAT-ALIST also arranges that any calls to RESET-FORMATS will reinstall that formatting information in addition to the default information. It would be best, however, to get rid of format alists entirely and use defdefiners.

Documentation of Entries in the SEDIT:*LISP-FORMAT-ALIST*

Each entry in this list should be a symbol (or list of symbols) dotted with a format specification. The meaning of each entry (NAME . FSPEC) is: any list L whose car is NAME (or a member of NAME if it’s a list) should be formatted according to FSPEC.

Format Specifications

A format specification consists of an indentation specification (described below) followed by a bunch of options in PLIST format. The allowed options are:

:INLINE -- value can be T or NIL (default NIL). If T, the form will go all on one line if it fits. If NIL, the form will be broken across lines at arg boundaries even if it would all fit on one line. For example, OR has :INLINE T and LET has :INLINE NIL.

:MISER -- value can be :ALWAYS, :NEVER, or :TOFIT (default :TOFIT). Specifies when to use miser indentation. The default means use miser indentation if non-miser indentation would force the arguments into miser indentation.

:ARGS -- value should be a list of format specifications. These formats are assigned to the elements of the list L in order starting with the first element (which will be NAME). Note that these formats override any formats that would normally be assigned to the elements of L (based on their first elements). NIL is allowed in the :ARGS list, and means do not override the format of this element; that is, allow it to be
formatted normally. Also, a symbol S is allowed in the :ARGS list if S has earlier been assigned a format; this means to assign S’s format to this element. There are also two special keywords allowed as entries in the :ARGS list: :KEYWORD and :RECURSIVE. :KEYWORD means that if the element assigned this format is a symbol then treat it like a keyword, i.e., put it in bold face. (This list uses the convention that all symbols which allow declarations in their body [such as DO and LET] are formatted as keywords.) :RECURSIVE means to assign this element format FSPEC; that is, the entire top level format is assigned recursively to this element. This is very useful for formats like :DATA format. If L has more elements than there are entries in the :ARGS list, the last entry in the :ARGS list is repeated for all the extra elements of L. Hint: most :ARGS entries have NIL as their last element. If no :ARGS list is specified, the elements of L get their natural formatting.

-LAST -- value should be a format specification like those in the :ARGS list. This format specification will be applied to the last element of L but only if doing so would supercede the last entry in the :ARGS list. In other words, if the last element of L would receive the repeated format from the :ARGS list, it gets the :LAST format instead. This option is really only useful for pathologically formatted forms like Interlisp’s SELECTQ.

:SUBLISTS -- value should be a list of element positions (counting from 1) or T. T means all of the arguments should be parsed as lists even if they are NIL (so NIL will display as () rather than NIL). A list of element position means those element positions will be parsed as lists. For example LET has :SUBLISTS (2) meaning the second element of a form whose first element is LET is a list (i.e., the binding list). DO has :SUBLISTS (2 3), DEFUN has :SUBLISTS (3) and COND has :SUBLISTS T. Default is :SUBLISTS NIL meaning print all NIL args as NIL not ().

Indentation Specifications

An indentation specification is either a symbol (normally a keyword) or a list. If it’s a symbol, it’s looked up on the SEDIT::*INDENT-ALIST* (which see) and the SEdit-internal indent specification found there is used. If it’s a list, it consists of some optional keywords (described below) followed by argument group specifications. Each argument group specification is either a number or a list containing a single number. In both formats, the number indicates that that many arguments should be grouped together at a single indentation level. The simple number format means that each of those arguments should go on its own line (they will line up vertically with each other), while the number-in-a-list format means that the arguments in the group can go together on a single line if they fit. The indentation level for each argument group is determined by how many groups follow it in the indentation list. Each group is indented 1 level further in than the group which follows it; thus, the first argument group is indented most, the next one next most, and so on until the last one, which is always indented one step in from lambda-body level.

This is best explained with examples. A simple example is LET, whose indentation specification is (1). This means that LET will be followed by a single distinguished argument group consisting of one element (the binding list) which will be indented one step in from the let body. Another simple example is DO, whose indentation specification is (2). This means that DO will be followed by a single distinguished argument group consisting of two elements (the binding list and the termination clause) which will be indented one step in from the do body. It also means that the bindings and the termination will be required to go on separate lines. Contrast DO with DEFUN, whose indentation specification is ((2)). Like DO’s spec, DEFUN’s spec says there is one group with two members (the name and the lambda-list), but unlike DO’s spec, DEFUN’s spec says that the first two args can go on the same line if they fit there. Finally, consider a possible spec for MULTIPLE-VALUE-BIND of (1 1) which says that the first group consists of one arg (the variable list) and the second group consists of one arg (the form to eval). The form to eval will be indented one step in from the body, and the list of variables will be indented one step in from there.

Note that a group specification of 0 (zero) is allowed: this occupies an indentation step but does not put any arguments at that level. But we do not allow (0) as a group specification since this would not be any different than plain 0 and probably means that the specification is confused in some way.

The keywords allowed at the beginning of an indent specification are:
:BREAK or :NOBREAK or :FIT -- These specify placement of the first argument in the first group. Default is :FIT, which means put this arg on the same line as the CAR of the form if it fits there in preferred mode, otherwise put it on the next line. Note that if the first arg goes on the same line as the CAR, its placement specifies the indentation level for the entire first group. That way long CARs will move the first group over to the right. (This makes the binding and termination of both DO and DO* line up, for example.) Specifying :NOBREAK means the first arg is forced to go on the same line as the CAR. Specifying :BREAK means the first arg is forced to go on the next line (and thus at the indentation level derived from the number of groups). UNWIND-PROTECT is a good example of using :BREAK to force the first arg onto its own line. Note that you can only specify one of :NOBREAK, :BREAK, or :FIT.

:TAGBODY -- Normally all forms in the body (whether atomic or not) go at the same indent level. Specifying :TAGBODY indicates that atomic body elements (not atomic elements of the argument groups) should be exdented to line up with the CAR of the entire list (such as PROG or TAGBODY, which see for examples).

:STEP -- This can be specified as many times as desired and each time increases the indentation of the body (and thus all the argument groups) by one step. If you just want to move some of the groups in but not all of them (and not the body) then use 0 groups at the appropriate place instead of using :STEP at the beginning. :STEP is very useful with :TAGBODY.

By the way, the normal body indentation is taken from the INDENT-BASE field of the LISP edit environment, which is initialized to the width of a capital 'M' in the SEdit default font. The normal indentation step is taken from the INDENT-STEP field of the LISP edit environment, which is initialized to twice the width of a capital 'M' (that is, twice INDENT-BASE). These defaults are chosen so that, in a fixed-width font, the body of a form lines up two characters in from the '(' of the form, and each argument group line up two characters in from the next one (or the body). If you want non-standard values for either of these parameters, you can change the values in the LISP edit environment and then reinitialize your SEdit formats. Also, if you change font profiles, reinitializing SEdit will fix up the indents appropriately.
SEdit Internal Documentation

How Relinearization Works

The process by which SEdit optimizes formatting recomputation is strange and wonderful, so this is a long overdue attempt at explaining it.

We will start with a quick recap of SEdit’s formatting model and the responsibilities of three node type methods: assign-format, compute-format-values, and linearize. We then describe the assumptions SEdit makes about when these have to be redone, and then describe the algorithm it uses to achieve this. We’ll only go as far as getting the linear form fixed up; the step from there to updating the bits in the window is a whole ‘nother story...

The formatting model

Linearization is the generation of a sequence of format tokens (space, string, bitmap, line break) from the internal tree representation of the data structure being edited. Doing a reasonable job for complex hierarchical structures involves a large number of constraints; SEdit uses a three pass algorithm to get its results:

- **Formats**: first, the presentation of a data structure often depends on the context in which it appears. For instance, a list occurring as the second element of a list beginning with let gets special treatment. Another example is collapsing lists at a nesting level cut-off (actually, now that I think about it this would be much better done at parse time). SEdit currently does the first, but not the second (it ought to do both). To achieve this, each node can pass a ‘format’ to each of its subnodes. Exactly what constitutes a format is arbitrary; it’s up to the parent and child nodes to agree on what information will be passed (all current methods ignore format information they don’t understand). Present lists pass their sublists list-format structures describing the appropriate presentation, and sometimes pass the atom :keyword to atomic elements which are to be printed in boldface.

- **Width estimates**: second, the presentation of a composite data structure will often depend on the size of its components. Once the format information has been propagated to a node it will be asked to provide estimates of the size of its presentation, so that the nodes above it in the tree can plan their presentation intelligently. (Note: unfortunately, most of the code calls width estimates “format values”; hence the method responsible is called compute-format-values). Each node computes two numbers: inline-width and preferred-width. The inline width is the estimated width of this node’s presentation assuming that there is room to fit it all on one line, or nil if the node’s presentation will always span multiple lines. The preferred width is the width of the node’s presentation assuming that there is room to fit it all on one line, or nil if the node’s presentation will always span multiple lines. The preferred width is the width of the node’s presentation assuming that there is room to fit it all on one line, or nil if the node’s presentation will always span multiple lines. In computing these estimates a node needs access to the width estimates of its children; hence width estimates propagate from the bottom up.

- **Linear form**: finally, each node is asked to compute its linear form, by outputting a sequence of format tokens interspersed with the linear forms of its subnodes. The linearize method is told the horizontal position at which it is to begin, and the horizontal position of the right margin (which ought to try to stay within, but it’s free to ignore). To get the best formatting linearization procedures generally have two formats: a preferred, reasonably-indented format and a tighter “miser” format, and choose the miser format whenever the width estimates indicate that the preferred format won’t fit. Each node makes this choice independently. The linear form is computed top down.

Incremental changes

The three-pass computation described above places (relatively) simple requirements on the methods, and suffices for a one-shot presentation. However, this is insufficient for SEdit; the presentation changes after each character typed, and repeating the above computation each time over the whole tree would...
clearly be unacceptably expensive. Instead, SEdit tries to determine the regions of the tree whose presentation might have changed given the editing operations performed, and calls the presentation methods only when the results might be different.

**Formats:** in determining the format for its subnodes, a node is only allowed to base its decisions on its type, its own format, and the structure of it and its immediate subnodes. thus a list can change the format of its subnodes if it is edited, or one of its immediate subnodes is edited, but not if a nested subnode is edited. thus we only need to rerun a node’s assign-format method if

- it was edited, or
- one of its subnodes was edited, or
- the assign-format method of its supernode was run (for one of these three reasons) and it assigned a different format to this node than previously

**Width Estimates:** the width estimates of a node must be determined based on its structure, its format, and the width estimates of its subnodes. thus we only need to rerun a node’s compute-format-values method if

- it was edited, or
- its format changed, or
- the compute-format-values method of one of its subnodes was run (for one of these three reasons) and it changed that node’s width estimates

**Linear Form:** the linear form of a node also depends on its structure, its format, and the width estimates of its subnodes. in addition, it can depend on the space between its starting horizontal position and the right margin. thus we only need to rerun a node’s linearize method if

- it was edited, or
- its format changed, or
- the width estimates of any of its subnodes changed, or
- changes to one of its supernodes has caused its presentation to begin at a different horizontal position relative to the right margin

**Relinearization**

to implement the optimizations suggested above, SEdit must first know what parts of the tree have changed since it was last presented. therefore all procedures which change the tree structure are responsible for calling note-change on any node they change. also, all nodes added to the tree are marked as needing re-presentation. note-change inserts the changed node into a queue (the changed-nodes field in the edit-context) which is kept sorted by increasing depth. relinearize-where-necessary then implements the following algorithm:

1. for each node on the queue (from top to bottom), assign-format to its super node and add it to the queue (unless it’s already in the queue) and then assign-format to it.
2. for each node now in the queue (from bottom to top) recompute its width estimates, and if they’ve changed push its super on the queue (where it will be picked up later in this step); if they don’t change this is a point to start relinearizing from so push it onto another queue.
3. finally, reverse the new queue created in step 2 (so that it’s now ordered from bottom to top) and for each node on it check to see that none of its super nodes are awaiting relinearization — if one is found, mark all the nodes between them changed so that the super’s relinearization (yet to come) will include this node — otherwise just relinearize it.

relinearizing a node is guaranteed to call its linearize method. in addition, it will call the linearize method of any subnode which (a) has changed, or (b) has been moved (relative to the right margin) so
that it’s linear form is no longer likely to be appropriate (the test for this is at the beginning of generate-linear-form) (and so on recursively into its subnodes). (and as i mentioned before, there’s a whole extra story about how changes to the linear form are used to determine changes to the screen; this is yet to be documented at all). when relinearization of the original node is complete, an additional test is made: if the last line of the new linear form is a different length than the last line of the old linear form, this relinearization continues with the linear form of the super node, starting after the node just linearized (since the super may have made linearization decisions based on where that node ended). this process terminates when (a) a node’s new linear form ends at the same horizontal position as before, or (b) the top of the tree is reached.

MAINTAIN potentially sensitive (bvm)

=========

The following are the messages which lead to the creation of the above list:

Date: 11 Jun 84 15:42 PDT
From: Sannella.pa
Subject: Restricted Sources Files?
To: LispCore^pa
cc: Sannella.pa
Reply-To: Sannella.pa

Beau has asked me to collect a list of the source files that we want to give to customers. Please send me (Sannella) the names of any source files you are responsible for which contain sensitive or proprietary information that should not be let out to the public at large. For each file, I would also like a few words of description of what it contains --- a sentence would be fine. I will compile the results, and send out another message. Thanks.
NSFILING is definitely proprietary (implementation of Filing protocol).

I would also consider CLEARINGHOUSE sensitive for now. Even though Clearinghouse protocol is now public, I think there may still be some things in that file that aren’t.

All the LAFITE* files, as well as GRAPEVINE, MAILCLIENT, MTP and MAINTAIN are potentially sensitive. Of course, no customers are even getting the dcom’s of those, so there would be no reason to give them sources.

Stack and Function Header Format

Stack structure

The stack segment in the Interlisp-D virtual memory consists of a series of stack blocks, which represent frames for active invocations of Lisp functions and free space left over. There are actually four specific kinds of blocks that can appear in the stack space: basic frames (abbreviated BF), frame extensions (abbreviated FX), free blocks (FSB), and guard blocks (GUARD). Each BF holds the arguments of a particular function call, while the FX holds other locally-bound variables and temporary storage for the function. A BF and FX are created at each call or entry, and released upon return or exit. A FX and its associated BF will simply be referred to as a frame.

Basic frame

A Basic Frame consists of the n arguments to the function being called, possibly followed by a cell of padding, followed by the BF word containing flags and a pointer to the first argument. The BF word is quadword-aligned. Every frame extension is immediately preceded by a BF, either the actual BF, or by a "dummy" BF pointer in which the R bit is on and the IVAR pointer is valid. Only "slow" FX's can be preceded by a dummyBF.

IVAR: *-+-+-+-+-+-+-+-*-+-+-+-+-+-+-+-*-+-+-+-+-+-+-+-*-+-+-+-+-+-+-+-*
|       0       |                  V a l u e 1                  |
|      ...      |                      ...                      |
|       0       |                  V a l u e n                  |
*-+-+-+-+-+-+-+-*-+-+-+-+-+-+-+-*-+-+-+-+-+-+-+-*-+-+-+-+-+-+-+-*

BF: |1 0 0 0 0 0|R|P|   Ext. cnt.   |           IVAR                |
*-+-+-+-+-+-+-+-*-+-+-+-+-+-+-+-*-+-+-+-+-+-+-+-*-+-+-+-+-+-+-+-*

The fields are interpreted as follows:

IVAR     The 2nd word of the BF cell points back at the IVAR.
R         "Residual". This bit is on in "dummy" basic frames which are actually only 2-word quantities. Normal function call leaves the bit off. Dummy BF's are created when an FX has to move or be copied (on stack overflow or returning to a frame with non-zero use count). It's not clear these are really necessary—one could move/copy the entire frame (BF+FX).

P         "Padded". If 1, the actual number of arguments in the frame is 1 less than the size would indicate.

USECNT    Number of frame extensions (less 1) pointing at this BF. Initially 0.

Frame extension

A Frame extension consists of 10 words of control information, followed by storage for locally bound variables (FVARs), then binding slots for any variable referenced freely by the function, followed by dynamic storage ("the stack").
The fields are interpreted as follows:

**F**  
"Fast". This frame binds no variables. This bit is (optionally) copied from the definition cell (see below).

**C**  
"InCall". Used by microcode to denote a frame interrupted in the middle of function call. Returning to a function with C on should invoke APPLYFN immediately instead of doing the return (the N bit is still valid).

**V**  
"NameTableValid". The "name table pointer" field is valid (see below).

**N**  
"NoPush". When returning to this frame, throw out the return value (used by punts, interrupts.)

The bits C and N need only be checked in a frame when performing a "slow return" to it. It is guaranteed that they will not be on in a frame which can be fast-returned to. The V bit is tested by free variable lookup.

**ALink**  
This field (with the low bit denoting "slow return") contains the ALink field of this frame, i.e., the pointer followed when chasing free variable references. The ALink points to the PVAR of the relevant frame, i.e., FX+10. The ALink field is also the CLink when the X (slow) bit is off. The CLink indicates the control chain, i.e., the frame to be returned to by this one.

**X**  
"SlowReturn". Must be set if the returnee is not contiguous with this this frame’s BF, this frame’s BF is not contiguous with its FX, or if there is a need to set the CLink independently of the ALink. Thus, if set, (a) the BLink and CLink fields of this FX are valid, and (b) when returning from this frame, the microcode for RETURN must do the "slow" case (usually punting, unless it’s really a fast case after all).

**Fn Header**  
This is the pointer to the code base of this function (see Function Header format). Note that the high and low words of the function header are swapped.

**next**  
Points at the next stack word following this FX. Not valid while control is in this frame, of course—it is set when the frame is "closed out" by a function call or context switch of some sort.

**PC**  
Byte offset from FnHeader of next executable byte of this FX.

**NameTable**  
Where to find the table of names of arguments, prog variables, and free variable names. If the V bit in the flag word is off (normal case), this field is undefined, and the FnHeader field is used (the
table of names is inside the function header); otherwise this field points at something that has the same format as a function header (see below).

**BLink**
When X is set, points at the BF for this frame. When X is not set, BF=FX-2.

**CLink**
When X is set, points at the returnee for this frame. When X is not set, CLink=ALink. CLink, like ALink, points at the PVAR area of the FX rather than at the beginning of the FX.

**PVAR**
This area contains PROG/local variable values and free variable binding pointers. Initialized with all ones in the left half, which denotes {variable not bound} for PROG variables, and {variable not looked up} for free variables (see below). PVAR is quad-aligned (hence so are FX+1 and BF), and contains an even number of cells (so that TEMP is also quad-aligned).

**TEMP**
contains the temporaries (dynamic stack space) of the function. The first two cells of this region are garbage, for the benefit of the Dolphin hardware stack reloading. TEMP is quad-word aligned, if necessary by padding out the PVAR area.

When a function is called, its arguments appear at the end of the caller’s FX. The implementation is designed so that the bookkeeping for a BF appears at its high end, and for a FX at its low end, so that the arguments can be made into a new BF without having to copy them. After thus fabricating a new BF and shortening the old FX, the new FX is created. Upon return, the function value ("top of stack", which appears at the end of the returner’s FX) is preserved while the returner’s frame is deleted; then the value is pushed onto the caller’s FX and execution resumes in the caller.

**PVAR Slots and FVAR (Binding) Slots**

When a variable is bound, via the BIND opcode, the corresponding slot in the PVAR area is filled in with the value:

```
+----------------------------------+
| 0 |                              |
+----------------------------------+
```

When a free variable is found during free variable lookup, the variable’s binding slot is filled in with:

```
+----------------------------------+
| binding pointer (even) | 0 | bind-addr-hi | bind-addr-hi |
+----------------------------------+
```

This two word quantity is the (swapped) address of the location where the binding of the variable actually occurs. If the variable is not bound on the stack, this is the location of the variable’s top level value, or possibly some other piece of storage. Note that all legitimate pointers are double-word aligned, and so have the low order bit turned off.

Note: on Maiko, the bind-addr-hi is *not* duplicated, i.e.:

```
+----------------------------------+
| binding pointer (even) | 0 | bind-addr-hi |
+----------------------------------+
```

The only way to tell between the PVAR and the FVAR region is to look in the name table (or function header if V is off): (PV+1)*2 is the number of cells (doublewords) in the PVAR region; NLOCALS is the number of those which are PVAR slots; the rest are FVAR slots or padding.
FVAR_ (the free variable assignment opcode), tests whether the binding address of the variable is in stack space. If so, it can do the assignment directly. If not, it must do the assignment using RPLPTR, i.e., decrement the reference count of the old value and increment the reference count of the new. This can be done by punting to the ufn if desired: the arguments to the ufn are the new value and the address (in normal order) of the binding location.

Note that this architecture does not specify anything about where non-stack bindings can be. Ordinarily, if the binding pointer is not in stack space, it is the top-level value cell of the variable, but it can also be used for closures, etc. to allow data structure manipulation to look like variable reference. The only current instance of this use is that the binding of RESETVARS at the top level of each process is actually a pointer into the process handle, for the benefit of cleaning up after a HARDRESET.

Free blocks

The other two stack block types are used to manage free space on the stack and as markers for book-keeping purposes. They are:

Ordinary Free block

```
+-----------------+-----------------+-----------------+-----------------+
| 1 0 1 0 0 0 0 0|       0       |             Size              |
+-----------------+-----------------+-----------------+
```

Guard block

```
+-----------------+-----------------+-----------------+-----------------+
| 1 1 1 0 0 0 0 0|       0       |             Size              |
+-----------------+-----------------+-----------------+
```

The only difference between Free blocks and Guard blocks is that microcode is guaranteed not to "use" Guard blocks. They are used at the end of stack regions. Size is in words.

Stack blocks may be discriminated by selecting the leftmost three bits of the flags into:

- 000b Ordinary pointer (not a flag word)
- 100b Basic frame
- 101b Free block
- 110b Frame extension
- 111b Guard block
1. Function definition cells

Function definition cells are either:

Interpreted:

```
*+-------------------*+-------------------*+-------------------*+-------------------*
|                  |     0         |           ptr to definition (list/NIL)    |
*+-------------------*+-------------------*+-------------------*+-------------------*
```

Compiled:

```
*+-------------------*+-------------------*+-------------------*+-------------------*
|1|F|Aty|   0   |           ptr to definition (array block)     |
*+-------------------*+-------------------*+-------------------*+-------------------*
```

Compiled definitions have 1 in the high order bit. The \texttt{Aty} field contains the ‘argtype’ of the function, and is used only by the \texttt{CHECKAPPLY*} opcode. The \texttt{F} bit is set if the corresponding \texttt{NTSIZE} of the definition is zero, i.e., the function has an empty name table. Undefined functions appear as an 'Interpreted' function with definition = NIL.

2. Function header

A compiled function begins with a function header and a name table, which contains variable names; function names and other constants are stored in-line in the code. The first 8 words of the function are called the function header. The function header is quadword aligned. Format:

```
*+-------------------*+-------------------*+-------------------*+-------------------*
|               STK             |              NA               |
*+-------------------*+-------------------*+-------------------*+-------------------*
|               PV              |             START             |
*+-------------------*+-------------------*+-------------------*+-------------------*
|   |Aty|   0   |           function name                       |
*+-------------------*+-------------------*+-------------------*+-------------------*
|               NTSIZE          |    NLOCALS    |  FVAROFFSET   |
*+-------------------*+-------------------*+-------------------*+-------------------*
```

\texttt{NA} \quad The number of arguments this function expects. For \texttt{LAMBDA*} functions (arbitrary number of args, no adjustment) this field is \(\gamma 1\).

\texttt{PV} \quad Number of quadwords required for the \texttt{PVAR} region, less 1, i.e., \((#PVars + #Fvars + 1)/2 - 1\).

\texttt{STK} \quad Amount of stack space required to call this function:

\[2^\times (\text{max}(\text{NA}, 0) + (\text{PV}+1) \times 2) + \text{FrameOverhead} + \text{MinExtraStackWords}.\]

\text{max}(\text{NA}, 0) \) is maximum number of extra (doubleword) pushes to fill in unsupplied arguments; FrameOverhead=12 (includes BF overhead); MinExtraStackWords is the number of words microcode requires before punting, currently 32 (for D0 HStack microcode).

\texttt{START} \quad Initial PC of the function.

\texttt{Aty} \quad Argtype of the function: 0 = \texttt{LAMBDA}, 2 = \texttt{LAMBDA*}, 1 = \texttt{NLAMBDA}, 3 = \texttt{NLAMBDA*}). ignored by microcode, but transcribed to the definition cell, where \texttt{CHECKAPPLY*} tests it.

\texttt{NTSIZE} \quad Name table size (in words). This is a multiple of 4.
NLOCALS   Number of PROG variables.

FVAROFFSET   Offset (from start of header) of first FVAR in name table.

This is then followed by the specvar Name Table (not to be confused with the NAMETABLE field of the FX, which always points at something looking like a function header), which is actually two parallel tables.

The first table contains atom numbers ("value index"), terminated with enough zeros to fill out a quadword, but always at least one word of zero. Thus the size of the table in words is NTSIZE+1 rounded up to a multiple of 4. Note that in the special case where NTSIZE is 0, there is still a quad-word of zeros. The name table is arranged with PVAR names in reverse order of binding, IVAR names, and then FVAR names. Thus, when free variable lookup scans the name table in order, it will find the most recent bindings first.

The second table (which starts NTSIZE words beyond) contains entries of the form:

```
|vty|     0     |     offset    |
```

vty codes are as follows:

00   This name corresponds to an IVAR.
10   This name corresponds to a PVAR.
11   This name corresponds to a FVAR.

Offset is a zero-based doubleword offset from the start of the corresponding section of the BF or FX. Both PVAR and FVAR offsets are relative to PVAR, i.e., PVAR n is followed by FVAR n+1.

Free variable lookup scans the first table for a match of the "looked up variable". If a match is found, the word at the same offset in the second table is fetched to determine whether the value is in the IVAR section (vty=0), in the PVAR section (vty=2) or pointed to by the FVAR section (vty=3).

The regular name table is followed by the "localvar argument" name table, which is not visible to the microcode. It is in the same format as the regular name table, but lists names of arguments to the function that are declared LOCALVARS and hence would otherwise be invisible. This table is for the benefit of ARGLIST and the debugger.
An Interlisp Stream is an object of datatype STREAM that is capable of performing, at the least, sequential input and/or output of bytes. Some streams can do much more. Streams are used for access to open files, for writing to the display, for chatting to remote hosts, and whatever other uses people come up with. This document describes how one goes about defining a new device, the meanings of the record fields of the STREAM and FDEV datatypes, and anything else that seemed relevant at the time.

The implementation of Streams is strongly object-oriented. Every STREAM has a pointer to a device (the datatype FDEV), which contains a vector of functions to be called when certain operations are required of the stream. There can be many streams with the same device. In the object-oriented terms of LOOPS, one can think of the device as a class, which provides a set of methods that implement class operations, and the streams as instances. Devices and streams also have local state, which might be thought of as class and instance variables. Declarations for STREAM and FDEV can be obtained by loading EXPORTS.ALL.

OPENSTREAM, CLOSEP, FORCEOUTPUT, READP, EOFP, GETEOFPTR, GETFILEINFO, SETFILEINFO, DIRECTORY, COPYBYTES, DELFILE, RENAMEFILE, FULLNAME are some of the Lisp functions called by the programmer that ultimately turn into operations at the device level. The descriptions that follow sometimes allude to these functions, and knowledge of how they operate may occasionally give the reader additional clues as to how the device operations work.

Typically, some part of the operation is handled by the “generic” file system code, which then calls on the device to handle that part of the operation that is device-specific. For example, the function OPENSTREAM takes the name of the file it is to open and fills in host and directory defaults, and decides which device handles such a file. It then calls on the particular device to actually open the file. After the file is opened, the generic file system code registers the file on (OPENP). As another example, operations involving open streams first coerce non-streams (e.g. filenames) to open streams before calling the device-specific operation. With the advent of multiple streams per file, the last two examples will soon no longer obtain.

Devices

A device is an object of type FDEV (so named for historical reasons: “File Device”). The standard way to define a new device to create such an object, by performing (create FDEV --), and then pass the newly created FDEV to the function \DEFINEDEVICE. \DEFINEDEVICE is the way a device “announces” itself to the generic file system.

(\DEFINEDEVICE NAME DEV) [Function]

Installs device DEV, giving it the name NAME. NAME must be an uppercase litatom. The generic file system code makes use of the name to locate the device that is willing to deal with files whose full name begins [NAME]. It is permissible to have more than one name map to the same device; this effectively provides device synonyms. Devices are encouraged, however, to always create file names using the canonical device name, independent of what name was passed in.
NAME can be NIL, in which case the generic file system code never consults the device directly. However, its EVENTFN is still run around Lisp exits, and it can be used as the device for a stream created by nonstandard methods.

If a device never wants to be invoked by name, and has no interesting EVENTFN or HOSTNAMEP methods, then there is no need to ever register it with \DEFINEDEVICE.

\(\text{\texttt{\textbackslash REMOVEDEVICE \textit{DEV}}}\) [Function]

Removes device \textit{DEV} from the list of known devices, as well as any name that maps to that device.

\(\text{\texttt{\textbackslash GETDEVICEFROMNAME \textit{NAME NOERROR DONTCREATE}}}\) [Function]

Returns the device associated with \textit{NAME}. \textit{NAME} can be a litatom or string; it is coerced to uppercase, and if it begins with an open brace, is assumed to be a file name, from which the host name is extracted. If no such device is known, attempts to find one by polling the HOSTNAMEP methods of all known devices (see below); if a device is still not found, causes a FILE NOT FOUND error unless NOERROR is true. If DONTCREATE is true, it never attempts to create a device, just returns an existing device if there is one, NIL otherwise.

The fields of an FDEV are divided up into informational fields and ‘‘methods’’.

<table>
<thead>
<tr>
<th>Field</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>DEVICENAME</td>
<td>A pointer field, the name of the device, standardly a litatom. Use of this field is largely up to the device, but it is usually selected to be the name that appears inside braces in filenames opened on this device. For devices that do not support the notion of named files, DEVICENAME can be anything that the implementor cares to use for debugging assistance.</td>
</tr>
<tr>
<td>RESETABLE</td>
<td>A flag, true if (SETFILEPTR stream 0) can be performed. Currently unused.</td>
</tr>
<tr>
<td>RANDOMACCESSP</td>
<td>True if the stream is randomly accessible, i.e., if SETFILEPTR works on this kind of stream.</td>
</tr>
<tr>
<td>NODIRECTORIES</td>
<td>True if files opened on this device do not (usually) have a directory as part of their name. The principal use for this is by the CONN command, which will not try to connect to the user’s home directory if given a host only, e.g., CONN {DSK}.</td>
</tr>
<tr>
<td>BUFFERED</td>
<td>True if streams of this sort are buffered in a manner compatible with the microcoded versions of BIN and BOUT. More specifically, BUFFERED implies that the device implements the GETNEXTBUFFER method. See description of buffered streams.</td>
</tr>
<tr>
<td>PAGEMAPPED</td>
<td>True if this stream is implemented by the pagemapped functions. All pagemapped streams are also buffered, so if this flag is true, so should be BUFFERED. See description of pagemapped streams.</td>
</tr>
<tr>
<td>FDBINABLE</td>
<td>True if streams on this device obey the rules for microcoded BIN whenever such stream is open for input access.</td>
</tr>
<tr>
<td>FDBOUTABLE</td>
<td>True if streams on this device obey the rules for microcoded BOUT whenever such stream is open for output access. Currently unused, as the spec needs revision.</td>
</tr>
<tr>
<td>FDEXTENDABLE</td>
<td>Special kind of FDBOUTABLE. Currently unused, as the spec needs revision.</td>
</tr>
</tbody>
</table>
DEVICEINFO A pointer to arbitrary device-specific information. The standard use for this is to hold local state specific to one of several similar devices that share methods. For example, the Dolphin disk provides a separate FDEV for each partition of the machine; the DEVICEINFO field of each has pointers to the partition’s directory and other information specific to files on that partition only.

OPENFILELST A list of all streams open on this device. Not required; it’s provided for convenience only.

The following fields are all pointer fields, and contain functions for implementing various device operations. Not all devices need have all fields filled in; the required ones are listed first and so indicated. Some ‘‘required’’ fields have defaults specified in the FDEV (or STREAM) record declaration, so the implementor need not explicitly fill those fields if the default is reasonable. Each field is presented with its arguments, in the style of a function definition; of course, it is the contents of the field, not the field name, that is the function. Using object-oriented terminology, the occupants of these fields are referred to as ‘‘methods’’. For example, ‘‘the BIN method’’ means ‘‘the function that occupies the BIN field’’.

One of the arguments to each method is usually either the device itself, or a stream open on the device, so that the device (and hence its DEVICEINFO) is usually accessible to all these functions. Arguments that are file names or patterns or pieces of file names can be either litatoms or strings, and already have their host and/or directory parts appropriately filled in from the connected directory defaults. The device may assume that the host field of the file name is indeed a name that the device has said it implements (see HOSTNAMEP). ‘‘Full’’ file names returned by these functions (or stored in the FULLFILENAME field of a stream) should be litatoms, and at least in the current implementation should be all uppercase.

Fields required of every device:

(HOSTNAMEP HOSTNAME DEVICE)

Called by the generic file system code when presented with a host name for which there is as yet no device defined. The function should return non-NIL if it ‘‘recognizes’’ HOSTNAME. There are two ways in which this method is invoked:

(1) To obtain a device for HOSTNAME, for example, so that a file can be opened on it. In this case, DEVICE is an already defined device (the one whose HOSTNAMEP method is being called), and the function should return either a new device, or T, meaning it is willing to take responsibility for this host name as well as any previous name under which the device was registered. In either case, the caller will install the returned device, or DEVICE if value was T, as the device to which HOSTNAME maps.

(2) As a pure predicate. In this case, DEVICE is NIL, and the function need only return T or NIL, indicating whether it believes that HOSTNAME is the name of a host.

In practice, the HOSTNAMEP method need only take care of the first case, since that also takes care of the second case. The second case is provided so that the device need not be created until there is an actual use for it, should the device wish to avoid unnecessary work. In practice it is rare that anyone tests a host name without subsequently needing to have the device created in full.

There are basically three kinds of devices in the system as distinguished by their HOSTNAMEP methods.

(1) Predefined devices with exactly one name, or strictly internal devices with no notion of name. For example, the CORE device always exists, and has exactly one name; the SPP device (a network byte stream) has no name (it supports no files directly). Such devices have a HOSTNAMEP method of NIL—the only name they ever go by is the one they gave to \DEFINEDEVICE, if any. This is the default.
(2) Devices that don’t know ahead of time what their name will be, but for which there might be many incarnations. This is the model for remote file servers. The standard way of handling this case is to define a dummy device that has only a HOSTNAMEP method, and no name. When the HOSTNAMEP method gets called with a name that the device knows it can service, it creates a device by that name. If given a name that is a synonym of another name, it might just return the existing device of the canonical name (using \GETDEVICEFROMNAME to find the right device). In either case, the HOSTNAMEP method of the new device is usually NILL—the original device is the only one that worries about creating new instances of this class of device.

(3) Like (2), but all the different names are handled by a single device, which takes care internally of the multiplexing among, say, different remote hosts. HOSTNAMEP returns T in this case. This is usually clumsier than (3), so discouraged.

(EVENTFN DEVICE EVENT)

Called around Lisp exits, to allow the device to do any necessary cleaning up, clearing of caches, disconnects with remote hosts, revalidation of files, etc. EVENT is one of the following litatoms: BEFORELOGOUT, BEFORESYSOUT, BEFOREMAKESYS, BEFORESAVEVM, AFTERLOGOUT, AFTERSYSOUT, AFTERMAKESYS, AFTERSAVEVM, AFTERDOYSOUT, AFTERDOMAKEYSYS, AFTERDOSAVEVM. The AFTERxxx events are all run when Lisp is booted from a memory image that resulted from a LOGOUT, SYSOUT, etc. The AFTEROxxx events run when continuing Lisp in the same incarnation following the SYSOUT, etc. (there is no such event for LOGOUT, of course). The ‘‘after’’ events are called in the same order in which the devices were defined; the ‘‘before’’ events in the reverse order.

For example, the BEFORELOGOUT event for the Leaf remote file server devices performs a FORCEOUTPUT on all its open files and then breaks the connection with the file server. The AFTERDOxxx events for the Leaf devices calls \REMOVEDEVICE on itself to flush any connection between the name and the server (since names and addresses can change over exit), and then revalidates all of the device’s open files. The AFTERDOxxx events for the Dorado disk device rebuilds its cache of the disk’s directory.

There are a few devices in the system that exist only for their EVENTFN. In most cases, a simpler way to tell the system you want something performed around exit is to add your event function to the list AROUNDEXITFNS instead of going to the expense of defining a device for it. There is yet another list, \SYSTEMCACHEVARS, for handling a more specialized ‘‘around exit’’ operation: every time Lisp is booted, each of the variables in the list \SYSTEMCACHEVARS is set to NIL.

The following are required of all named devices, that is, devices that map from some hostname to the device, upon which files might be opened or otherwise manipulated:

(DIRECTORYNAMEP HOST/DIR DEVICE)

True if HOST/DIR is a valid directory name on DEVICE. Function should ideally perform recognition as well, and return the ‘‘true’’ name. For example, given ‘‘{PHYLEX:}<LISP>’’ as argument, it might return {Phylex:PARC:Xerox}<Lisp>. HOST/DIR might include a subdirectory name. The device should attempt to tell the truth about whether the subdirectory exists or not, though this may not be possible for devices with fake subdirectories. Defaults to NILL, i.e., device supports no directories. Used by the command CONN and the function DIRECTORYNAMEP.

(OPENFILE NAME ACCESS RECOG PARAMETERS DEVICE)

Used to implement the OPENFILE and OPENSTREAM functions. Opens the file named NAME on this device for access ACCESS, returning a STREAM. The stream is usually on DEVICE (its DEVICE field is DEVICE), but is not required to be. The arguments ACCESS, RECOG, PARAMETERS are as with the
OPENFILE function in the manual. Thus, if \textit{name} does not include a version number, recognition is according to \textit{recog}, which should be appropriately defaulted per \textit{access} (\texttt{input} implies \texttt{old}, \texttt{output} implies \texttt{new}, \texttt{both} implies \texttt{old/new}).

The argument \textit{name} can also be a \texttt{stream}, which must be a closed stream. OPENFILE should ‘reopen’ the stream. The value returned in this case may be a new stream (with the same name as the old), or the old stream (\textit{name}) itself. It is likely that the specification will be changed at some point to require that the old stream itself be returned, suitably reopened.

The argument \textit{parameters} is a list of pairs (\textit{option value}). The most interesting \textit{options} are as follows:

\begin{itemize}
  \item \textbf{type} For new files, the type of the file (\texttt{text} or \texttt{binary}). If this parameter is not specified, the value of the global variable \texttt{defaultfiletype} (initially \texttt{text}) should be used.
  \item \textbf{creationdate} For new files, the date of its creation. The device should use this if at all possible instead of letting the creation date default to the current date and time.
  \item \textbf{length} The intended length of the file, in bytes. This need not be accurate—it is only a hint that may allow smarter allocation. For example, if the device knows that it does not have room for a file of the specified length, it should immediately cause a \texttt{file system resources exceeded} error for the intended file.
  \item \textbf{don't change date} For old files being opened for access \texttt{both}, don’t change the creation date of the file. \texttt{access = both} would normally imply that the content of the file is to change, and thus its creation date should be updated. Use of this parameter is a form of ‘‘cheating’’ to make it look as though the file had not changed. For example, the code that rewrites filemaps uses this parameter, since rewriting the filemap does not logically change the file’s content.
  \item \textbf{sequential} If \texttt{T}, is a hint that the file will, or need, only be accessed sequentially, which may allow the device to open the file in a more efficient mode.
\end{itemize}

Any parameters that the device does not understand should be ignored, rather than be cause for an error. All devices are encouraged to support at least \textit{type} and \textit{creationdate}.

The additional options \texttt{endofstreamop} and \texttt{buffers} are handled by the generic file system code; specifying them is equivalent to calling \texttt{setfileinfo} (q.v.) immediately after the open.

Fine point about \textit{access = output}: this operation always produces a new, empty file, independent of whether its name is exactly the name of an existing file. That is, it replaces any old file by the same name. On opening, such a file has an end of file of zero. Of course, since \textit{recog} defaults to \texttt{new} in this case, the name can only clash with an old file name if a version was explicitly specified, or \textit{recog} is \texttt{old} or \texttt{old/new}. To open an old file for output but preserve its contents, i.e., only write over part of the file, one should open for \textit{access = both} (since to preserve the old contents one implicitly reads them).

Exception handling: If the desired file is not found, the \texttt{openfile} method should return \texttt{nil} rather than cause a \texttt{file not found} error. This is so that the generic file system code can cause the error using the original file name, not the one packed with host and directory passed in to the \texttt{openfile} method. The device should feel free to signal any other errors itself on failing to open the file, e.g., \texttt{file won’t open} for a busy file, \texttt{protection error}, or \texttt{file system resources exceeded}. Ideally, this error should be signaled in a way that is resumable, i.e., so that a user could,
in the break, take some action to remedy the condition and then type OK to continue. In most cases it suffices that all the internal functions below the OPENFILE be named with backslashes, so that the error code will choose to resume by reverting to the OPENFILE and trying again.

The device must keep track of the set of files open on it, for use in access-conflict detection, and as an assist to the user in closing "dropped" streams. This is done by the generic file system, employing the REGISTERFILE method, below.

(CLOSEFILE STREAM)

Closes STREAM. Performs all necessary “finalization” on STREAM, including doing a FORCEOUTPUT or equivalent if STREAM was open for output. De-registers STREAM from its device’s list of open streams.

(REOPENFILE NAME ACCESS RECOG PARAMETERS DEVICE OLDSTREAM)

This is exactly like OPENFILE, except that it is called after LOGOUT (or other “after” events) by the device’s EVENTFN on the name of any stream that was left open over exit. The idea is to maintain the illusion that the file really was open over LOGOUT, but check and make sure nothing changed. The generic file system code uses the VALIDATION field to test whether the file changed behind your back.

OLDSTREAM is the stream that was open before exit, and is supplied for the benefit of devices where there is no possibility that the file changed (e.g., \{CORE\}), so that they can just return OLDSTREAM directly. OLDSTREAM is also of use for those devices that have to cheat in order to maintain the illusion.

(GETFILENAME NAME RECOG DEVICE)

Performs “recognition” on NAME. That is, it returns the full name of the file that would be opened by OPENFILE in the indicated recognition mode, or NIL if the file is not found. It is not necessary that OPENFILE actually be capable of opening the file (there is no need to check protection, for example). Used by INFILEP, OUTFILEP, FULLNAME.

(DELETEFILE NAME DEVICE)

Deletes the file named NAME, returning its full name on success, NIL on failure. Recognition mode is implicitly OLDEST. Local devices, after recognizing the file, should make sure that it is not among the device’s open files (open files cannot be deleted). This, OPENFILE, and RENAMEFILE are usually the only device methods that need to know anything about what files are open.

(GENERATEFILES DEVICE PATTERN DESIREDPROPS OPTIONS)

Enumerates files matching PATTERN. Returns a “file generator object” of the form (NEXTFILEFN INFOFN : ArbitraryState). This is described in more gory detail under Directory Enumeration.

(RENAMEFILE OLD-DEVICE OLD-NAME NEW-DEVICE NEW-NAME)

(A method of OLD-DEVICE.) Renames the file named OLDNAME on device OLD-DEVICE to have name NEWNAME on NEW-DEVICE. Returns the full name of the new file if successful, NIL if not. Recognition mode is implicitly OLD for OLDNAME, NEW for NEWNAME. The generic file system code always invokes this method to implement the function RENAMEFILE. If OLD-DEVICE and NEW-DEVICE are not EQ, the RENAMEFILE method can call \\GENERIC.RENAMEFILE to do the job; \\GENERIC.RENAMEFILE is defined to copy OLDNAME to NEWNAME and then delete OLDNAME. Defaults to \\GENERIC.RENAMEFILE. RENAMEFILE needs to check if OLD-NAME is open; only closed files can be renamed.

(OPENP FILENAME ACCESS DEVICE)
Returns all of \textit{DEVICE}'s open streams with name \textit{FILENAME} that are open in mode \textit{ACCESS}. \textit{FILENAME} and/or \textit{ACCESS} may be \texttt{NIL}, which matches all names and access modes. If supplied, \textit{FILENAME} should be a complete and exact filename, including a version number. The device field \texttt{OPENFILELST} provides a convenient place to store the open streams. \texttt{\textasciitilde\texttt{GENERIC\texttt{.OPENP}}} is a sample OPENP method that can be used in conjunction with \texttt{\textasciitilde\texttt{ADD-OPEN-STREAM}} and \texttt{\textasciitilde\texttt{DELETE-OPEN-STREAM}}; it consults the device's \texttt{OPENFILELST}.

\textbf{(REGISTERFILE \texttt{DEVICE STREAM})}

Invoked by \texttt{\textasciitilde\texttt{OPENFILE}}, the \texttt{REGISTERFILE} method places the newly-opened stream on \texttt{DEVICE}'s list of open streams. Note that this need not be an actual list, but might be contained in the device's directory data structure or other convenient place. The function \texttt{\textasciitilde\texttt{ADD-OPEN-STREAM}}, though not the default, is a simple function that adds \texttt{STREAM} to \texttt{DEVICE}'s \texttt{OPENFILELST}.

\textbf{(UNREGISTERFILE \texttt{DEVICE STREAM})}

Invoked by \texttt{\textasciitilde\texttt{CLOSEFILE}}, the \texttt{UNREGISTERFILE} method removes \texttt{STREAM} from \texttt{DEVICE}'s list of open streams. The revalidation code also uses this method to silently remove a device's invalid streams. Note that this need not be an actual list, but might be contained in the device's directory data structure.

The function \texttt{\textasciitilde\texttt{GENERIC\texttt{-UNREGISTER-STREAM}}}, though not the default, is a simple function that removes \texttt{STREAM} from \texttt{DEVICE}'s \texttt{OPENFILELST}. The revalidation code also uses this method to silently remove a device's invalid streams.

The following methods are invoked for open streams. They are all required:

\textbf{(BIN \texttt{STREAM})}

Returns the next byte of input from \texttt{STREAM}, or takes the appropriate action if at end of file. Unless a device has a good reason not to, it should call \texttt{\textasciitilde\texttt{EOF\texttt{.ACTION \texttt{STREAM}}}} at end of file/stream.

The device \texttt{BIN} method is actually not used directly. Rather, every stream has a \texttt{STRMBINFN} field, which is the function actually applied to do the input. The \texttt{STRMBINFN} field could thus be used to fake a specialization of the device differing only in the \texttt{BIN} method. However, the typical use of \texttt{STRMBINFN} is to temporarily override the device default. In particular, setting a stream's access to \texttt{INPUT} or \texttt{BOTH} automatically sets the stream's \texttt{STRMBINFN} to be the device's \texttt{BIN} method; setting access to \texttt{NIL} or \texttt{OUTPUT} sets the \texttt{STRMBINFN} to be an error. This relieves the device's \texttt{BIN} method of any need to check the stream's access on every call to \texttt{BIN}. Some network streams temporarily set their \texttt{STRMBINFN} to be an input eater when they receive a "clear output" command.

Currently, all Interlisp-D streams have bytesize 8, so \texttt{BIN} always returns an 8-bit integer.

Calls to the function \texttt{BIN} are compiled into the \texttt{BIN} opcode, which runs in microcode on some machines if the requirements for it are met. More on this later.

\textbf{(BOUT \texttt{STREAM \texttt{BYTE}})}

Outputs \texttt{BYTE} to \texttt{STREAM}. As with \texttt{BIN}, this method is not used directly. Rather, every stream has a \texttt{STRMBOUTFN} field, which is the function actually applied to do the output. Setting a stream's access to \texttt{OUTPUT} or \texttt{BOTH} automatically sets the stream's \texttt{STRMBOUTFN} to be the device's \texttt{BOUT} method.

There exists a \texttt{BOUT} opcode, but the design is incomplete.

\textbf{(PEEKBIN \texttt{STREAM NOERRORFLG})}

Returns the next input byte from \texttt{STREAM}, but does not advance the stream pointer. Thus a subsequent \texttt{PEEKBIN} or \texttt{BIN} will return the same byte. At end of stream, the device should take eof action as with \texttt{BIN}, unless \texttt{NOERRORFLG} is true, in which case it should return \texttt{NIL}. 
(READP STREAM FLG)

Returns true if input is available from STREAM, that is, if a BIN right now would succeed without waiting. Defaults to \GENERIC.READP, which uses EOFP and PEEKBIN.

Roughly speaking, READP is the complement of EOFP for streams that are not arriving in real time. It is interestingly different for network streams, or the keyboard.

FLG is a bit of cruft that not everyone pays attention to, and may be flushed at some point: if FLG is NIL, then READP should return NIL if the only input waiting is an end of line character.

(EOFP STREAM)

Returns true when STREAM is ‘‘at end of file’’, i.e., a BIN would cause an end of file action to occur. Note that for a network stream, it is possible for both EOFP and READP to be false simultaneously, viz. when there is no input waiting (buffered locally), but the remote end of the stream has not indicated that there is no more input.

There are some who call EOFP on streams open only for output. This is a crock; output streams are always at end of file. But to avoid complaints, a device could return T for EOFP on an output stream.

(BLOCKIN STREAM BUFFER BYTEOFFSET NBYTES)

Performs bulk input transfer: retrieves the next NBYTES bytes from STREAM and stores them in successive byte positions in BUFFER starting at BYTEOFFSET. Defaults to \GENERIC.BINS, which repeatedly calls BIN and \PUTBASEBYTE.

It is almost always the case that a device with a non-trivial BLOCKIN method can be made to be a Buffered device, thereby benefiting from other Buffered operations as well.

(BLOCKOUT STREAM BUFFER BYTEOFFSET NBYTES)

Performs bulk output transfer: outputs NBYTES bytes to STREAM, taking the bytes from BUFFER starting at BYTEOFFSET. Defaults to \GENERIC.BOUTS, which repeatedly calls \GETBASEBYTE and BOUT.

(FORCEOUTPUT STREAM WAITFORFINISH)

Forces to its ultimate destination any output buffered on STREAM but not yet sent. WAITFORFINISH means that the function should not return until it is confident that the output has reached its destination and been committed. Defaults to NIL, which is reasonable for unbuffered streams.

For example, for a network stream, FORCEOUTPUT sends the current packet being buffered up. For a buffered stream to the disk, FORCEOUTPUT writes out to the disk any ‘‘dirty’’ pages, and makes sure the file is in such a state that if the machine were booted after FORCEOUTPUT returns, that the file could be successfully reopened with no information lost.

(GETFILEINFO NAME/STREAM ATTRIBUTE DEVICE)

Returns the value of the specified ATTRIBUTE of NAME/STREAM, which can be an open Stream or the name of a (closed) file. Returns NIL for attributes it doesn’t know about. It is considered good citizenship, though not absolutely required, to know about the following attributes:

LENGTH Length of the stream/file in bytes. If the device’s method returns NIL, but the stream is random access, the generic GETFILEINFO code tries the device’s GETEOPF PTR method instead.
SIZE Length in pages, i.e., \(FOLD\text{H}I~\text{length}~\text{BYTESPERPAGE}\).

CREATIONDATE Date when the file’s contents were created, as a string. The creationdate does not change when a file is copied or renamed, only when it is changed.

WRITEDATE Date when the file was written to its current place of storage.

READDATE Date when the file was last read.

ICREATIONDATE, IWRIITEDATE, IREADDATE The creation, write and read dates as integers, such as from the function IDATE.

TYPE Type of the contents: TEXT for files that contain only ‘‘text’’ (generally meaning 7-bit ascii), BINARY for all others. NIL means unknown.

AUTHOR Name of the user who created the file (a string).

The following ‘‘generic’’ attributes are generally handled by the generic side of GETFILEINFO if the device’s GETFILEINFO method returns NIL:

EOL The end of line convention of the stream (CR, CRLF or LF).

BUFFERS The number of pagemap buffers for use by the stream (see description of MAXBUFFERS field of pagemapped streams).

ENDOFSTREAMOP Action to take on any attempt to read beyond the end of file. This is a function of one argument, the stream. The function can cause an error, or return a value, which is interpreted as a value to return from BIN. The default ENDOFSTREAMOP causes an END OF FILE error.

ACCESS An atom describing the access mode of the stream (INPUT, OUTPUT, etc). This is so generic that it is handled before the device’s method ever sees it.

BYTESIZE, OPENBYTESIZE The size of bytes transmitted on the stream. Always 8 these days.

\((\text{SETFILEINFO NAME/STREAM ATTRIBUTE VALUE DEVICE})\)

Sets the value of the specified ATTRIBUTE of NAME/STREAM to be VALUE. Returns T if successful, NIL if unsuccessful, or for attributes it doesn’t know about.

It is not generally required that SETFILEINFO recognize any attributes at all—NIL is a perfectly good filler for this slot. Most devices recognize no more than TYPE and CREATIONDATE (ICREATIONDATE), and even those are not very important, as most applications set those attributes in the PARAMETERS argument to OPENFILE when creating a file.

\(\text{ATTRIBUTE} = \text{LENGTH}\) implies actually truncating (or lengthening) the file; however, the SETFILEINFO need not handle this itself—if it returns NIL, then the generic file system will attempt to use the SETEOPFTR method instead.

The following operations are only required of random access streams. They default to the function \(\text{\small IS.NOT.RANDACCESSP}\), which causes a ‘‘Stream is not randaccessp’’ error when called.

\((\text{GETFILEPTR STREAM})\)

Returns the current file pointer (byte position) in STREAM. The file pointer is zero when the stream is opened (except for ACCESS = APPEND), and is incremented by one for each byte read.
Although this operation is only absolutely required for random access streams, it is desirable to supply it for other streams where possible. For example, when reading a file sequentially through PupFtp, the stream can count the bytes as they go by and thus give an accurate value for GETFILEPTR. If a stream has no idea at all of position, it can make its GETFILEPTR be the function ZERO and thereby at least avoid breaks from code that calls GETFILEPTR carelessly.

(GETEOPTR STREAM)

Returns the file pointer of the end of STREAM, i.e., the file pointer that GETFILEPTR would return after the last byte of STREAM is read. Same as the LENGTH attribute for a stream that represents a file. Of course, non-random access streams may have no idea where the end is, and causing a non-random access error is perfectly acceptable.

(SETFILEPTR STREAM BYTENUMBER)

Sets the file pointer of STREAM to be BYTENUMBER. The special value BYTENUMBER = ÿ1 means the end of the stream; other negative values are illegal.

SETFILEPTR beyond the end of the stream is permissible, but it has no immediate effect beyond changing the logical file pointer. Attempting to then BIN causes an EOF error. Attempting to BOUT (for a file open for write) should extend the file, so that its eof is immediately beyond the newly BOUTed byte.

As with GETFILEPTR, there is no requirement that this work on non-random access streams, and it may be completely impossible on some of them. However, for those non-random access streams that perform GETFILEPTR, it is possible to fake SETFILEPTR for values larger than the current file pointer by skipping some number of bytes in the file, e.g., by performing (RPTQ (DIFFERENCE BYTENUMBER (GETFILEPTR STREAM)) (BIN STREAM)). There are some applications for which forward SETFILEPTR is all the random access that is actually required, so it is nice to be able to accommodate such applications.

(BACKFILEPTR STREAM)

Backs up the file pointer in STREAM by one byte. Functionally the same as (SETFILEPTR STREAM (SUB1 (GETFILEPTR STREAM))), but may be possible on non-random access streams by maintaining a one-character buffer, which is all the backing up this operation is formally required to perform. I believe the main use for this is in READ, which needs to back up the stream one character when, for example, it reads a break character terminating an atom.

(SETEOPTR STREAM LENGTH)

Changes the length of STREAM to be LENGTH, i.e., “sets” its end of file pointer. This may require lengthening or truncating the file. Used by the function \SETEOPTR and by SETFILEINFO for attribute LENGTH when the device’s SETFILEINFO method doesn’t handle it.

The following three fields are place holders for possible future extensions. These fields are not currently used at all:

(LASTC STREAM)

Returns the last character read from STREAM, i.e., the last byte that was BINed, as a character. LASTC is currently implemented via BACKFILEPTR.

(FREEPAGECOUNT HOST/DIR DEVICE)
Intended use is to return the number of free pages on \textit{HOST/DIR}. May be folded into a general GET/SET device/directory info operation.

\textbf{(MAKEDIRECTORY \textit{HOST/DIR \textit{DEVICE}})}

Intended use is to create a new directory \textit{HOST/DIR}.

The remaining fields in the \textit{FDEV} are for buffered and page-mapped streams, and are ignored for non-buffered devices. These fields are described in separate sections.

\textbf{Streams}

The following fields are used by all streams:

\begin{itemize}
  \item \textbf{DEVICE} \hfill Pointer to this stream’s FDEV.
  \item \textbf{FULLFILENAME} \hfill ‘‘Full’’ name by which this file is known to the user. Should be an uppercase litatom, fully qualified so that giving the same name back to the file system should produce the same file (to the extent that the device can support such uniqueness). Is \texttt{NIL} for unnamed streams.
  \item \textbf{FULLNAME} \hfill Access field. Is the same as \textbf{FULLFILENAME}, unless that is \texttt{NIL}, in which case it is the stream itself. This avoids the circularity that would result if the \textbf{FULLFILENAME} field contained the stream datum.
  \item \textbf{NAMEDP} \hfill Access field. Is \texttt{T} if the streams is named, i.e., its \textbf{FULLFILENAME} is non-\texttt{NIL}.
  \item \textbf{ACCESSBITS} \hfill Contains a numeric code describing what access mode the file is open for: there are read, write and append bits. This field is usually accessed indirectly via the \textbf{ACCESS} field. However, there are macros for referring to particular types of access using more efficient bit test operations:

\begin{itemize}
  \item \textbf{(OPENED \textit{STREAM})} \hfill \textbf{ACCESS} is not \texttt{NIL}.
  \item \textbf{(READABLE \textit{STREAM})} \hfill Read bit is on: \textbf{ACCESS} is \texttt{INPUT} or \texttt{BOTH}.
  \item \textbf{(READONLY \textit{STREAM})} \hfill Only the read bit is on: \textbf{ACCESS} is \texttt{INPUT}.
  \item \textbf{(APPENDABLE \textit{STREAM})} \hfill Append bit is on: \textbf{ACCESS} is \texttt{OUTPUT, BOTH} or \texttt{APPEND}.
  \item \textbf{(APPENDONLY \textit{STREAM})} \hfill Only the append bit is on: \textbf{ACCESS} is \texttt{APPEND}.
  \item \textbf{(DIRTYABLE \textit{STREAM})} \hfill Append or write bit is on: \textbf{ACCESS} is \texttt{OUTPUT, BOTH} or \texttt{APPEND}. Yes, this is operationally the same as \textbf{APPENDABLE}, given the four possible values of \textbf{ACCESS}.
  \item \textbf{(OVERWRITEABLE \textit{STREAM})} \hfill Write bit is on: \textbf{ACCESS} is \texttt{OUTPUT} or \texttt{BOTH}.
  \item \textbf{(WRITEABLE \textit{STREAM})} \hfill Write bit is on, or append bit is on and file is at EOF. Avoid using this one, it’s a little strange.
\end{itemize}

\end{itemize}

Access field for referring to the \textbf{ACCESSBITS} field symbolically. Its value is one of the legal values of the \textbf{ACCESS} argument to \textit{OPENFILE: INPUT, OUTPUT, BOTH, APPEND}; or \texttt{NIL} when the stream is closed. Replacing this field has the side effect of setting the
BINABLE, BOUTABLE, STRMBINFN and STRMBOUTFN fields appropriately (from the corresponding device fields, or to values consistent with no access).

USERCLOSEABLE Flag, true if the stream can be closed by CLOSE. Default is T, but is NIL for such things as dribble files and the terminal.

USERVISIBLE Flag, true if the stream is to be listed in the result of (OPENP). Default is T, but is NIL for such things as dribble files and the terminal.

BINABLE True if BIN microcode can be used. Normally set automatically from FDBINABLE when input access is set.

BOUTABLE True if BOUT microcode can be used. Normally set automatically from FDBOUTABLE when output access is set.

EXTENDABLE True if BOUT can extend the buffer when OFFSET reaches CBUFSIZE. Obsolete.

STRMBINFN Function called by BIN. This is normally set indirectly as a side effect of setting the ACCESS field. Setting ACCESS to an input access (INPUT or BOTH) sets the STRMBINFN to be the stream’s device’s BIN method. Setting to any other access sets the STRMBINFN to be a “file not open” trap.

STRMBOUTFN Function called by BOUT. As with STRMBINFN, this is normally set indirectly (from the device’s BOUT method) as a side effect of setting the ACCESS field.

OUTCHARFN Function called to output a single byte. This is like STRMBOUTFN, except for being one level higher: it is intended for text output. Hence, this function should convert (CHARCODE EOL) into the stream’s actual end of line sequence, and should adjust CHARPOSITION appropriately before invoking the stream’s STRMBOUTFN to actually put the character. Defaults to \FILEOUTCHARFN. The OUTCHARFN for the display additionally worries about such things as ECHOCONTROL.

CHARPOSITION Current horizontal character position in the stream. Incremented (and reset to zero) by OUTCHARFN. Used by the function POSITION.

LINELENGTH Maximum line length of the stream, in characters. Used by the function LINELENGTH. Defaults (at creation time) to the value of the global variable FILELINELENGTH.

EOLCONVENTION The stream’s end of line convention: the manner in which “end of line” is encoded on this stream. That is, output of an end of line (function TERPRI) produces the stream’s end of line sequence, and on input, the stream’s end of line sequence is converted to (CHARCODE EOL) by READC. This is not necessarily the same as the way that end of line is encoded in the actual file written by, say, a file server. For example, Lisp might open a stream to a Tenex file server with EOLCONVENTION of CR, while the server might choose to take each of the CRs in the stream and actually store a CR, LF sequence in the physical file.

The convention is encoded as a two-bit field; the constants CR.EOLC, LF.EOLC, CRLF.EOLC can be used to refer to the currently known values symbolically. Default in Interlisp-D is CR.EOLC.
ENDOFSTREAMOP  Function of one argument (the stream) called when an attempt to read beyond the end of file occurs. If this function returns something, it should be interpreted as a value to return from BIN (the value T is currently prohibited). Defaults to \EOSERROR, which causes an END OF FILE error.

VALIDATION  Pointer field, some compact encoding of the state of the file such that if the file’s content changes, the VALIDATION changes. The file’s ICREATIONDATE attribute usually works well enough. The only use for this field is to check whether the file changed over LOGOUT, etc.—if the VALIDATION of the stream returned from REOPENFILE is EQUAL to the VALIDATION of the stream open before LOGOUT, the stream is assumed to be unchanged. This will probably be the sole concern of the device when we go to multiple streams per file.

BYTESIZE  Byte size of the file, i.e., what BIN and BOUT traffic in. Defaults to 8. This field is not used by many; there are probably a lot of things that won’t work if the byte size is not 8.

OTHERPROPS  List in property list format used by the function STREAMPROP. Analogous to WINDOWPROP, etc.

IMAGEOPS  Image operations vector (object of type IMAGEOPS) for use of device-independent graphics operations, such as DSPXPOSITION, DSPFONT. Defaults to \NOIMAGEOPS, a vector suitably defined for non-display devices. See the implementors’ manual chapter Device-Independent Graphics.

IMAGEDATA  Device-dependent data for use by IMAGEOPS.

REVALIDATEFLG  Flag. The standard use of this flag is to solve a problem with correctly maintaining the creation date. The problem is that the definition of “creation date” is that the creation date changes whenever the contents of the file change. If followed literally, this would mean, for example, that ever time you wrote out a page of a \DSK file, you would also have to rewrite its leader page with a new creation date. However, it suffices in practice to only change the creation date when it would matter, i.e., when there would be any possibility of some agent other than the currently running Lisp to see the change. Usually, this means the only time to worry about is when the Lisp vmem is saved and a file that was open before the save is written to again afterwards.

Thus, the use of this flag (for those devices that care) is as follows: the device’s BEFORExxx events set this flag true for any streams open on the device. Then, whenever the device is about to do something that would change the file’s content, e.g., write out a new page, it first tests REVALIDATEFLG. If the flag is true, it updates the file’s creation date and clears the flag.

NONDEFAULTDATEFLG  Flag. Standard use is in conjunction with REVALIDATEFLG, to mark a file that was opened in a way that the user constrained the creation date of the file (e.g., the PARAMETERS argument to OPENFILE included an explicit creation date, or the option DON’T CHANGE DATE).

F1, F2, F3, F4, F5  Pointer fields for private use by the stream, to maintain stream-specific state of concern only to the device. Stream clients that wish to hang information on a stream without regard to what kind of stream it is should use the function STREAMPROP.

FW6, FW7, FW8, FW9  16-bit word fields for private use by the stream.
Buffered Streams

Buffered streams are ones that constrain themselves to obey a set of conventions that make it easy for an agent (e.g., microcode) to perform input or output on the stream without knowing about the details of the stream’s physical i/o. The stream maintains a ‘‘current buffer’’ and two indices into that buffer, the offset of the next byte, and the offset of the end of the buffer. As long as the former index is less than the latter, the stream guarantees that the bytes in the buffer between those indices are the true contents of the file/stream starting at the current file pointer. Advancing the first index effectively advances the file pointer. When it reaches the second index, a stream-specific operation is called to ‘‘refill’’ the buffer.

The following fields are used by buffered streams:

- **COFFSET**: Byte offset in the buffer CBUPTR of the next BIN or BOUT.
- **CBUFSIZE**: ‘‘Size’’ of the current buffer, i.e., byte offset that is one beyond the last byte.
- **CBUFMAXSIZE**: For output, the maximum size the buffer can be written to. If COFFSET reaches CBUFSIZE, but CBUFSIZE is less than CBUFMAXSIZE, then the buffer can be extended.
- **CBUPTR**: Pointer to current buffer. Must be valid if COFFSET is less than CBUFSIZE and BINABLE or BOUTABLE is true. It is not necessary that this ‘‘buffer’’ be anything other than some chunk of memory, a portion of which contains interesting data. Thus, the bytes from offset COFFSET to CBUFSIZE must be valid, but COFFSET need not start at zero, nor need CBUFSIZE or CBUFMAXSIZE coincide with the end of the underlying structure.
- **CBUFDIRTY**: Flag, true if current buffer has been written to.

In general, the device has sole responsibility for setting CBUFSIZE, CBUFMAXSIZE, and CBUPTR; generic code does not touch those. The fields COFFSET and CBUFDIRTY can be changed by generic stream clients as well as by device-specific code. For example, code that simulates a BIN increments COFFSET; code that writes directly to the stream’s buffer sets CBUFDIRTY true.

The following methods are defined for devices implementing buffered streams:

```
(GETNEXTBUFFER STREAM WHATFOR NOERRORFLG) [Device method]
```

Called when STREAM needs to have its buffer fixed, i.e., the state of STREAM is such that BIN (WHATFOR = READ) or BOUT (WHATFOR = WRITE) cannot proceed. This method should do whatever is necessary to allow the operation to proceed. This typically includes disposing of the current buffer somehow (if GETNEXTBUFFER was invoked because the buffer was exhausted), and fetching a new buffer consistent with STREAM’s current position.

In the case of WHATFOR = READ, GETNEXTBUFFER returns T on success, i.e., if STREAM is not at end of file. When STREAM is at end of file, GETNEXTBUFFER should take standard end of stream action, returning whatever \EOF.ACTION returns (if anything). However, if NOERRORFLG is true, GETNEXTBUFFER should just return NIL immediately.
Performs any device-specific operation required when \textit{BUFFER}, which is the current value of \textit{STREAM}'s \texttt{CBUF PTR} field, is “released” (when the \texttt{CBUF PTR} field is replaced). This is used so that different pagemap-like devices can share certain code. For example, in the case of pagemapped streams, \texttt{RELEASEBUFFER} marks the buffer dirty in the case that the stream’s \texttt{CBUFDIRTY} field has been set.

This method is not currently used.

The functions \texttt{BUFFERED.BIN}, \texttt{BUFFERED.PEEKBIN}, \texttt{BUFFERED.BOUT}, \texttt{BUFFERED.BINS} and \texttt{BUFFERED.BOUTS} are supplied for use by buffered streams; they are standardly used to implement the \texttt{BIN}, \texttt{PEEKBIN}, \texttt{BOUT}, \texttt{BLOCKIN} and \texttt{BLOCKOUT} device methods. In addition, the function \texttt{COPYBYTES}, when presented with a source stream that is buffered, utilizes the \texttt{GETNEXTBUFFER} method to efficiently copy bytes to the destination a buffer-full at a time.

### Pagemapped Streams

Pagemapped streams are a particular kind of random access Buffered stream that buffers its data in units of pages. The device provides methods that read or write data in units of pages, while system-supplied Pagemapped functions handle the responsibilities of a Buffered stream, as well as managing the file pointer for random access. In general, a stream can have several pages of a file buffered at a time, allowing the code to make some effort to make efficient use of multi-paged transfers where applicable.

To create a pagemapped device, create an \texttt{FDEV}, fill in the necessary private fields, then call the following function:

\begin{verbatim}
(\MAKE.PMAP.DEVICE \textit{DEVICE}) \hfill [Function]
\end{verbatim}

Fills in fields in the device appropriate for pagemapped devices, and returns the updated device. The fields it fills are the flag fields \texttt{FDBINABLE}, \texttt{FDBOUTABLE}, \texttt{RESETABLE}, \texttt{RANDOMACCESSP}, \texttt{PAGEMAPPED}, \texttt{BUFFERED} (all true), and the methods \texttt{BIN}, \texttt{BOUT}, \texttt{PEEKBIN}, \texttt{BLOCKIN}, \texttt{BLOCKOUT}, \texttt{READP}, \texttt{EOFP}, \texttt{GETFILEPTR}, \texttt{BACKFILEPTR}, \texttt{SETFILEPTR}, \texttt{GETEOFPTR}, \texttt{SETEOFPTR}, \texttt{GETNEXTBUFFER} and \texttt{FORCEOUTPUT}.

A Pagemapped device is required to supply the following methods (in addition to those required of all devices and not filled in by \texttt{MAKE.PMAP.DEVICE}):

\begin{verbatim}
(\READPAGES \textit{STREAM} \textit{FIRSTPAGE#} \textit{BUFFERS}) \hfill [Device method]
\end{verbatim}

Causes pages of \textit{STREAM} to be read into \textit{BUFFERS}. The first page read is \textit{FIRSTPAGE#} (zero for the first page of the file). \textit{BUFFERS} is either a single page-sized buffer (a \texttt{VMEMPAGEP}), in which case exactly one page is read, or it is a list of such buffers. \texttt{READPAGES} returns the total number of bytes read. If the last page read is not a full page, \texttt{READPAGES} should zero out the rest of its buffer. \texttt{READPAGES} can assume that the buffers are page-aligned, although they need not be consecutive.

\begin{verbatim}
(\WRITEPAGES \textit{STREAM} \textit{FIRSTPAGE#} \textit{BUFFERS}) \hfill [Device method]
\end{verbatim}

Writes data from \textit{BUFFERS} out to \textit{STREAM}. The first page written is \textit{FIRSTPAGE#}. \textit{BUFFERS} is as with \texttt{READPAGES}.

Neither \texttt{READPAGES} nor \texttt{WRITEPAGES} affects \textit{STREAM}'s file pointer or end of file; those are managed by higher-level pagemapped routines. \texttt{WRITEPAGES} might, however, want to look at \textit{STREAM}'s \texttt{EPAGE} and \texttt{EOFFSET} fields if it needs to take any special action around the end of the file. It is possible, for no particularly good reason, for
READPAGES to get called for a page beyond the end of file; in fact, this standardly happens when writing a new file. The READPAGES method in this case should just clear the buffer and return zero.

(TRUNCATEFILE STREAM PAGE# OFFSET) [Device method]

Truncates STREAM so that its end of file is PAGE#, OFFSET, which should be defaulted to STREAM’s EPAGE and EOFFSET. Can be used to either shorten or lengthen a file; if lengthening, the file should be padded with nulls. Used by \PAGED.SETEOPTR and \PAGED.FORCEOUTPUT. As of this writing there are still bugs in this code in certain funny cases, such as when you SETFILEPTR beyond eof and then BOUT.

The following fields of a stream are meaningful for a pagemapped device. The generic pagemapped codes maintain them as operations on the file are performed, but they should all be initialized appropriately by the device’s OPENFILE method:

CPAGE For pagemapped streams, the current page position in the stream. Together with COFFSET, this constitutes the stream’s file pointer. The device’s OPENFILE method should set CPAGE and COFFSET to zero, except for files opened with access APPEND, in which case they should be set to the end of file.

EPAGE, EOFFSET For pagemapped files, the page and byte offset of the end of file. Note that this is the logical end of the file; it need have nothing to do with the physical end of file, except that when a file is closed, the device should see to it that its logical and physical EOFs are the same (normally seen to by the TRUNCATEFILE inside of \CLEARMAP, below). In fact, as a typical file is being written, EPAGE tends to stay several pages ahead of the physical end of file by virtue of the fact that pages are being buffered before being written out.

BUFFS For pagemapped streams, a pointer to the stream’s BUFFER chain. Initially NIL (no buffers allocated). The device usually has no direct interest in this field.

MAXBUFFERS For pagemapped streams, the maximum number of buffers desired in the stream’s BUFFS chain. If the code needs another buffer and there are already MAXBUFFERS buffers, it will try to recycle the least recently referenced buffer. Defaults to \STREAM.DEFAULT.MAXBUFFERS. The user can change this field for an open stream by calling SETFILEINFO with attribute BUFFERS.

MULTIBUFFERHINT Flag. For pagemapped streams, is a hint to the pagemap code that the device prefers to transfer data more than one buffer at a time. If this flag is true, the pagemap code tries to write out (WRITEPAGES) more than one buffer at a time when the opportunity arises. A similar improvement is planned, but not implemented, for reading multiple buffers at a time.

The following functions are of use for pagemapped devices:

(\PAGED.FORCEOUTPUT STREAM WAITFORFINISH) [Function]

This function implements the FORCEOUTPUT method for pagemapped streams: it causes any dirty pages to be written out (using WRITEPAGES), then calls the TRUNCATEFILE method to set the end of file.

This function is normally installed as the FORCEOUTPUT method by the function \MAKE.PMAP.DEVICE. However, the device can override this default (by supplying its own function in that field), in which case it might want to call the function \PAGED.FORCEOUTPUT explicitly as part of its more comprehensive FORCEOUTPUT method.
There is an unpleasantness in the implementation of pagemapped devices that stems from the fact that originally all devices (the few that existed in the distant past) were made to support the PMAP package, a means whereby a programmer could get direct access to the buffers of a file, much as one can with the PMAP JSYS in Tenex. As a result, the buffers used by pagemapped streams are set up in a special manner so that the garbage collector can tell when the user no longer has access to a PMAP buffer. The PMAP package is being phased out.

This is all exceedingly crufty, and is of little concern to the device implementer, except for the fact that it requires that the buffers be explicitly released when a stream is closed; the buffers are not automatically collected when the stream is dropped.

**(FORGETPAGES STREAM FROMPAGE TOPAGE)**

‘Forgets’ pages FROMPAGE thru TOPAGE of STREAM; i.e., removes those pages from the set of pages being currently buffered, and frees the buffers they were occupying. If FROMPAGE = TOPAGE = NIL, forgets all pages, and releases all of STREAM’s buffers.

**(\CLEARMAP STREAM)**

Performs a FORCEOUTPUT (if STREAM is open for output) followed by a FORGETPAGES. This is the standard action that should be taken by a pagemapped stream’s CLOSEFILE method.

**Directory Enumeration**

This section describes how directory enumeration works—what you need to know in order to implement the GENERATEFILES device method, and what you need to know as a programmer trying to enumerate a directory via anything more elaborate than the function DIRECTORY.

The general idea is that the directory enumeration code is given a pattern, and it returns a generator that, each time it is poked, returns another file name matching the pattern. In addition, the generator provides a handle for getting file attributes of each enumerated file. This second handle is important for efficiency: although one could just take the file name given by the enumerator and pass it to GETFILEINFO, the device, in the course of enumeration, usually has its fingers on the file closely enough that it need not perform the second directory lookup that a GETFILEINFO out of the blue would require. The caller of the directory enumeration code specifies ahead of time which, if any, attributes will be required (a necessity for most file server implementations).

**Information for device implementors.** A file generator is an object represented as a list described by the record FILEGENOBJ, exported from FILEIO:

**(RECORD FILEGENOBJ (NEXTFILEFN FILEINFOFN . GENFILESTATE))**

NEXTFILEFN and FILEINFOFN are functions of the device’s choosing that when called will return the next file, and attributes for that file. GENFILESTATE is arbitrary state maintained by the generator. With that as background, here are the pieces of directory enumeration:

**(GENERATEFILES DEVICE PATTERN DESIREDPROPS OPTIONS)**

Returns a generator that enumerates files matching PATTERN, which is a string that has host and directories suitably filled in from defaults, and may contain the pattern character ‘*’ to match an arbitrary number of characters. DESIREDPROPS is a list of file attributes that may be requested during the enumeration; they must be valid ATTRIBUTE arguments to GETFILEINFO. OPTIONS is a list of options to the enumeration, chosen from among the following:
The files should be enumerated in sorted order. If this option is not specified, the device is free to enumerate files in any convenient order.

There is some question as to whether files should be enumerated lowest version first (as IFS’s do) or highest version first (as Twenex does). I prefer the latter, but given servers that do the former, we currently make no requirement about version order.

Informs the enumerator that the enumeration context is surrounded by a \RESETLST, so that it may perform \RESETSAVEs to clean up after itself if the enumeration is aborted. Cleaning up can be a very messy business without this information about the scope of the enumeration, so all callers of \GENERATEFILES are strongly encouraged to provide it.

\GENERATEFILES should return a file generator with a suitable NEXTFILEFN and FILEINFOFN.

Fine point about missing fields in the pattern: null fields in \PATTERN match only files for which the corresponding field is null. A null version is interpreted as highest. Thus,

\[ \text{DIR } *= \text{DIR } *. *= \text{DIR } *. *; * \] enumerates everything.

\[ \text{DIR } *. = \text{DIR } *. ; * \] enumerates all versions of files with null extension.

\[ \text{DIR } *.; \] enumerates highest version of files with null extension.

\[ \text{DIR } *.*; \] enumerates highest version of everything.

It is difficult for some devices to enumerate only highest version of files; there are several devices in the system that treat a null version the same as version \(*\). However, every device should try its best. With some work, any device that can enumerate all versions can enumerate just highest version if it enumerates in sorted order and uses perhaps a little lookahead to assure that any name it returns is the one of highest version.

\( \text{(NEXTFILEFN } \text{GENFILESTATE } \text{NAMEONLY})\) [File Generator Component]

Generates the next file, returning its name as a string, or NIL if the generator is exhausted. \GENFILESTATE is the state component of the file generator returned from \GENERATEFILES. \NAMEONLY means that the caller is only interested in the file’s Name.Ext fields, not the full file name (and no more than one version of the file need be enumerated); however, it is always permissible to return the full file name. The \NAMEONLY option is used by \SPELLFILE.

\( \text{(FILEINFOFN } \text{GENFILESTATE } \text{ATTRIBUTE})\) [File Generator Component]

Returns the value of the \ATTRIBUTE property of the file most recently generated by the NEXTFILEFN, i.e., effectively \GETFILEINFO latest-name \ATTRIBUTE), but hopefully much faster. \ATTRIBUTE must have been a member of the \DESIREDPROPS argument to \GENERATEFILES.

Not all device implementors are enthused about implementing a pattern matcher for file names. The following functions are provided to help out:

\( \text{(DIRECTORY.MATCH.SETUP } \text{PATTERN})\) [Function]

Accepts as \PATTERN a file name string such as passed to \GENERATEFILES. Returns an object suitable as a filter to \DIRECTORY.MATCH.

\( \text{(DIRECTORY.MATCH } \text{FILTER } \text{TESTNAME})\) [Function]
Matches \textit{TESTNAME}, a file name, against \textit{FILTER}, the object returned from \texttt{DIRECTORY.MATCH.SETUP}. Returns true if \textit{TESTNAME} matches the pattern, false if not. The match is case-insensitive.

\texttt{(\texttt{NULLFILEGENERATOR})} \hfill [Function]

Returns a file generator that produces no files.

\texttt{(\texttt{GENERATENOFILES DEVICE PATTERN DESIREDPROPS OPTIONS})} \hfill [Function]

Returns a “stupid” file generator for devices that don’t know how to enumerate in general. If \texttt{PATTERN} contains no wildcards, but names a file that is \texttt{INFILEP}, then the generator produces exactly that file. If \texttt{PATTERN} contains a wildcard in the version field, it uses \texttt{GETFILENAME} to laboriously generate all the versions of the file. In all other cases, \texttt{\textbackslash GENERATENOFILES} returns a null file generator.

\textbf{Information for clients of device enumeration.}  The following functions make up the “public” interface to directory enumeration:

\texttt{(\texttt{GENERATEFILES PATTERN DESIREDPROPS OPTIONS})} \hfill [Function]

Returns a file generator object for enumerating the files matching \texttt{PATTERN}. \texttt{PATTERN} is expanded by adding the default host and/or directory if appropriate. See description of the \texttt{GENERATEFILES} method for description of \texttt{DESIREDPROPS} and \texttt{OPTIONS}.

\texttt{(\texttt{GENERATENEXTFILE GENERATOR NAMEONLY})} \hfill [Function]

Returns the next file, as a string. \texttt{GENERATOR} is the object returned from \texttt{\textbackslash GENERATEFILES}; \texttt{NAMEONLY} indicates caller does not require that the full name be returned, but that the name and extension are sufficient.

\texttt{(\texttt{GENERATEFILEINFO GENERATOR ATTRIBUTE})} \hfill [Function]

Returns the value of the \texttt{ATTRIBUTE} property of the file most recently generated by \texttt{\textbackslash GENERATENEXTFILE}, i.e., effectively \texttt{(GETFILEINFO latest-name ATTRIBUTE)}. \texttt{ATTRIBUTE} must have been a member of the \texttt{DESIREDPROPS} argument to \texttt{\textbackslash GENERATEFILES}.

\texttt{(\texttt{DIRECTORY.FILL.PATTERN PATTERN DEFAULTTEXT DEFAULTVERS})} \hfill [Function]

This function is used to fill in defaults in \texttt{PATTERN} before passing it to \texttt{\textbackslash GENERATEFILES}. If \texttt{PATTERN} does not include an extension or version, but those fields are not explicitly omitted (e.g., “\texttt{FOO}”, but not “\texttt{FOO.}”; “\texttt{FOO.BAR}”, but not “\texttt{FOO.BAR;}”), they are filled in with \texttt{DEFAULTTEXT} and \texttt{DEFAULTVERS}, which themselves default to “\texttt{*}”. This function is used by the \texttt{DIR} command, and should probably be used by any code that takes a user-supplied pattern and enumerates files from it.
Streams and File Devices

Edited 30 Nov 84, van Melle

An Interlisp Stream is an object of datatype STREAM that is capable of performing, at the least, sequential input and/or output of bytes. Some streams can do much more. Streams are used for access to open files, for writing to the display, for chatting to remote hosts, and whatever other uses people come up with. This document describes how one goes about defining a new device, the meanings of the record fields of the STREAM and FDEV datatypes, and anything else that seemed relevant at the time.

The implementation of Streams is strongly object-oriented. Every STREAM has a pointer to a device (the datatype FDEV), which contains a vector of functions to be called when certain operations are required of the stream. There can be many streams with the same device. In the object-oriented terms of LOOPS, one can think of the device as a class, which provides a set of methods that implement class operations, and the streams as instances. Devices and streams also have local state, which might be thought of as class and instance variables. Declarations for STREAM and FDEV can be obtained by loading EXPORTS.ALL.

OPENSTREAM, CLOSEF, FORCEOUTPUT, READP, EOFP, GETEOFPTR, GETFILEINFO, SETFILEINFO, DIRECTORY, COPYBYTES, DELFILE, RENAMEFILE, FULLNAME are some of the Lisp functions called by the programmer that ultimately turn into operations at the device level. The descriptions that follow sometimes allude to these functions, and knowledge of how they operate may occasionally give the reader additional clues as to how the device operations work.

Typically, some part of the operation is handled by the “generic” file system code, which then calls on the device to handle that part of the operation that is device-specific. For example, the function OPENFILE takes the name of the file it is to open and fills in host and directory defaults, and decides which device handles such a file. It then calls on the particular device to actually open the file. After the file is opened, the generic file system code registers the file on (OPENP). As another example, operations involving open streams first coerce non-streams (e.g. filenames) to open streams before calling the device-specific operation.

Devices

A device is an object of type FDEV (so named for historical reasons: “File Device”). The standard way to define a new device is to create such an object, by performing (create FDEV --), and then pass the newly created FDEV to the function \DEFINEDEVICE. \DEFINEDEVICE is the way a device “announces” itself to the generic file system.

(\DEFINEDEVICE NAME DEV) [Function]

Installs device DEV, giving it the name NAME. NAME must be an uppercase litatom. The generic file system code makes use of the name to locate the device that is willing to deal with files whose full name begins [NAME]. It is permissible to have more than one name map to the same device; this effectively provides device synonyms. Devices are encouraged, however, to always create file names using the canonical device name, independent of what name was passed in.

NAME can be NIL, in which case the generic file system code never consults the device directly. However, its EVENTFN is still run around Lisp exits, and it can be used as the device for a stream created by nonstandard methods.

If a device never wants to be invoked by name, and has no interesting EVENTFN or HOSTNAMEP methods, then there is no need to ever register it with \DEFINEDEVICE.
\(\text{\texttt{\textbackslash REMOVEDEVICE \textit{DEV}}}\) [Function]

Removes device \textit{DEV} from the list of known devices, as well as any name that maps to that device.

\(\text{\texttt{\textbackslash GETDEVICEFROMNAME \textit{NAME NOERROR DONTCREATE}}}\) [Function]

Returns the device associated with \textit{NAME}. \textit{NAME} can be a litatom or string; it is coerced to uppercase, and if it begins with an open brace, is assumed to be a file name, from which the host name is extracted. If no such device is known, attempts to find one by polling the \texttt{HOSTNAMEP} methods of all known devices (see below); if a device is still not found, causes a \texttt{FILE NOT FOUND} error unless \textit{NOERROR} is true. If \textit{DONTCREATE} is true, it never attempts to create a device, just returns an existing device if there is one, \texttt{NIL} otherwise.

The fields of an \texttt{FDEV} are divided up into informational fields and \texttt{`methods'}.

**DEVICENAME**
A pointer field, the name of the device, standardly a litatom. Use of this field is largely up to the device, but it is usually selected to be the name that appears inside braces in filenames opened on this device. For devices that do not support the notion of named files, \texttt{DEVICENAME} can be anything that the implementor cares to use for debugging assistance.

**RESETABLE**
A flag, true if \(\text{\texttt{(SETFILEPTR stream 0)}}\) can be performed. Currently unused.

**RANDOMACCESSP**
True if the stream is randomly accessible, i.e., if \texttt{SETFILEPTR} works on this kind of stream.

**NODIRECTORIES**
True if files opened on this device do not (usually) have a directory as part of their name. The principal use for this is by the \texttt{CONN} command, which will not try to connect to the user’s home directory if given a host only, e.g., \texttt{CONN \{DSK\}}.

**BUFFERED**
True if streams of this sort are buffered in a manner compatible with the microcoded versions of \texttt{BIN} and \texttt{BOUT}. More specifically, \texttt{BUFFERED} implies that the device implements the \texttt{GETNEXTBUFFER} method. See description of buffered streams.

**PAGEMAPPED**
True if this stream is implemented by the pagemapped functions. All pagemapped streams are also buffered, so if this flag is true, so should be \texttt{BUFFERED}. See description of pagemapped streams.

**FDBINABLE**
True if streams on this device obey the rules for microcoded \texttt{BIN} whenever such stream is open for input access.

**FDBOUTABLE**
True if streams on this device obey the rules for microcoded \texttt{BOUT} whenever such stream is open for output access. Currently unused, as the spec needs revision.

**FDEXTENDABLE**
Special kind of \texttt{FDBOUTABLE}. Currently unused, as the spec needs revision.

**DEVICEINFO**
A pointer to arbitrary device-specific information. The standard use for this is to hold local state specific to one of several similar devices that share methods. For example, the Dolphin disk provides a separate \texttt{FDEV} for each partition of the machine; the \texttt{DEVICEINFO} field of each has pointers to the partition’s directory and other information specific to files on that partition only.
The following fields are all pointer fields, and contain functions for implementing various device operations. Not all devices need have all fields filled in; the required ones are listed first and so indicated. Some “required” fields have defaults specified in the FDEV (or STREAM) record declaration, so the implementor need not explicitly fill those fields if the default is reasonable. Each field is presented with its arguments, in the style of a function definition; of course, it is the contents of the field, not the field name, that is the function. Using object-oriented terminology, the occupants of these fields are referred to as “methods”. For example, “the BIN method” means “the function that occupies the BIN field”.

One of the arguments to each method is usually either the device itself, or a stream open on the device, so that the device (and hence its DEVICEINFO) is usually accessible to all these functions. Arguments that are file names or patterns or pieces of file names can be either litatoms or strings, and already have their host and/or directory parts appropriately filled in from the connected directory defaults. The device may assume that the host field of the file name is indeed a name that the device has said it implements (see HOSTNAMEP). “Full” file names returned by these functions (or stored in the FULLFILENAME field of a stream) should be litatoms, and at least in the current implementation should be all uppercase.

Fields required of every device:

(HOSTNAMEP HOSTNAME DEVICE)

Called by the generic file system code when presented with a host name for which there is as yet no device defined. The function should return non-NIL if it “recognizes” HOSTNAME. There are two ways in which this method is invoked:

1. To obtain a device for HOSTNAME, for example, so that a file can be opened on it. In this case, DEVICE is an already defined device (the one whose HOSTNAMEP method is being called), and the function should return either a new device, or T, meaning it is willing to take responsibility for this host name as well as any previous name under which the device was registered. In either case, the caller will install the returned device, or DEVICE if value was T, as the device to which HOSTNAME maps.

2. As a pure predicate. In this case, DEVICE is NIL, and the function need only return T or NIL, indicating whether it believes that HOSTNAME is the name of a host.

In practice, the HOSTNAMEP method need only take care of the first case, since that also takes care of the second case. The second case is provided so that the device need not be created until there is an actual use for it, should the device wish to avoid unnecessary work. In practice it is rare that anyone tests a host name without subsequently needing to have the device created in full.

There are basically three kinds of devices in the system as distinguished by their HOSTNAMEP methods.

1. Predefined devices with exactly one name, or strictly internal devices with no notion of name. For example, the CORE device always exists, and has exactly one name; the SPP device (a network byte stream) has no name (it supports no files directly). Such devices have a HOSTNAMEP method of NIL— the only name they ever go by is the one they gave to \DEFINEDEVICE, if any. This is the default.

2. Devices that don’t know ahead of time what their name will be, but for which there might be many incarnations. This is the model for remote file servers. The standard way of handling this case is to define a dummy device that has only a HOSTNAMEP method, and no name. When the HOSTNAMEP method gets called with a name that the device knows it can service, it creates a device by that name. If given a name that is a synonym of another name, it might just return the existing device of the canonical name (using \GETDEVICEFROMNAME to find the right device).
In either case, the HOSTNAMEP method of the new device is usually NIL—the original device is the only one that worries about creating new instances of this class of device.

(3) Like (2), but all the different names are handled by a single device, which takes care internally of the multiplexing among, say, different remote hosts. HOSTNAMEP returns T in this case. This is usually clumsier than (3), so discouraged.

(EVENTFN DEVICE EVENT)

Called around Lisp exits, to allow the device to do any necessary cleaning up, clearing of caches, disconnects with remote hosts, etc. EVENT is one of the following litatoms: BEFORELOGOUT, BEFORESYSOUT, BEFOREMAKESYS, BEFORESAVEVM, AFTERLOGOUT, AFTERSYSOUT, AFTERMakesys, AFTERSAVEVM, AFTERDOSYSOUT, AFTERDOMakesys, AFTERDOSAVEVM. The AFTERxxx events are all run when Lisp is booted from a memory image that resulted from a LOGOUT, SYSOUT, etc. The AFTERDOxxx events run when continuing Lisp in the same incarnation following the SYSOUT, etc. (there is no such event for LOGOUT, of course). The “after” events are called in the same order in which the devices were defined; the “before” events in the reverse order.

For example, the BEFORELOGOUT event for the Leaf remote file server devices performs a FORCEOUTPUT on all its open files and then breaks the connection with the file server. The AFTERxxx events for the Leaf devices calls \REMOVEDDEVICE on itself to flush any connection between the name and the server (since names and addresses can change over exit). The AFTERxxx events for the Dorado disk device rebuilds its cache of the disk’s directory.

There are a few devices in the system that exist only for their EVENTFN. In most cases, a simpler way to tell the system you want something performed around exit is to add your event function to the list AROUNDEXITFNs instead of going to the expense of defining a device for it. There is yet another list, \SYSTEMCACHEVARS, for handling a more specialized “around exit” operation: every time Lisp is booted, each of the variables in the list \SYSTEMCACHEVARS is set to NIL.

The following are required of all named devices, that is, devices that map from some hostname to the device, upon which files might be opened or otherwise manipulated:

(DIRECTORYNAMEP HOST/DIR DEVICE)

True if HOST/DIR is a valid directory name on DEVICE. Function should ideally perform recognition as well, and return the “true” name. For example, given “{PHYLEX:}<LISP>” as argument, it might return {Phylex:PARC:Xerox}<Lisp>. HOST/DIR might include a subdirectory name. The device should attempt to tell the truth about whether the subdirectory exists or not, though this may not be possible for devices with fake subdirectories. Defaults to NIL, i.e., device supports no directories. Used by the command CONN and the function DIRECTORYNAMEP.

(OPENFILE NAME ACCESS RECOG PARAMETERS DEVICE)

Used to implement the OPENFILE and OPENSTREAM functions. Opens the file named NAME on this device for access ACCESS, returning a STREAM. The stream is usually on DEVICE (its DEVICE field is DEVICE), but is not required to be. The arguments ACCESS, RECOG, PARAMETERS are as with the OPENFILE function in the manual. Thus, if NAME does not include a version number, recognition is according to RECOG, which should be appropriately defaulted per ACCESS (INPUT implies OLD, OUTPUT implies NEW, BOTH implies OLD/NEW).

The argument NAME can also be a STREAM, which must be a closed stream. OPENFILE should “reopen” the stream. The value returned in this case may be a new stream (with the same name as the
old), or the old stream (NAME) itself. It is likely that the specification will be changed at some point to require that the old stream itself be returned, suitably reopened.

The argument PARAMETERS is a list of pairs (OPTION VALUE). The most interesting OPTIONS are as follows:

- **TYPE**: For new files, the type of the file (TEXT or BINARY). If this parameter is not specified, the value of the global variable DEFAULTFILETYPE (initially TEXT) should be used.

- **CREATIONDATE**: For new files, the date of its creation. The device should use this if at all possible instead of letting the creation date default to the current date and time.

- **LENGTH**: The intended length of the file, in bytes. This need not be accurate—it is only a hint that may allow smarter allocation. For example, if the device knows that it does not have room for a file of the specified length, it should immediately cause a FILE SYSTEM RESOURCES EXCEEDED error for the intended file.

- **DON’T.CHANGE.DATE**: For old files being opened for access BOTH, don’t change the creation date of the file. ACCESS = BOTH would normally imply that the content of the file is to change, and thus its creation date should be updated. Use of this parameter is a form of “cheating” to make it look as though the file had not changed. For example, the code that rewrites filemaps uses this parameter, since rewriting the filemap does not logically change the file’s content.

- **SEQUENTIAL**: If T, is a hint that the file will, or need, only be accessed sequentially, which may allow the device to open the file in a more efficient mode.

Any parameters that the device does not understand should be ignored, rather than be cause for an error. All devices are encouraged to support at least TYPE and CREATIONDATE.

The additional options ENDOFSTREAMOP and BUFFERS are handled by the generic file system code; specifying them is equivalent to calling SETFILEINFO (q.v.) immediately after the open.

Fine point about ACCESS = OUTPUT: this operation always produces a new, empty file, independent of whether its name is exactly the name of an existing file. That is, it replaces any old file by the same name. On opening, such a file has an end of file of zero. Of course, since RECOG defaults to NEW in this case, the name can only clash with an old file name if a version was explicitly specified, or RECOG is OLD or OLD/NEW. To open an old file for output but preserve its contents, i.e., only write over part of the file, one should open for ACCESS = BOTH (since to preserve the old contents one implicitly reads them).

Exception handling: If the desired file is not found, the OPENFILE method should return NIL rather than cause a FILE NOT FOUND error. This is so that the generic file system code can cause the error using the original file name, not the one packed with host and directory passed in to the OPENFILE method. The device should feel free to signal any other errors itself on failing to open the file, e.g., FILE WON’T OPEN for a busy file, PROTECTION ERROR, or FILE SYSTEM RESOURCES EXCEEDED. Ideally, this error should be signaled in a way that is resumable, i.e., so that a user could, in the break, take some action to remedy the condition and then type OK to continue. In most cases it suffices that all the internal functions below the OPENFILE be named with backslashes, so that the error code will choose to resume by reverting to the OPENFILE and trying again.

The device does not need to know about the set of open files (i.e., the value of (OPENP)), and in general should ignore it. That is, the device should perform the open as if there were no other files open.
and hence no conflict. The generic file system code looks at the stream returned from the OPENFILE method and then worries about whether there is actually another stream open by the same name. If there is, it closes the newly opened stream and then either returns the pre-existing stream, or causes a FILE WON’T OPEN error if the new and old access modes are in conflict. This design is cruddy, but I believe it stems principally from the recognition problem—you don’t know the full name of a file until you open it, so you can’t tell until then whether you should have tried to open it in the first place. It will, of course, have to be completely changed when we go to multiple streams per file.

(REOPENFILE NAME ACCESS RECOG PARAMETERS DEVICE OLDESTREAM)

This is exactly like OPENFILE, except that it is called after LOGOUT (or other “after” events) on the name of any stream that was left open over exit. The idea is to maintain the illusion that the file really was open over LOGOUT, but check and make sure nothing changed. The generic file system code uses the VALIDATION field to test whether the file changed behind your back.

OLDESTREAM is the stream that was open before exit, and is supplied for the benefit of devices where there is no possibility that the file changed (e.g., \{CORE\}), so that they can just return OLDESTREAM directly. OLDESTREAM is also of use for those devices that have to cheat in order to maintain the illusion.

This will have to change when we go to multiple streams per file.

(GETFILENAME NAME RECOG DEVICE)

Performs “recognition” on NAME. That is, it returns the full name of the file that would be opened by OPENFILE in the indicated recognition mode, or NIL if the file is not found. It is not necessary that OPENFILE actually be capable of opening the file (there is no need to check protection, for example). Used by INFILEP, OUTFILEP, FULLNAME.

(DELETEFILE NAME DEVICE)

Deletes the file named NAME, returning its full name on success, NIL on failure. Recognition mode is implicitly OLDEST. Local devices, after recognizing the file, should make sure that it is not OPENP (open files can not be deleted). This and RENAMEFILE are usually the only device methods that need to know anything about what files are open.

(GENERATEFILES DEVICE PATTERN DESIREDPROPS OPTIONS)

Enumerates files matching PATTERN. Returns a “file generator object” of the form (NEXTFILEFN INFOFN . ArbitraryState). This is described in more gory detail under Directory Enumeration.

(RENAMEFILE OLDNAME NEWNAME DEVICE)

Renames the file named OLDNAME to have name NEWNAME. Returns the full name of the new file if successful, NIL if not. Recognition mode is implicitly OLD for OLDNAME, NEW for NEWNAME. The generic file system code invokes this method to implement the function RENAMEFILE only when the host fields of both filenames map to the same device. Defaults to \GENERIC.RENAMEFILE, which is also the function that the system calls when the old and new names are on different devices. \GENERIC.RENAMEFILE is defined to copy OLDNAME to NEWNAME and then delete OLDNAME.

The following methods are invoked for open streams. They are all required:

(BIN STREAM)

Returns the next byte of input from STREAM, or takes the appropriate action if at end of file. Unless a device has a good reason not to, it should call (\EOF.ACTION STREAM) at end of file/stream.
The device BIN method is actually not used directly. Rather, every stream has a STRMBINFN field, which is the function actually applied to do the input. The STRMBINFN field could thus be used to fake a specialization of the device differing only in the BIN method. However, the typical use of STRMBINFN is to temporarily override the device default. In particular, setting a stream’s access to INPUT or BOTH automatically sets the stream’s STRMBINFN to be the device’s BIN method; setting access to NIL or OUTPUT sets the STRMBINFN to be an error. This relieves the device’s BIN method of any need to check the stream’s access on every call to BIN. Some network streams temporarily set their STRMBINFN to be an input eater when they receive a “clear output” command.

Currently, all Interlisp-D streams have bytesize 8, so BIN always returns an 8-bit integer.

Calls to the function BIN are compiled into the BIN opcode, which runs in microcode on some machines if the requirements for it are met. More on this later.

(BOUT STREAM BYTE)

Outputs BYTE to STREAM. As with BIN, this method is not used directly. Rather, every stream has a STRMBOUTFN field, which is the function actually applied to do the output. Setting a stream’s access to OUTPUT or BOTH automatically sets the stream’s STRMBOUTFN to be the device’s BOUT method.

There exists a BOUT opcode, but the design is incomplete.

(PEEKBIN STREAM NOERRORFLG)

Returns the next input byte from STREAM, but does not advance the stream pointer. Thus a subsequent PEEKBIN or BIN will return the same byte. At end of stream, the device should take eof action as with BIN, unless NOERRORFLG is true, in which case it should return NIL.

(READP STREAM FLG)

Returns true if input is available from STREAM, that is, if a BIN right now would succeed without waiting. Defaults to \GENERIC.READP, which uses EOPP and PEEKBIN.

Roughly speaking, READP is the complement of EOPP for streams that are not arriving in real time. It is interestingly different for network streams, or the keyboard.

FLG is a bit of cruft that not everyone pays attention to, and may be flushed at some point: if FLG is NIL, then READP should return NIL if the only input waiting is an end of line character.

(EOPP STREAM)

Returns true when STREAM is “at end of file”, i.e., a BIN would cause an end of file action to occur. Note that for a network stream, it is possible for both EOPP and READP to be false simultaneously, viz. when there is no input waiting (buffered locally), but the remote end of the stream has not indicated that there is no more input.

There are some who call EOPP on streams open only for output. This is a crock; output streams are always at end of file. But to avoid complaints, a device could return T for EOPP on an output stream.

(BLOCKIN STREAM BUFFER BYTEOFFSET NBYTES)

Performs bulk input transfer: retrieves the next NBYTES bytes from STREAM and stores them in successive byte positions in BUFFER starting at BYTEOFFSET. Defaults to \GENERIC.BINS, which repeatedly calls BIN and PUTBASEBYTE.
It is almost always the case that a device with a non-trivial \texttt{BLOCKIN} method can be made to be a Buffered device, thereby benefiting from other Buffered operations as well.

\begin{verbatim}
(BLOCKOUT STREAM BUFFER BYTEOFFSET NBYTES)

Performs bulk output transfer: outputs \texttt{NBYTES} bytes to \texttt{STREAM}, taking the bytes from \texttt{BUFFER} starting at \texttt{BYTEOFFSET}. Defaults to \texttt{\GENERIC\:BOUTS}, which repeatedly calls \texttt{\GETBASEBYTE} and \texttt{BOUT}.

(FORCEOUTPUT STREAM WAITFORFINISH)

Forces to its ultimate destination any output buffered on \texttt{STREAM} but not yet sent. \texttt{WAITFORFINISH} means that the function should not return until it is confident that the output has reached its destination and been committed. Defaults to \texttt{NIL}, which is reasonable for unbuffered streams.

For example, for a network stream, \textbf{FORCEOUTPUT} sends the current packet being buffered up. For a buffered stream to the disk, \textbf{FORCEOUTPUT} writes out to the disk any "dirty" pages, and makes sure the file is in such a state that if the machine were booted after \textbf{FORCEOUTPUT} returns, that the file could be successfully reopened with no information lost.

(GETFILEINFO NAME/STREAM ATTRIBUTE DEVICE)

Returns the value of the specified \texttt{ATTRIBUTE} of \texttt{NAME/STREAM}, which can be an open Stream or the name of a (closed) file. Returns \texttt{NIL} for attributes it doesn't know about. It is considered good citizenship, though not absolutely required, to know about the following attributes:

- \texttt{LENGTH} Length of the stream/file in bytes. If the device’s method returns \texttt{NIL}, but the stream is random access, the generic \texttt{GETFILEINFO} code tries the device’s \texttt{GETEOPTR} method instead.
- \texttt{SIZE} Length in pages, i.e., \texttt{(FOLDHI length \texttt{BYTESPERPAGE})}.
- \texttt{CREATIONDATE} Date when the file’s contents were created, as a string. The creationdate does not change when a file is copied or renamed, only when it is changed.
- \texttt{WRITEDATE} Date when the file was written to its current place of storage.
- \texttt{READDATE} Date when the file was last read.
- \texttt{ICREATIONDATE, IWRIEDATE, IREADDATE} The creation, write and read dates as integers, such as from the function \texttt{IDATE}.
- \texttt{TYPE} Type of the contents: \texttt{TEXT} for files that contain only "text" (generally meaning 7-bit ascii), \texttt{BINARY} for all others. \texttt{NIL} means unknown.
- \texttt{AUTHOR} Name of the user who created the file (a string).

The following "generic" attributes are generally handled by the generic side of \textbf{GETFILEINFO} if the device’s \textbf{GETFILEINFO} method returns \texttt{NIL}:

- \texttt{EOL} The end of line convention of the stream (\texttt{CR}, \texttt{CRLF} or \texttt{LF}).
- \texttt{BUFFERS} The number of pagemap buffers for use by the stream (see description of \texttt{MAXBUFFERS} field of pagemapped streams).
- \texttt{ENDOFSTREAMOP} Action to take on any attempt to read beyond the end of file. This is a function of one argument, the stream. The function can cause an error, or return
\end{verbatim}
a value, which is interpreted as a value to return from BIN. The default ENDOFSSTREAMOP causes an END OF FILE error.

**ACCESS**  
An atom describing the access mode of the stream (INPUT, OUTPUT, etc). This is so generic that it is handled before the device’s method ever sees it.

**BYTESIZE, OPENBYTESIZE**  
The size of bytes transmitted on the stream. Always 8 these days.

**SETFILEINFO NAME/STREAM ATTRIBUTE VALUE DEVICE**

Sets the value of the specified **ATTRIBUTE** of **NAME/STREAM** to be **VALUE**. Returns T if successful, NIL if unsuccessful, or for attributes it doesn’t know about.

It is not generally required that SETFILEINFO recognize any attributes at all—NILL is a perfectly good filler for this slot. Most devices recognize no more than TYPE and CREATIONDATE (ICREATIONDATE), and even those are not very important, as most applications set those attributes in the PARAMETERS argument to OPENFILE when creating a file.

**ATTRIBUTE = LENGTH** implies actually truncating (or lengthening) the file; however, the SETFILEINFO need not handle this itself—if it returns NIL, then the generic file system will attempt to use the SETEOFPTR method instead.

The following operations are only required of random access streams. They default to the function \IS.NOT.RANDACCESSP, which causes a “Stream is not randaccessp” error when called.

**GETFILEPTR STREAM**

Returns the current file pointer (byte position) in **STREAM**. The file pointer is zero when the stream is opened (except for **ACCESS = APPEND**), and is incremented by one for each byte read.

Although this operation is only absolutely required for random access streams, it is desirable to supply it for other streams where possible. For example, when reading a file sequentially through PupFtp, the stream can count the bytes as they go by and thus give an accurate value for GETFILEPTR. If a stream has no idea at all of position, it can make its GETFILEPTR be the function ZERO and thereby at least avoid breaks from code that calls GETFILEPTR carelessly.

**GETEOFPTR STREAM**

Returns the file pointer of the end of **STREAM**, i.e., the file pointer that GETFILEPTR would return after the last byte of **STREAM** is read. Same as the LENGTH attribute for a stream that represents a file. Of course, non-random access streams may have no idea where the end is, and causing a non-randaccessp error is perfectly acceptable.

**SETFILEPTR STREAM BYTEENUMBER**

Sets the file pointer of **STREAM** to be **BYTEENUMBER**. The special value **BYTEENUMBER = ÿ1** means the end of the stream; other negative values are illegal.

**SETFILEPTR** beyond the end of the stream is permissible, but it has no immediate effect beyond changing the logical file pointer. Attempting to then BIN causes an EOF error. Attempting to BOUT (for a file open for write) should extend the file, so that its eof is immediately beyond the newly BOUTed byte.

As with GETFILEPTR, there is no requirement that this work on non-random access streams, and it may be completely impossible on some of them. However, for those non-random access streams that
perform GETFILEPTR, it is possible to fake SETFILEPTR for values larger than the current file pointer by skipping some number of bytes in the file, e.g., by performing \( \text{RPTQ (DIFFERENCE BYTENUMBER (GETFILEPTR STREAM)) (BIN STREAM)} \). There are some applications for which forward SETFILEPTR is all the random access that is actually required, so it is nice to be able to accommodate such applications.

**(BACKFILEPTR STREAM)**

Backs up the file pointer in \( \text{STREAM} \) by one byte. Functionally the same as \( \text{(SETFILEPTR STREAM (SUB1 (GETFILEPTR STREAM))} \), but may be possible on non-random access streams by maintaining a one-character buffer, which is all the backing up this operation is formally required to perform. I believe the main use for this is in \text{READ}, which needs to back up the stream one character when, for example, it reads a break character terminating an atom.

**(SETEOFPTR STREAM LENGTH)**

Changes the length of \( \text{STREAM} \) to be \( \text{LENGTH} \), i.e., “sets” its end of file pointer. This may require lengthening or truncating the file. Used by the function \text{SETEOFPTR} and by SETFILEINFO for attribute \text{LENGTH} when the device’s SETFILEINFO method doesn’t handle it.

The following three fields are place holders for possible future extensions. These fields are not currently used at all:

**(LASTC STREAM)**

Returns the last character read from \( \text{STREAM} \), i.e., the last byte that was BINed, as a character. LASTC is currently implemented via BACKFILEPTR.

**(FREEPAGECOUNT HOST/DIR DEVICE)**

Intended use is to return the number of free pages on \( \text{HOST/DIR} \). May be folded into a general GET/SET device/directory info operation.

**(MAKEDIRECTORY HOST/DIR DEVICE)**

Intended use is to create a new directory \( \text{HOST/DIR} \).

The remaining fields in the \text{FDEV} are for buffered and page-mapped streams, and are ignored for non-buffered devices. These fields are described in separate sections.

**Streams**

The following fields are used by all streams:

**DEVICE**

Pointer to this stream’s \text{FDEV}.

**FULLFILENAME**

“Full” name by which this file is known to the user. Should be an uppercase litatom, fully qualified so that giving the same name back to the file system should produce the same file (to the extent that the device can support such uniqueness). Is \text{NIL} for unnamed streams.

**FULLNAME**

Access field. Is the same as \text{FULLFILENAME}, unless that is \text{NIL}, in which case it is the stream itself. This avoids the circularity that would result if the \text{FULLFILENAME} field contained the stream datum.
NAMEDP

Access field. Is T if the stream is named, i.e., its FULLFILENAME is non-NIL.

ACCESSBITS

Contains a numeric code describing what access mode the file is open for: there are read, write and append bits. This field is usually accessed indirectly via the ACCESS field. However, there are macros for referring to particular types of access using more efficient bit test operations:

(OPENED STREAM) ACCESS is not NIL.

(READABLE STREAM) Read bit is on: ACCESS is INPUT or BOTH.

(READONLY STREAM) Only the read bit is on: ACCESS is INPUT.

(APPENDABLE STREAM) Append bit is on: ACCESS is OUTPUT, BOTH or APPEND.

(APPENDONLY STREAM) Only the append bit is on: ACCESS is APPEND.

(DIRTYABLE STREAM) Append or write bit is on: ACCESS is OUTPUT, BOTH or APPEND. Yes, this is operationally the same as APPENDABLE, given the four possible values of ACCESS.

(OVERWRITEABLE STREAM) Write bit is on: ACCESS is OUTPUT or BOTH.

(WRITEABLE STREAM) Write bit is on, or append bit is on and file is at EOF. Avoid using this one, it’s a little strange.

ACCESS

Access field for referring to the ACCESSBITS field symbolically. Its value is one of the legal values of the ACCESS argument to OPENFILE: INPUT, OUTPUT, BOTH, APPEND; or NIL when the stream is closed. Replacing this field has the side effect of setting the BINABLE, BOUTABLE, STRMBINFN and STRMBOUTFN fields appropriately (from the corresponding device fields, or to values consistent with no access).

USERCLOSEABLE

Flag, true if the stream can be closed by CLOSEF. Default is T, but is NIL for such things as dribble files and the terminal.

USERVISIBLE

Flag, true if the stream is to be listed in the result of (OPENP). Default is T, but is NIL for such things as dribble files and the terminal.

BINABLE

True if BIN microcode can be used. Normally set automatically from FDBINABLE when input access is set.

BOUTABLE

True if BOUT microcode can be used. Normally set automatically from FDBOUTABLE when output access is set.

EXTENDABLE

True if BOUT can extend the buffer when COFFSET reaches CBFSIZE. Obsolete.

STRMBINFN

Function called by BIN. This is normally set indirectly as a side effect of setting the ACCESS field. Setting ACCESS to an input access (INPUT or BOTH) sets the STRMBINFN to be the stream’s device’s BIN method. Setting to any other access sets the STRMBINFN to be a “file not open” trap.

STRMBOUTFN

Function called by BOUT. As with STRMBINFN, this is normally set indirectly (from the device’s BOUT method) as a side effect of setting the ACCESS field.
OUTCHARFN

Function called to output a single byte. This is like STRMBOUTFN, except for being one level higher: it is intended for text output. Hence, this function should convert (CHARCODE EOL) into the stream’s actual end of line sequence, and should adjust CHARPOSITION appropriately before invoking the stream’s STRMBOUTFN to actually put the character.Defaults to \FILEOUTCHARFN. The OUTCHARFN for the display additionally worries about such things as ECHOCONTROL.

CHARPOSITION

Current horizontal character position in the stream. Incremented (and reset to zero) by OUTCHARFN. Used by the function POSITION.

LINELENGTH

Maximum line length of the stream, in characters. Used by the function LINELENGTH. Defaults (at creation time) to the value of the global variable FILELINELENGTH.

EOLCONVENTION

The stream’s end of line convention: the manner in which “end of line” is encoded on this stream. That is, output of an end of line (function TERPRI) produces the stream’s end of line sequence, and on input, the stream’s end of line sequence is converted to (CHARCODE EOL) by READC. This is not necessarily the same as the way that end of line is encoded in the actual file written by, say, a file server. For example, Lisp might open a stream to a Tenex file server with EOLCONVENTION of CR, while the server might choose to take each of the CRs in the stream and actually store a CR, LF sequence in the physical file.
The convention is encoded as a two-bit field; the constants CR.EOLC, LF.EOLC, CRLF.EOLC can be used to refer to the currently known values symbolically. Default in Interlisp-D is CR.EOLC.

ENDOFSTREAMOP

Function of one argument (the stream) called when an attempt to read beyond the end of file occurs. If this function returns something, it should be interpreted as a value to return from BIN (the value T is currently prohibited). Defaults to \EOSERROR, which causes an END OF FILE error.

VALIDATION

Pointer field, some compact encoding of the state of the file such that if the file’s content changes, the VALIDATION changes. The file’s ICREATIONDATE attribute usually works well enough. The only use for this field is to check whether the file changed over LOGOUT, etc.—if the VALIDATION of the stream returned from REOPENFILE is EQUAL to the VALIDATION of the stream open before LOGOUT, the stream is assumed to be unchanged. This will probably be the sole concern of the device when we go to multiple streams per file.

BYTESIZE

Byte size of the file, i.e., what BIN and BOUT traffic in. Defaults to 8. This field is not used by many; there are probably a lot of things that won’t work if the byte size is not 8.

OTHERPROPS

List in property list format used by the function STREAMPROP. Analogous to WINDOWPROP, etc.

IMAGEOPS

Image operations vector (object of type IMAGEOPS) for use of device-independent graphics operations, such as DSPXPOSITION, DSPFON'T. Defaults to \NOIMAGEOPS, a vector suitably defined for non-display devices. See the implementors’ manual chapter Device-Independent Graphics.

IMAGEDATA

Device-dependent data for use by IMAGEOPS.

REVALIDATEFLG

Flag. The standard use of this flag is to solve a problem with correctly maintaining the creation date. The problem is that the definition of “creation date” is that the creation date changes whenever the contents of the file change. If followed literally, this would mean, for example, that ever time you wrote out a page of a {DSK} file, you would also have to
rewrite its leader page with a new creation date. However, it suffices in practice to only change the creation date when it would matter, i.e., when there would be any possibility of some agent other than the currently running Lisp to see the change. Usually, this means the only time to worry about is when the Lisp vmem is saved and a file that was open before the save is written to again afterwards.

Thus, the use of this flag (for those devices that care) is as follows: the device’s BEFORE.xxx events set this flag true for any streams open on the device. Then, whenever the device is about to do something that would change the file’s content, e.g., write out a new page, it first tests REVALIDATEFLG. If the flag is true, it updates the file’s creation date and clears the flag.

NONDEFAULTDATEFLG Flag. Standard use is in conjunction with REVALIDATEFLG, to mark a file that was opened in a way that the user constrained the creation date of the file (e.g., the PARAMETERS argument to OPENFILE included an explicit creation date, or the option DON’T.CHANGE.DATE).

F1, F2, F3, F4, F5 Pointer fields for private use by the stream, to maintain stream-specific state of concern only to the device. Stream clients that wish to hang information on a stream without regard to what kind of stream it is should use the function STREAMPROP.

FW6, FW7, FW8, FW9 16-bit word fields for private use by the stream.

DIRTYBITS Obsolete.

EXTRASTREAMOP ?

Buffered Streams

Buffered streams are ones that constrain themselves to obey a set of conventions that make it easy for an agent (e.g., microcode) to perform input or output on the stream without knowing about the details of the stream’s physical i/o. The stream maintains a “current buffer” and two indices into that buffer, the offset of the next byte, and the offset of the end of the buffer. As long as the former index is less than the latter, the stream guarantees that the bytes in the buffer between those indices are the true contents of the file/stream starting at the current file pointer. Advancing the first index effectively advances the file pointer. When it reaches the second index, a stream-specific operation is called to “refill” the buffer.

The following fields are used by buffered streams:

COFFSET Byte offset in the buffer CBUFPTR of the next BIN or BOUT.

CBUFSIZE “Size” of the current buffer, i.e., byte offset that is one beyond the last byte.

CBUFMAXSIZE For output, the maximum size the buffer can be written to. If COFFSET reaches CBUFSIZE, but CBUFSIZE is less than CBUFMAXSIZE, then the buffer can be extended.

CBUF PTR Pointer to current buffer. Must be valid if COFFSET is less than CBUFSIZE and BINABLE or BOUTABLE is true. It is not necessary that this “buffer” be anything other than some chunk of memory, a portion of which contains interesting data. Thus, the bytes from offset COFFSET to CBUFSIZE must be valid, but COFFSET need not start at zero, nor need CBUFSIZE or CBUFMAXSIZE coincide with the end of the underlying structure.
CBUFDIRTY  Flag, true if current buffer has been written to.

In general, the device has sole responsibility for setting CBUFSIZE, CBUFMAXSIZE, and CBUFFPTR; generic code does not touch those. The fields COFFSET and CBUFDIRTY can be changed by generic stream clients as well as by device-specific code. For example, code that simulates a BIN increments COFFSET; code that writes directly to the stream’s buffer sets CBUFDIRTY true.

The following methods are defined for devices implementing buffered streams:

(GETNEXTBUFFER  STREAM  WHATFOR  NOERRORFLG)  [Device method]

Called when STREAM needs to have its buffer fixed, i.e., the state of STREAM is such that BIN (WHATFOR = READ) or BOUT (WHATFOR = WRITE) cannot proceed. This method should do whatever is necessary to allow the operation to proceed. This typically includes disposing of the current buffer somehow (if GETNEXTBUFFER was invoked because the buffer was exhausted), and fetching a new buffer consistent with STREAM’s current position.

In the case of WHATFOR = READ, GETNEXTBUFFER returns T on success, i.e., if STREAM is not at end of file. When STREAM is at end of file, GETNEXTBUFFER should take standard end of stream action, returning whatever \EOF.ACTION returns (if anything). However, if NOERRORFLG is true, GETNEXTBUFFER should just return NIL immediately.

(RELEASEBUFFER  STREAM  BUFFER)  [Device method]

Performs any device-specific operation required when BUFFER, which is the current value of STREAM’s CBUFFPTR field, is “released” (when the CBUFFPTR field is replaced). This is used so that different pagemap-like devices can share certain code. For example, in the case of pagemapped streams, RELEASEBUFFER marks the buffer dirty in the case that the stream’s CBUFDIRTY field has been set.

This method is not currently used.

The functions \BUFFERED.BIN, \BUFFERED.PEEKBIN, \BUFFERED.BOUT, \BUFFERED.BINS and \BUFFERED.BOUTS are supplied for use by buffered streams; they are standardly used to implement the BIN, PEEKBIN, BOUT, BLOCKIN and BLOCKOUT device methods. In addition, the function COPYBYTES, when presented with a source stream that is buffered, utilizes the GETNEXTBUFFER method to efficiently copy bytes to the destination a buffer-full at a time.

Pagemapped Streams

Pagemapped streams are a particular kind of random access Buffered stream that buffers its data in units of pages. The device provides methods that read or write data in units of pages, while system-supplied Pagemapped functions handle the responsibilities of a Buffered stream, as well as managing the file pointer for random access. In general, a stream can have several pages of a file buffered at a time, allowing the code to make some effort to make efficient use of multi-paged transfers where applicable.

To create a pagemapped device, create an FDEV, fill in the necessary private fields, then call the following function:

(\MAKE.PMAP.DEVICE DEVICE)  [Function]

Fills in fields in the device appropriate for pagemapped devices, and returns the updated device. The fields it fills are the flag fields FDBINABLE, FDBOUTABLE, RESETABLE, RANDOMACCESSP, PAGEMAPPED, BUFFERED (all true), and the methods BIN, BOUT, PEEKBIN, BLOCKIN, BLOCKOUT,
A Pagemapped device is required to supply the following methods (in addition to those required of all devices and not filled in by `\MAKE.PMAP.DEVICE`):

**(READPAGES STREAM FIRSTPAGE# BUFFERS)**  
Causes pages of `STREAM` to be read into `BUFFERS`. The first page read is `FIRSTPAGE#` (zero for the first page of the file). `BUFFERS` is either a single page-sized buffer (a `VMEMPAGEP`), in which case exactly one page is read, or it is a list of such buffers. `READPAGES` returns the total number of bytes read. If the last page read is not a full page, `READPAGES` should zero out the rest of its buffer. `READPAGES` can assume that the buffers are page-aligned, although they need not be consecutive.

**(WRITEPAGES STREAM FIRSTPAGE# BUFFERS)**  
Writes data from `BUFFERS` out to `STREAM`. The first page written is `FIRSTPAGE#`. `BUFFERS` is as with `READPAGES`.

Neither `READPAGES` nor `WRITEPAGES` affects `STREAM`’s file pointer or end of file; those are managed by higher-level pagemapped routines. `WRITEPAGES` might, however, want to look at `STREAM`’s `EPAGE` and `EOFFSET` fields if it needs to take any special action around the end of the file. It is possible, for no particularly good reason, for `READPAGES` to get called for a page beyond the end of file; in fact, this standardly happens when writing a new file. The `READPAGES` method in this case should just clear the buffer and return zero.

**(TRUNCATEFILE STREAM PAGE# OFFSET)**  
Truncates `STREAM` so that its end of file is `PAGE#`, `OFFSET`, which should be defaulted to `STREAM`’s `EPAGE` and `EOFFSET`. Can be used to either shorten or lengthen a file; if lengthening, the file should be padded with nulls. Used by `\PAGED.SETEOPTR` and `\PAGED.FORCEOUTPUT`. As of this writing there are still bugs in this code in certain funny cases, such as when you SETFILEPTR beyond eof and then BOUT.

The following fields of a stream are meaningful for a pagemapped device. The generic pagemapped codes maintain them as operations on the file are performed, but they should all be initialized appropriately by the device’s `OPENFILE` method:

**CPAGE**  
For pagemapped streams, the current page position in the stream. Together with `COFFSET`, this constitutes the stream’s file pointer. The device’s `OPENFILE` method should set `CPAGE` and `COFFSET` to zero, except for files opened with access `APPEND`, in which case they should be set to the end of file.

**EPAGE, EOFFSET**  
For pagemapped files, the page and byte offset of the end of file. Note that this is the logical end of the file; it need have nothing to do with the physical end of file, except that when a file is closed, the device should see to it that its logical and physical EOFs are the same (normally seen to by the TRUNCATEFILE inside of `\CLEARMAP`, below). In fact, as a typical file is being written, `EPAGE` tends to stay several pages ahead of the physical end of file by virtue of the fact that pages are being buffered before being written out.

**BUFFS**  
For pagemapped streams, a pointer to the stream’s BUFFER chain. Initially NIL (no buffers allocated). The device usually has no direct interest in this field.

**MAXBUFFERS**  
For pagemapped streams, the maximum number of buffers desired in the stream’s `BUFFS` chain. If the code needs another buffer and there are already `MAXBUFFERS` buffers, it will
try to recycle the least recently referenced buffer. Defaults to \STREAM.DEFAULT.MAXBUFFERS. The user can change this field for an open stream by calling SETFILEINFO with attribute BUFFERS.

MULTIBUFFERHINT Flag. For pagemapped streams, is a hint to the pagemap code that the device prefers to transfer data more than one buffer at a time. If this flag is true, the pagemap code tries to write out (WRITEPAGES) more than one buffer at a time when the opportunity arises. A similar improvement is planned, but not implemented, for reading multiple buffers at a time.

The following functions are of use for pagemapped devices:

\PAGED.FORCEOUTPUT STREAM WAITFORFINISH) [Function]

This function implements the FORCEOUTPUT method for pagemapped streams: it causes any dirty pages to be written out (using WRITEPAGES), then calls the TRUNCATEFILE method to set the end of file.

This function is normally installed as the FORCEOUTPUT method by the function \MAKE.PMAP.DEVICE. However, the device can override this default (by supplying its own function in that field), in which case it might want to call the function PAGED.FORCEOUTPUT explicitly as part of its more comprehensive FORCEOUTPUT method.

There is an unpleasantness in the implementation of pagemapped devices that stems from the fact that originally all devices (the few that existed in the distant past) were made to support the PMAP package, a means whereby a programmer could get direct access to the buffers of a file, much as one can with the PMAP JSYS in Tenex. As a result, the buffers used by pagemapped streams are set up in a special manner so that the garbage collector can tell when the user no longer has access to a PMAP buffer. The PMAP package is being phased out.

This is all exceedingly crufty, and is of little concern to the device implementer, except for the fact that it requires that the buffers be explicitly released when a stream is closed; the buffers are not automatically collected when the stream is dropped.

\FORGETPAGES STREAM FROMPAGE TOPAGE) [Function]

“Forgets” pages FROMPAGE thru TOPAGE of STREAM; i.e., removes those pages from the set of pages being currently buffered, and frees the buffers they were occupying. If FROMPAGE = TOPAGE = NIL, forgets all pages, and releases all of STREAM’s buffers.

\CLEARMAP STREAM) [Function]

Performs a FORCEOUTPUT (if STREAM is open for output) followed by a FORGETPAGES. This is the standard action that should be taken by a pagemapped stream’s CLOSEFILE method.

**Directory Enumeration**

This section describes how directory enumeration works—what you need to know in order to implement the GENERATEFILES device method, and what you need to know as a programmer trying to enumerate a directory via anything more elaborate than the function DIRECTORY.

The general idea is that the directory enumeration code is given a pattern, and it returns a generator that, each time it is poked, returns another file name matching the pattern. In addition, the generator provides a handle for getting file attributes of each enumerated file. This second handle is important for efficiency: although one could just take the
file name given by the enumerator and pass it to GETFILEINFO, the device, in the course of enumeration, usually has its fingers on the file closely enough that it need not perform the second directory lookup that a GETFILEINFO out of the blue would require. The caller of the directory enumeration code specifies ahead of time which, if any, attributes will be required (a necessity for most file server implementations).

**Information for device implementors.** A *file generator* is an object represented as a list described by the record FILEGENOBJ, exported from FILEIO:

\[
\text{(RECORD FILEGENOBJ (NEXTFILEFN FILEINFOFN . GENFILESTATE))}
\]

NEXTFILEFN and FILEINFOFN are functions of the device’s choosing that when called will return the next file, and attributes for that file. GENFILESTATE is arbitrary state maintained by the generator. With that as background, here are the pieces of directory enumeration:

\[
\text{(GENERATEFILES } \text{DEVICE } \text{PATTERN } \text{DESIREDPROPS } \text{OPTIONS})
\]

Returns a generator that enumerates files matching PATTERN, which is a string that has host and directories suitably filled in from defaults, and may contain the pattern character ‘*’ to match an arbitrary number of characters. DESIREDPROPS is a list of file attributes that may be requested during the enumeration; they must be valid ATTRIBUTE arguments to GETFILEINFO. OPTIONS is a list of options to the enumeration, chosen from among the following:

- **SORT**
  The files should be enumerated in sorted order. If this option is not specified, the device is free to enumerate files in any convenient order.
  
  There is some question as to whether files should be enumerated lowest version first (as IFS’s do) or highest version first (as Twenex does). I prefer the latter, but given servers that do the former, we currently make no requirement about version order.

- **RESETLST**
  Informs the enumerator that the enumeration context is surrounded by a RESETLST, so that it may perform RESETSAVEs to clean up after itself if the enumeration is aborted. Cleaning up can be a very messy business without this information about the scope of the enumeration, so all callers of \GENERATEFILES\ are strongly encouraged to provide it.

\GENERATEFILES should return a file generator with a suitable NEXTFILEFN and FILEINFOFN.

Fine point about missing fields in the pattern: null fields in PATTERN match only files for which the corresponding field is null. A null version is interpreted as highest. Thus,

- `DIR * = DIR *.*` enumerates everything.
- `DIR *. = DIR *.*` enumerates all versions of files with null extension.
- `DIR *.;` enumerates highest version of files with null extension.
- `DIR *..*` enumerates highest version of everything.

It is difficult for some devices to enumerate only highest version of files; there are several devices in the system that treat a null version the same as version `*`. However, every device should try its best. With some work, any device that can enumerate all versions can enumerate just highest version if it enumerates in sorted order and uses perhaps a little lookahead to assure that any name it returns is the one of highest version.

\[
\text{(NEXTFILEFN GENFILESTATE NAMEONLY)}
\]

[File Generator Component]
Generates the next file, returning its name as a string, or NIL if the generator is exhausted. *GENFILESTATE* is the state component of the file generator returned from GENERATEFILES. *NAMEONLY* means that the caller is only interested in the file’s Name. Ext fields, not the full file name (and no more than one version of the file need be enumerated); however, it is always permissible to return the full file name. The *NAMEONLY* option is used by SPELLFILE.

(FILEINFOFN GENFILESTATE ATTRIBUTE) [File Generator Component]

Returns the value of the *ATTRIBUTE* property of the file most recently generated by the NEXTFILEFN, i.e., effectively (GETFILEINFO latest-name *ATTRIBUTE*), but hopefully much faster. *ATTRIBUTE* must have been a member of the DESIREDPROPS argument to GENERATEFILES.

Not all device implementors are enthused about implementing a pattern matcher for file names. The following functions are provided to help out:

(DIRECTORY.MATCH.SETUP PATTERN) [Function]

Accepts as *PATTERN* a file name string such as passed to GENERATEFILES. Returns an object suitable as a filter to DIRECTORY.MATCH.

(DIRECTORY.MATCH FILTER TESTNAME) [Function]

Matches *TESTNAME*, a file name, against *FILTER*, the object returned from DIRECTORY.MATCH.SETUP. Returns true if *TESTNAME* matches the pattern, false if not. The match is case-insensitive.

(NULLFILEGENERATOR) [Function]

Returns a file generator that produces no files.

(GENERATENOFILES DEVICE PATTERN DESIREDPROPS OPTIONS) [Function]

Returns a “stupid” file generator for devices that don’t know how to enumerate in general. If *PATTERN* contains no wildcards, but names a file that is INFILEP, then the generator produces exactly that file. If *PATTERN* contains a wildcard in the version field, it uses GETFILENAME to laboriously generate all the versions of the file. In all other cases, \GENERATENOFILES returns a null file generator.

Information for clients of device enumeration. The following functions make up the “public” interface to directory enumeration:

(GENERATEFILES PATTERN DESIREDPROPS OPTIONS) [Function]

Returns a file generator object for enumerating the files matching *PATTERN*. *PATTERN* is expanded by adding the default host and/or directory if appropriate. See description of the GENERATEFILES method for description of DESIREDPROPS and OPTIONS.

(GENERATENEXTFILE GENERATOR NAMEONLY) [Function]

Returns the next file, as a string. *GENERATOR* is the object returned from \GENERATEFILES; *NAMEONLY* indicates caller does not require that the full name be returned, but that the name and extension are sufficient.

(GENERATEFILEINFO GENERATOR ATTRIBUTE) [Function]
Returns the value of the \textit{ATTRIBUTE} property of the file most recently generated by \texttt{\\$\GENERATENEXTFILE}, i.e., effectively (\texttt{\GETFILEINFO latest-name \textit{ATTRIBUTE}}). \textit{ATTRIBUTE} must have been a member of the \textit{DESIREDPROPS} argument to \texttt{\\$\GENERATEFILES}.

\texttt{(DIRECTORY.FILL.PATTERN PATTERN DEFAULTTEXT DEFAULTVERS)} \hfill [Function]

This function is used to fill in defaults in \textit{PATTERN} before passing it to \texttt{\\$\GENERATEFILES}. If \textit{PATTERN} does not include an extension or version, but those fields are not explicitly omitted (e.g., "\texttt{\textasciitilde FOO}"', but not "\texttt{\textasciitilde FOO.\textasciitilde}"; "\texttt{\textasciitilde FOO.BAR}"', but not "\texttt{\textasciitilde FOO.BAR.\textasciitilde}"), they are filled in with \textit{DEFAULTTEXT} and \textit{DEFAULTVERS}, which themselves default to "\textasciitilde\textasciitilde". This function is used by the \texttt{DIR} command, and should probably be used by any code that takes a user-supplied pattern and enumerates files from it.
This paper is a list of issues and alternatives to designing and implementing TEDIT behind EXEC windows.

KNOWN ISSUES TO BE SOLVED

1. Certain functions which normally expect a display stream as the argument have to be changed to accept a textstream as a valid type of stream (or whatever kind of stream it ends up being, for now I will refer to it as a TEDITSTREAM). Some example functions are TTYDISPLAYSTREAM, (or whatever mechanism we use to replace WFROMDS functionality).

2. There has to be a place holder or mechanism by which it is know to TEDIT where the already processed text ends, and the current edible text starts and where/when it becomes processed, so that unprocessed may be edited and already processed input may not be.

3. The input may be different or at least have different "looks" (echoing) than the output. Examples, raising lower case to upper case; confirmation by carriage return may be replaced by "Yes" in the output stream, etc. How do we handle this?

4. Other functionality of TTYIN which at the time of this writing I am not yet familiar yet.

5. To what level do we support display stream graphic operations, such as MOVETO, DRAWLINE, clippingregion, XY coordinates, etc. Do we just paint graphics and don't capture them in any way, do we create imageobjects, or what?

6. Should we support two kinds of EXEC, one which uses the display stream to insure that all old programs will work as before, and a new type of EXEC which uses TEDITSTREAMS.

7. Do we implement this in one window in which it operates as one TEDITSTREAM, or do use a readonly TEDITSTREAM for backing, and use a separate window below the TEDIT window (with no border) to contain the current text which would use TTYIN to do the editing.

One advantage to implementing it as one TEDITSTREAM is that we could provide one standard method of backing display streams and handling text (ie, change the standard TEDIT interface to work this way) and possibly eliminate duplication of code such as TTYIN, thus making the system easier to maintain. On the other hand, it may turn out, that trying to handle this case as a general case in TEDIT is too envolved or too slow, and keeping them in two separate windows makes more sense.
Venue MEDLEY LANGUAGE REFERENCE
1. INTRODUCTION

Medley is a programming system that consists of a programming language, a large number of predefined programs (or functions) that you can use directly or as subroutines, and an environment that supports you with a variety of specialized programming tools. The language and predefined functions of Lisp are rich, but similar to those of other modern programming languages. The Medley programming environment, on the other hand, is very distinctive. Its main feature is an integrated set of programming tools that know enough about Interlisp and Common Lisp to act as semi-autonomous, intelligent "assistants" to you. This environment provides a completely self-contained world for creating, debugging and maintaining Lisp programs.

This manual describes all three parts of Medley. There are discussions of the language, about the pieces of the system that can be incorporated into your programs, and about the environment. The line between your code and the environment is thin and changing. Most users extend the environment with some special features of their own. Because Medley is so easily extended, the system has grown over time to incorporate many different ideas about effective and useful ways to program. This gradual accumulation over many years has resulted in a rich and diverse system. It is also the reason this manual is so large.

The rest of this manual describes the individual pieces of Medley; this chapter describes system as a whole—including the otherwise-unstated philosophies that tie it all together. It will give you a global view of Medley.

Lisp as a Programming Language

This manual is not an introduction to programming in Lisp. This section highlights a few key points about lisp that will make the rest of the manual clear.

In Lisp, large programs (or functions) are built up by composing the results of smaller ones. Although Medley, like most modern Lisps, lets you program in almost any style you can imagine, the natural style of Lisp is functional and recursive—each function computes its result by calling lower-level “building-block” functions, then passing that result back to its caller (rather than by producing “side-effects” on external data structures, for example).

Lisp is also a list-manipulation language. Like other languages, Lisp can process characters and numbers. But you get more power if you program at a higher level. The primitive data objects of Lisp are “atoms” (symbols or identifiers) and “lists” (sequences of atoms or lists), which you use to represent information and relationships. Each Lisp dialect has a set of operations that act on atoms and lists, and these operations comprise the core of the language.

Invisible in the programs, but essential to the Lisp style of programming, is an automatic memory management system (an “allocator” and a “garbage collector”). New storage is allocated automatically whenever you create a new data object. And that storage is automatically reclaimed for reuse when no other object refers to it. Automated memory management is essential for rapid,
large-scale program development because it frees you from the task of maintaining the details of memory administration, which change constantly during rapid program evolution.

A key property of Lisp is that Lisp function definitions are just pieces of Lisp list data. Each subfunction "call" (or function application) is written as a list with the function first, followed by its arguments. Thus, \( (\text{PLUS } 1 \ 2) \) represents the expression \( 1+2 \). A function's definition, then, is just a list of such function applications, to be evaluated in order. This representation of program as data lets you use the same operations on programs that you use on data—making it very easy to write Lisp programs that look at and change other Lisp programs. This, in turn, makes it easy to develop programming tools and translators, which was essential to the development of the Medley environment.

The most important benefit of this is that you can extend the Lisp programming language itself. Do you miss some favorite programming idiom? Just define a function that translates the desired expression into simpler Lisp. Now your idiom is part of the language. Medley has extensive facilities for making this type of language extension. Using this ability to extend itself, Interlisp has incorporated many of the constructs that have been developed in other modern programming languages (e.g. if-then-else, do loops, etc.).

**Medley as an Interactive Environment**

Medley programs should not be thought of as simple files of source code. All Medley programming takes place within the Medley environment, which is a completely self-sufficient environment for developing and using Medley programs. Beyond the obvious programming facilities (e.g., program editors, compilers, debuggers, etc.), the environment also contains a variety of tools that "keep track" of what happens. For example, the Medley File Manager notices when programs or data have been changed, so the system will know what needs to be saved at the end of a session. The "residential" style, where you stay inside the environment throughout the development, is essential for these tools to operate. Furthermore, this same environment is available to support the final production version, some parts providing run time support and other parts being ignored until the need arises for further debugging or development.

For terminal interaction, Medley provides a top level "Read-Eval-Print" executive, which reads whatever you type in, evaluates it, and prints the result. (This interaction is also recorded, so you can ask to do an action again, or even to undo the effects of a previous action.) Although Executives understand some specialized commands, most of the interaction will consist of simple Lisp expressions. So rather than special commands for operations like manipulating your files, you just type the same expressions that you would use to accomplish them in a Lisp program. This creates a very rich, simple, and uniform set of interactive commands, since any Lisp expression can be typed at an executive and evaluated immediately.

In normal use, you write a program (or rather, "define a function") by typing in an expression that invokes the "function defining" function \( \text{(DEFINEQ)} \), giving it the name of the function being defined and its new definition. The newly-defined function can be executed immediately, simply by using it in a Lisp expression.
In addition to these basic programming tools, Medley also provides a wide variety of programming support mechanisms:

List structure editor Since Lisp programs are represented as list structure, Medley provides an editor which allows one to change the list structure of a function’s definition directly. See Chapter 16.

Pretty-printer The pretty printer is a function that prints Lisp function definitions so that their syntactic structure is displayed by the indentation and fonts used. See page Chapter 26.

Debugger When errors occur, the debugger is called, allowing you to examine and modify the context at the point of the error. Often, this lets you continue execution without starting from the beginning. Within a break, the full power of Interlisp is available to you. Thus, the broken function can be edited, data structures can be inspected and changed, other computations carried out, and so on. All of this occurs in the context of the suspended computation, which remains available to be resumed. See Chapter 14.

DWIM The “Do What I Mean” package automatically fixes misspellings and errors in typing. See Chapter 20.

Programmer’s Assistant Medley keeps track of your actions during a session and allows each one to be replayed, undone, or altered. See Chapter 13.

Masterscope Masterscope is a program analysis and management tool which can analyze users’ functions and build (and automatically maintain) a data base of the results. This allows you to ask questions like “WHO CALLS ARCTAN” or “WHO USES COEF1 FREELY” or to request systematic changes like “EDIT WHERE ANY [function] FETCHES ANY FIELD OF [the data structure] FOO”. See Chapter 19.

Record/Datatype Package Medley allows you to define new data structures. This enables one to separate the issues of data access from the details of how the data is actually stored. See Chapter 8.

File Manager Source code files in Medley are managed by the system, removing the problem of ensuring timely file updates from the user. The file manager can be modified and extended to accommodate new types of data. See Chapter 17.

Performance Analysis These tools allow statistics on program operation to be collected and analyzed. See Chapter 22.

Multiple Processes Multiple and independent processes simplify problems which require logically separate pieces of code to operate in parallel. See Chapter 23.
Windows The ability to have multiple, independent windows on the display allows many different processes or activities to be active on the screen at once. See Chapter 28.

Inspector The inspector is a display tool for examining complex data structures encountered during debugging. See Chapter 26.

These facilities are tightly integrated, so they know about and use each other, just as they can be used by user programs. For example, Masterscope uses the structural editor to make systematic changes. By combining the program analysis features of Masterscope with the features of the structural editor, large scale system changes can be made with a single command. For example, when the lowest-level interface of the Medley I/O system was changed to a new format, the entire edit was made by a single call to Masterscope of the form EDIT WHERE ANY CALLS '(BIN BOUT ...). [Burton et al., 1980] This caused Masterscope to invoke the editor at each point in the system where any of the functions in the list '(BIN BOUT ...) were called. This ensured that no functions used in input or output were overlooked during the modification.

Philosophy

Medley's extensive environmental support has developed over the years to support a particular style of programming called "exploratory programming" [Sheil, 1983]. For many complex programming problems, the task of program creation is not simply one of writing a program to fulfill specifications. Instead, it is a matter of exploring the problem (trying out various solutions expressed as partial programs) until one finds a good solution (or sometimes, any solution at all!). Such programs are by nature evolutionary; they are transformed over time from one realization to another in response to a growing understanding of the problem. This point of view has lead to an emphasis on having the tools available to analyze, alter, and test programs easily. One important aspect of this is that the tools be designed to work together in an integrated fashion, so that knowledge about the user's programs, once gained, is available throughout the environment.

The development of programming tools to support exploratory programming is itself an exploration. No one knows all the tools that will eventually be found useful, and not all programmers want all of the tools to behave the same way. In response to this diversity, Interlisp has been shaped, by its implementors and by its users, to be easily extensible in several different ways. First, there are many places in the system where its behavior can be adjusted by the user. One way that this can be done is by changing the value of various "flags" or variables whose values are examined by system code to enable or suppress certain behavior. The other is where the user can provide functions or other behavioral specifications of what is to happen in certain contexts. For example, the format used for each type of list structure when it is printed by the pretty-printer is determined by specifications that are found on the list PRETTYPRINTMACROS. Thus, this format can be changed for a given type simply by putting a printing specification for it on that list.

Another way in which users can affect Medley's behavior is by redefining or changing system functions. The "Advise" capability, for instance, lets you modify the operation of virtually any function in the system by wrapping code "around" the selected function. (This same philosophy extends to breaking and tracing, so almost any function in the system can be broken or traced.) Since
the entire system is implemented in Lisp, there are few places where the system’s behavior depends on anything that you can’t modify (such as a low level system implementation language).

While these techniques provide a fair amount of tailorability, there’s a price: Medley is complex. There are many flags, parameters, and controls that affect its behavior. Because of this complexity, Interlisp tends to be more comfortable for experts, rather than casual users. Beginning users of Interlisp should depend on the default settings of parameters until they learn what dimensions of flexibility are available. At that point, they can begin to “tune” the system to their preferences.

Appropriately enough, even Medley’s underlying philosophy was itself discovered during Medley’s development, rather than laid out beforehand. The Medley environment and its interactive style were first analyzed in Sandewall’s excellent paper [Sandewall, 1978]. The notion of “exploratory programming” and the genesis of the Interlisp programming tools in terms of the characteristic demands of this style of programming was developed in [Sheil, 1983]. The evolution and structure of the Interlisp programming environment are discussed in greater depth in [Teitelman & Masinter, 1981].

How to Use this Manual

This document is a reference manual, not a primer. We have tried to provide a manual that is complete, and that lets you find particular items as easily as possible. Sometimes, these goals have been achieved at the expense of simplicity. For example, many functions have a number of arguments that are rarely used. In the interest of providing a complete reference, these arguments are fully explained, even though you will normally let them default. There is a lot of information in this manual that is of interest only to experts.

Do not try to read straight through this manual, like a novel. In general, the chapters are organized with overview explanations and the most useful functions at the beginning of the chapter, and implementation details towards the end. If you are interested in becoming acquainted with Medley, we urge you to work through An Introduction to Medley before attempting this manual.

A few comments about the notational conventions used in this manual:

Lisp object notation: All Interlisp objects in this manual are printed in the same font: Functions (AND, PLUS, DEFINEQ, LOAD); Variables (MAX.INTEGER, FILELST, DFNFLG); and arbitrary Interlisp expressions: (PLUS 2 3), (PROG ((A 1)) ...), etc.

Case is significant: In Interlisp, upper and lower case is significant. The variable FOO is not the same as the variable foo or the variable Foo. By convention, most Interlisp system functions and variables are all uppercase, but users are free to use upper and lower case for their own functions and variables as they wish.

One exception to the case-significance rule is provided by the CLISP facility, which lets you type iterative statements and record operations in either all uppercase or all lowercase letters: (for X
from 1 to 5 ...) is the same as (FOR X FROM 1 TO 5 ...) The few situations where this is the case are explicitly mentioned in the manual. Generally, assume that case is significant.

This manual contains a large number of descriptions of functions, variables, commands, etc, which are printed in the following standard format:

\[ \text{[Function]} \]

This is a description for the function named \text{FOO}. \text{FOO} has two arguments, \text{BAR} and \text{BAZ}. Some system functions have extra optional arguments that are not documented and should not be used. These extra arguments are indicated by "—".

The descriptor [Function] indicates that this is a function, rather than a [Variable], [Macro], etc. For function definitions only, this can also indicate whether the function takes a fixed or variable number of arguments, and whether the arguments are evaluated or not. [Function] indicates a lambda spread function (fixed number of arguments, evaluated), the most common type.

References

2. SYMBOLS (LITATOMS)

A litatom (for “literal atom”) is an object that conceptually consists of a print name, a value, a function definition, and a property list. Litatoms are also known as “symbols” in Common Lisp. For clarity, we will use the term “symbol”.

A symbol is read as any string of non-delimiting characters that cannot be interpreted as a number. The syntactic characters that delimit symbols are called “separator” or “break” characters (see Chapter 25) and normally are space, end-of-line, line-feed, left parenthesis (, right parenthesis ), double quote ”, left square bracket [, and right square bracket ]. However, any character may be included in a symbol by preceding it with the character %.

Here are some examples of symbols:

A wxyz 23SKIDOO %]
Long% Litatom% With% Embedded% Spaces

(LITATOM X) [Function]
Returns T if X is a symbol, NIL otherwise. Note that a number is not a symbol.

(LITATOM NIL) = T

(ATOM X) [Function]
Returns T if X is an atom (i.e., a symbol or a number) or NIL (e.g. (ATOM NIL) = T); otherwise returns NIL.

Warning: (ATOM X) is NIL if X is an array, string, etc. In Common Lisp, the function CL:ATOM is defined equivalent to the Interlisp function NLISTP.

Each symbol has a print name, a string of characters that uniquely identifies that symbol: Those characters that are output when the symbol is printed using PRIN1, e.g., the print name of the symbol ABC% (D consists of the five characters ABC (D.

Symbols are unique: If two symbols print the same, they will always be EQ. Note that this is not true for strings, large integers, floating-point numbers, etc.: they all can print the same without being EQ.

Thus, if PACK or MKATOM is given a list of characters corresponding to a symbol that already exists, they return a pointer to that symbol, and do not make a new symbol. Similarly, if the read program is given as input a sequence of characters for which a symbol already exists, it returns a pointer to that symbol.

Symbol names are limited to 255 characters. Attempting to create a larger symbol will cause an error: Atom too long.

Sometimes we’ll refer to a “PRIN2-name”. The PRIN2-name of a symbol is those characters output when it is printed using PRIN2. So the PRIN2-name of the symbol ABC% (D is the six characters ABC (D. The PRIN2-name depends on what readable is being used (see Chapter 25), since this determines where %s will be inserted. Many of the functions below allow either print names or PRIN2-names to be used, as specified by FLG and RDTBL arguments. If FLG is NIL, print names are used. Otherwise, PRIN2-names are used, computed with respect to the readable RDTBL (or the current readable, if RDTBL = NIL).
(MKATOM X)  [Function]

Creates and returns a symbol whose print name is the name as that of the string X or, if X
is not a string, the same as that of (MKSTRING X). Examples:

(MKATOM '(A B C)) => (%(A% B% C%)
(MKATOM "1.5") => 1.5

Note that the last example returns a number, not a symbol. It is a deeply-ingrained
feature of Interlisp that no symbol can have the print name of a number.

(SUBATOM X N M)  [Function]

Returns a symbol made from the Nth through Mth characters of the print name of X. If N or
M are negative, they specify positions counting backwards from the end of the print name.
Equivalent to (MKATOM (SUBSTRING X N M)). Examples:

(SUBATOM "FOO1.5BAR" 4 6) => 1.5
(SUBATOM '(A B C) 2 -2) => A% B% C

(PACK X)  [Function]

If X is a list of symbols, PACK returns a single symbol whose print name is the
concatenation of the print names of the symbols in X. If the concatenated print name is
the same as that of a number, PACK returns that number. For example:

(PACK '(A BC DEF G)) => ABCDEFG
(PACK '(1 3.4)) => 13.4
(PACK '(1 E -2)) => .01

Although X is usually a list of symbols, it can be a list of arbitrary objects. The value of
PACK is still a single symbol whose print name is the concatenation of the print names of
all the elements of X, e.g.,

(PACK '((A B) "CD")) => (%(A% B%)CD

If X is not a list or NIL, PACK generates the error Illegal arg.

(PACK* X₁ X₂... Xₙ)  [NoSpread Function]

Version of PACK that takes an arbitrary number of arguments, instead of a list. Examples:

(PACK* 'A 'BC 'DEF 'G => ABCDEFG
(PACK* 1 3.4)) => 13.4

(GENSYM PREFIX -- -- -- )  [Function]

Returns a symbol of the form Xnnnn, where X = PREFIX (or A if PREFIX is NIL) and
nnnn is an integer. Thus, the first one generated is A0001, the second A0002, etc. The
integer suffix is always at least four characters long, but it can grow beyond that. For
example, the next symbol produced after A9999 would be A10000. GENSYM provides a
way of generating symbols for various uses within the system.

Note: The Common Lisp function CL:GENSYM is not the same as Interlisp’s GENSYM.
Interlisp always creates interned symbols whereas CL:GENSYM creates uninterned
symbols.
GENNUM

The value of GENNUM, initially 0, determines the next GENSYM, e.g., if GENNUM is set to 23, (GENSYM) = A0024.

The term "gensym" is used to indicate a symbol that was produced by the function GENSYM. Symbols generated by GENSYM are the same as any other symbols: they have property lists, and can be given function definitions. The symbols are not guaranteed to be new. For example, if the user has previously created A0012, either by typing it in, or via PACK or GENSYM itself, then if GENNUM is set to 11, the next symbol returned by GENSYM will be the A0012 already in existence.

(MAPATOMS FN)

Applies FN (a function or lambda expression) to every symbol in the system. Returns NIL. For example:

(MAPATOMS (FUNCTION (LAMBDA(X) (if (GETD X) then (PRINTX)))

will print every symbol with a function definition.

Warning: Be careful if FN is a lambda expression or an interpreted function: since NOBIND is a symbol, it will eventually be passed as an argument. The first reference to that argument within the function will signal an error.

A way around this problem is to use a Common Lisp function, so that the Common Lisp interpreter will be invoked. It will treat the argument as local, not special and no error will be signaled. An alternative solution is to include the argument to the Interlisp function in a LOCALVARS declaration and then compile the function before passing it to MAPATOMS. This will significantly speed up MAPATOMS.

(APROPOS STRING ALLFLG QUITFLG OUTPUT)

APROPOS scans all symbols in the system for those which have STRING as a substring and prints them on the terminal along with a line for each relevant item defined for each selected symbol. Relevant items are:

• function definitions, for which only the arglist is printed
• dynamic variable values
• non-null property lists

PRINTLEVEL (see Chapter 25) is set to (3 . 5) when APROPOS is printing.

If ALLFLG is NIL, then symbols with no relevant items and "internal" symbols are omitted ("internal" currently means those symbols whose print name begins with a \ or those symbols produced by GENSYM). If ALLFLG is a function, it is used as a predicate on symbols selected by the substring match, with value NIL meaning to omit the symbol. If ALLFLG is any other non-NIL value, then no symbols are omitted.

Note: Unlike CL:APROPOS which lets you designate the package to search, APROPOS searches all packages.
Using Symbols as Variables

Symbols are commonly used as variable names. Each symbol has a “top level” value, which can be an arbitrary object. Symbols may also be given special variable bindings within PROGS or functions, which only exist for the duration of the function. When a symbol is evaluated, the “current” variable binding is returned. This is the most recent special variable binding, or the top-level binding if the symbol hasn’t been rebound. SETQ is used to change the current binding. For more information on variable bindings in Interlisp, see Chapter 11.

A symbol whose top-level value is the symbol NOBIND is considered to have no value. If a symbol has no local bindings, and its top-level value is NOBIND, trying to evaluate it will cause an unbound-atom error. In addition, if a symbol’s local binding is to NOBIND, trying to evaluate it will cause an error.

The symbols T and NIL always evaluate to themselves. Attempting to change the value of T or NIL with the functions below will generate the error; Attempt to set T or Attempt to set NIL.

The following functions (except BOUNDP) will also generate the error Arg not litatom, if not given a symbol.

(BOUNDP VAR) [Function]
Returns T if VAR has a special variable binding, or if VAR has a top-level value other than NOBIND; otherwise NIL. That is, if X is a symbol, (EVAL X) will cause an Unbound atom error if and only if (BOUNDP X) returns NIL.

Note: The Interlisp interpreter has been modified so that it will generate an Unbound Variable error when it encounters any symbol bound to NOBIND. This is a change from previous releases that only signaled an error when a symbol had a top-level binding of NOBIND in addition to no dynamic binding.

(SET VAR VALUE) [NoSpread Function]
Sets the “current” value of VAR to VALUE, and returns VALUE.

SET is a normal function, so both VAR and VALUE are evaluated before it is called. Thus, if the value of X is B, and value of Y is C, then (SET X Y) would result in B being set to C, and C being returned as the value of SET.

(SETQ VAR VALUE) [NoSpread Function]
Like SET, but VAR is not evaluated, VALUE is. Thus, if the value of X is B and the value of Y is C, (SETQ X Y) would result in X (not B) being set to C, and C being returned.

Actually, neither argument is evaluated during the calling process. However, SETQ itself calls EVAL on its second argument. As a result, typing (SETQ VAR FORM) and SETQ (VAR FORM) to the Interlisp Executive are equivalent: in both cases VAR is not evaluated, and FORM is.

(SETQQ VAR VALUE) [NoSpread Function]
Like SETQ, but neither argument is evaluated, e.g., (SETQQ X (A B C)) sets X to (A B C).
SYMBOLS (LITATOMS)

(PSETQ VAR₁ VALUE₁ ... VARₙ VALUEₙ)  [Macro]

Does a SETQ in parallel of VAR₁ (unevaluated) to VALUE₁, VAR₂ to VALUE₂, etc. All of the VALUEᵢ terms are evaluated before any of the assignments. Therefore, (PSETQ A B B A) can be used to swap the values of the variables A and B.

(GETTOPVAL VAR)  [Function]

Returns the top level value of VAR (even if NOBIND), regardless of any intervening local bindings.

(SETTOPVAL VAR VALUE)  [Function]

Sets the top level value of VAR to VALUE, regardless of any intervening bindings, and returns VALUE.

(GETATOMVAL VAR)  [Function]

Same as (GETTOPVAL VAR).

(SETATOMVAL VAR VALUE)  [Function]

Same as SETTOPVAL.

Note: The compiler (see Chapter 18) treats variables somewhat differently from the interpreter, and you need to be aware of these differences when writing functions that will be compiled. For example, variable references in compiled code are not checked for NOBIND, so compiled code will not generate unbound-atom errors. In general, it is better to debug interpreted code before compiling it for speed. The compiler offers some facilities to increase the efficiency of variable use in compiled functions: Global variables can be defined so that the entire stack is not searched at each variable reference. Local variables have bindings that are not visible outside the function, which reduces variable conflicts and makes variable lookup faster.

Function Definition Cells

Each symbol has a function-definition cell, which is accessed when that symbol is used as a function. This is described in detail in Chapter 10.

Property Lists

Each symbol has an associated property list, which allows a set of named objects to be associated with the symbol. A property list associates a name (known as a “property name” or “property”) with an arbitrary object (the “property value” or “value”). Sometimes the phrase “to store on the property X” is used, meaning to place the indicated information on a property list under the property name X.

Property names are usually symbols or numbers, although no checks are made. However, the standard property list functions all use EQ to search for property names, so they may not work with non-atomic property names. The same object can be used as both a property name and a property value.

Many symbols in the system already have property lists, with properties used by the compiler, the break package, DWIM, etc. Be careful not to clobber such system properties. The variable SYSPROPS is a list of property names used by the system.
The functions below are used to manipulate the property lists of symbols. Except when indicated, they generate the error ATM is not a SYMBOL if given an object that is not a symbol.

\[\text{(GETPROP \ ATM \ PROP)}\]

Returns the property value for PROP from the property list of ATM. Returns NIL if ATM is not a symbol, or PROP is not found. GETPROP also returns NIL if there is an occurrence of PROP but the corresponding property value is NIL. This can be a source of program errors.

Note: GETPROP used to be called GETP.

\[\text{(PUTPROP \ ATM \ PROP \ VAL)}\]

Puts the property PROP with value VAL on the property list of ATM. VAL replaces any previous value for the property PROP on this property list. Returns VAL.

\[\text{(ADDPROP \ ATM \ PROP \ NEW \ FLG)}\]

Adds the value NEW to the list which is the value of property PROP on the property list of the ATM. If FLG is T, NEW is CONSed onto the front of the property value of PROP; otherwise, it is NCONCed on the end (using NCONC1). If ATM does not have a property PROP, or the value is not a list, then the effect is the same as \((\text{PUTPROP \ ATM \ PROP \ (LIST NEW)})\). ADDPROP returns the (new) property value. Example:
\[
\begin{align*}
\text{← (PUTPROP ‘POCKET ‘CONTENTS NIL)} \\
\text{NIL) } \\
\text{← (ADDPROP ‘POCKET ‘CONTENTS ‘COMB)} \\
\text{COMB) } \\
\text{← (ADDPROP ‘POCKET ‘CONTENTS ‘WALLET)} \\
\text{COMB WALLET) }
\end{align*}
\]

\[\text{(REMPROP \ ATM \ PROP)}\]

Removes all occurrences of the property PROP (and its value) from the property list of ATM. Returns PROP if any were found (T if PROP is NIL), otherwise NIL.

\[\text{(CHANGEPROP \ X \ PROP1 \ PROP2)}\]

Changes the property name of property PROP1 to PROP2 on the property list of X (but does not affect the value of the property). Returns X, unless PROP1 is not found, in which case it returns NIL.

\[\text{(PROP NAMES \ ATM)}\]

Returns a list of the property names on the property list of ATM.

\[\text{(DEFLIST \ L \ PROP)}\]

Used to put values under the same property name on the property lists of several symbols. L is a list of two-element lists. The first element of each is a symbol, and the second element is the property vvalue of the property PROP. Returns NIL. For example:
\[
\begin{align*}
\text{DEFLIST ‘((FOO MA) (BAR CA) (BAZ RI)) ‘STATE)
\end{align*}
\]
puts MA on FOO’s STATE property, CA on BAR’s STATE property, and RI on BAZ’s STATE property.

Property lists are conventionally implemented as lists of the form

\[(NAME_1 \ VALUE_1 \ NAME_2 \ VALUE_2 \ldots)\]

although the user can store anything as the property list of a symbol. However, the functions which manipulate property lists observe this convention by searching down the property lists two CDRs at a time. Most of these functions also generate the error Arg not litatom if given an argument which is not a symbol, so they cannot be used directly on lists. (LISTPUT, LISTPUT1, LISTGET, and LISTGET1 are functions similar to PUTPROP and GETPROP that work directly on lists (see Chapter 3). The property lists of symbols can be directly accessed with the following functions.

\[(GETPROPLIST \ ATM)\]  

Returns the property list of \(ATM\).

\[(SETPROPLIST \ ATM \ LST)\]  

If \(ATM\) is a symbol, sets the property list of \(ATM\) to be \(LST\), and returns \(LST\) as its value.

\[(GETLIS \ X \ PROPS)\]  

Searches the property list of \(X\), and returns the property list as of the first property on \(PROPS\) that it finds. For example:

\[
\leftrightarrow (GETPROPLIST 'X) \\
(PROP1 A PROP3 B A C) \\
\leftrightarrow (GETLIS 'X '(PROP2 PROP3)) \\
(PROP3 B A C)
\]

Returns NIL if no element on props is found. \(X\) can also be a list itself, in which case it is searched as described above. If \(X\) is not a symbol or a list, returns NIL.

\[(REMPROPLIST \ ATM \ PROPS)\]  

Removes all occurrences of all properties on the list \(PROPS\) (and their corresponding property values) from the property list of \(ATM\). Returns NIL.

**Print Names**

The term “print name” has an extended meaning: The characters that are output when any object is printed. In Medley, all objects have print names, although only symbols and strings have their print names explicitly stored. Symbol print names are limited to 255 characters.

This section describes a set of functions that can be used to access and manipulate the print names of any object, though they are primarily used with the print names of symbols. In Medley, print functions qualify symbol names with a package prefix if the symbol is not accessible in the current package. The exception is Interlisp’s \texttt{PRIN1}, which does not include a package prefix.

The print name of an object is those characters that are output when the object is printed using \texttt{PRIN1}, e.g., the print name of the list \((A \ B \ "C")\) consists of the seven characters \((A \ B \ C)\) (two of the characters are spaces).
The PRIN2-name of an object is those characters output when the object is printed using PRIN2. Thus the PRIN2-name of the list (A B "C") is the 9 characters (A B "C") (including the two spaces). The PRIN2-name depends on what readtable is being used (see Chapter 25), since this determines where %s will be inserted. Many of the functions below allow either print names of PRIN2-names to be used, as specified by FLG and RDTBL arguments. If FLG is NIL, print names are used. Otherwise, PRIN2-names are used, computed with respect to the readtable RDTBL (or the current readtable, if RDTBL = NIL).

The print name of an integer depends on the setting of RADIX (see Chapter 25). The functions described in this section (UNPACK, NCHARS, etc.) define the print name of an integer as though the radix was 10, so that (PACK (UNPACK 'X9)) will always be X9 (and not X11, if RADIX is set to 8). However, integers will still be printed by PRIN1 using the current radix. The user can force these functions to use print names in the current radix by changing the setting of the variable PRXFLG (see Chapter 25).

(CL::SYMBOL-NAME SYM) [Common Lisp Function]
Returns a string displaced to the SYM print name. Strings returned from CL::SYMBOL-NAME may be destructively modified without affecting SYM's print name.

(NCHARS X FLG RDTBL) [Function]
Returns the number of characters in the print name of X. If FLG = T, the PRIN2-name is used. Examples:
  (NCHARS 'ABC) => 3
  (NCHARS "ABC" T) => 5

NCHARS works most efficiently on symbols and strings, but can be given any object.

(NTHCHAR X N FLG RDTBL) [Function]
Returns X, if X is a tail of the list Y; otherwise NIL. X is a tail of Y if it is EQ to 0 or more CDRs of Y.
  (NTHCHAR 'ABC 2) => B
  (NTHCHAR 15.6 2) => 5
  (NTHCHAR 'ABC%(D -3 T) => %
  (NTHCHAR "ABC" 2) => B
  (NTHCHAR "ABC" 2 T) => A

NTHCHAR and NCHARS work much faster on objects that actually have an internal representation of their print name, i.e., symbols and strings, than they do on numbers and lists, since they don’t have to simulate printing.

(L-CASE X FLG) [Function]
Returns a lowercase version of X. If FLG is T, the first letter is capitalized. If X is a string, the value of L-CASE is also a string. If X is a list, L-CASE returns a new list in which L-CASE is computed for each corresponding element and non-NIL tail of the original list. Examples:
  (L-CASE 'FOO) => foo
  (L-CASE 'FOO T) => Foo
  (L-CASE "FILE NOT FOUND" T) => "File not found"
SYMBOLS (LITATOMS)

(L-CASE '(JANUARY FEBRUARY (MARCH "APRIL")) T) => '(January February (March "April"))

(U-CASE X) [Function]

Like L-CASE, but returns the uppercase version of X.

(U-CASEP X) [Function]

Returns T if X contains no lowercase letters; NIL otherwise.

Characters and Character Codes

Characters are represented 3 different ways in Medley. In Interlisp they are single-character symbols or integer character codes. In Common Lisp they are instances of the CHARACTER datatype. In general Interlisp character functions don’t accept Common Lisp characters and vice versa. The only exceptions are Interlisp string-manipulation functions that accept “string or symbol” types as arguments.

You can convert between Interlisp and Common Lisp characters by using the functions CL:CODE-CHAR, CL:CHAR-CODE, and CHARCODE (see below).

Medley uses the 16-bit NS character set, described in the document Character Code Standard (Xerox System Integration Standards, XSIS 058404, April 1984). Legal character codes range from 0 to 65535. The NS (Network Systems) character encoding encompasses a much wider set of available characters than the 8-bit character standards (such as ASCII), including characters comprising many foreign alphabets and special symbols. For instance, Medley supports the display and printing of the following:

• Le système d’information Medley est remarquablement polyglotte
• Das Medley Kommunikationssystem bietet merkwürdige multilinguale Nutznmöglichkeiten
• $M \subseteq \mathcal{Q} [w] \Leftrightarrow \forall v \text{ with } Rwv: M \subseteq [v]$

These characters can be used in strings, symbol print names, symbolic files, or anywhere else 8-bit characters could be used. All of the standard string and print name functions (RPLSTRING, GNC, NCHARS, STRPOS, etc.) accept symbols and strings containing NS characters. For example:

\[
\begin{align*}
&\Rightarrow (\text{STRPOS "char""this is an 8-bit character string"}) \\
&\quad 18 \\
&\Rightarrow (\text{STRPOS "char""celui-ci comports des characteres NS"}) \\
&\quad 23
\end{align*}
\]

In almost all cases, a program does not have to distinguish between NS characters or 8-bit characters. The exception to this rule is the handling of input/output operations (see Chapter 25).

The function CHARCODE (see below) provides a simple way to create individual NS character codes. The VirtualKeyboards library module provides a set of virtual keyboards that allows keyboard or mouse entry of NS characters.

(PACKC X) [Function]

Like PACK except X is a list of character codes. For example,

(PACKC '(70 79 79)) => FOO
(CHCONS X FLG RDTBL) [Function]
Like UNPACK, but returns the print name of X as a list of character codes. If FLG = T, the PRIN2-name is used. For example:

(CHCONS 'FOO) => (70 79 79)

(DCHCONS X SCRATCHLIST FLG RDTBL) [Function]
Like DUNPACK.

(NTHCHARCODE X N FLG RDTBL) [Function]
Like NTHCHAR, but returns the character code of the Nth character of the print name of X. If N is negative, it is interpreted as a count backwards from the end of X. If the absolute value of N is greater than the number of characters in X, or 0, then the value of NTHCHARCODE is NIL.

If FLG is T, then the PRIN2-name of X is used, computed with respect to the readtable.

(CHCONS1 X) [Function]
Returns the character code of the first character of the print name of X; equal to (NTHCHARCODE X 1).

(CCHARACTER N) [Function]
N is a character code. Returns the symbol having the corresponding single character as its print name.

(CCHARACTER 70) => F

(FCHARACTER N) [Function]
Fast version of CCHARACTER that compiles open.

The following function makes it possible to gain the efficiency that comes from dealing with character codes without losing the symbolic advantages of character symbols.

(CCHARCODE CHAR) [Function]
Returns the character code specified by CHAR (unevaluated). If CHAR is a one-character symbol or string, the corresponding character code is simply returned. Thus, (CCHARCODE A) is 65, (CCHARCODE 0) is 48. If CHAR is a multi-character symbol or string, it specifies a character code as described below. If CHAR is NIL, CHARCODE simply returns NIL. Finally, if CHAR is a list structure, the value is a copy of CHAR with all the leaves replaced by the corresponding character codes. For instance, (CCHARCODE (A (B C))) => (65 (66 67)).

If a character is specified by a multi-character symbol or string, CHARCODE interprets it as follows:

CR, SPACE, etc.
The variable \texttt{CHARACTERNAMES} contains an association list mapping special symbols to character codes. Among the characters defined this way are CR (13), LF (10), SPACE or SP (32), ESCAPE or ESC (27), BELL (7), BS (8), TAB (9), NULL (0), and DEL (127). The symbol EOL maps into the appropriate end-of-line character code in the different Interlisp implementations (31 in Interlisp-10, 13 in Interlisp-D, 10 in Interlisp-VAX). Examples:

\begin{verbatim}
(CHARCODE SPACE) => 32
(CHARCODE CR) => 13
\end{verbatim}

\textbf{CHARSET, CHARNUM, CHARSET-CHARNUM}

If the character specification is a symbol or string of the form \texttt{CHARSET}, \texttt{CHARNUM}, or \texttt{CHARSET-CHARNUM}, the character code for the character number \texttt{CHARNUM} in the character set \texttt{CHARSET} is returned.

The 16-bit NS character encoding is divided into a large number of “character sets”. Each 16-bit character can be decoded into a character set (an integer from 0 to 254 inclusive) and a character number (also an integer from 0 to 254 inclusive). \texttt{CHARSET} is either an octal number, or a symbol in the association list \texttt{CHARACTERSETNAMES} (which defines the character sets for \texttt{GREEK}, \texttt{CYRILLIC}, etc.). \texttt{CHARNUM} is either an octal number, a single-character symbol, or a symbol from the association list \texttt{CHARACTERNAMES}. If \texttt{CHARNUM} is a single-digit number, it is interpreted as the character “2”, rather than as the octal number 2. Examples:

\begin{verbatim}
(CHARCODE 12,6) => 2566
(CHARCODE 12,SPACE) => 2592
(CHARCODE GREEK,A) => 9793
\end{verbatim}

\textbf{↑CHARSPEC (control chars)}

If the character specification is a symbol or string of one of the forms above, preceded by the character \texttt{↑}, this indicates a “control character,” derived from the normal character code by clearing the seventh bit of the character code (normally set). Examples:

\begin{verbatim}
(CHARCODE ↑A) => 1
(CHARCODE ↑GREEK,A) => 9729
\end{verbatim}

\textbf{#CHARSPEC (meta chars)}

If the character specification is a symbol or string of one of the forms above, preceded by the character \texttt{#}, this indicates a meta character, derived from the normal character code by setting the eighth bit of the character code (normally cleared). \texttt{↑} and \texttt{#} can both be set at once. Examples:

\begin{verbatim}
(CHARCODE #A) => 193
(CHARCODE #↑GREEK,A) => 9857
\end{verbatim}

A \texttt{CHARCODE} form can be used wherever a structure of character codes would be appropriate. For example:
There is a macro for CHARCODE which causes the character-code structure to be constructed at compile-time. Thus, the compiled code for these examples is exactly as efficient as the less readable:

\[
\begin{align*}
(FMEMB \ (NTHCHARCODE \ X \ 1) \ (CHARCODE \ (CR \ LF \ SPACE \ ^{\uparrow}A))) \\
(EQ \ (READCCODE \ FOO) \ (CHARCODE \ GREEK,A))
\end{align*}
\]

\[
\begin{align*}
(FMEMB \ (NTHCHARCODE \ X \ 1) \ (QUOTE \ (13 \ 10 \ 32 \ 1))) \\
(EQ \ (READCCODE \ FOO) \ 9793)
\end{align*}
\]

**(CL:CHAR-CODE CHAR )**  [Common Lisp Function]

Returns the Interlisp character code of CHAR. Use to convert a Common Lisp character to an Interlisp character code.

**(CL:CODE-CHAR N )**  [Common Lisp Function]

Returns a character with the given non-negative integer \( N \) code. Returns NIL if no character is possible with \( N \). Use to convert an Interlisp character code to a Common Lisp character.

**(SELCHARQ E CLAUSE1... CLAUSEN DEFAULT)**  [Function]

Lets you branch one of several ways, based on the character code \( E \). The first item in each CLAUSEN is a character code or list of character codes, given in the form CHARCODE would accept. If the value of \( E \) is a character code or NIL, and it is EQ or MEMB to the result of applying CHARCODE to the first element of a clause, the remaining forms of that clause are evaluated. Otherwise, the default is evaluated.

Thus

\[
\begin{align*}
(SELCHARQ \ (BIN \ FOO)) \\
((\SPACE \ \TAB) \ (FUM)) \\
((\uparrow D \ NIL) \ (BAR)) \\
(a \ (BAZ)) \\
(ZIP))
\end{align*}
\]

is exactly equivalent to

\[
\begin{align*}
(SELECTQ \ (BIN \ FOO)) \\
((32.9) \ (FUM)) \\
((4 \ NIL) \ (BAR)) \\
(97 \ (BAZ)) \\
(ZIP))
\end{align*}
\]

If (BIN FOO) returned 32 (the SPACE character), the function FUM would be called.

Glossary ........................................................................ GLOSSARY-1

Index ............................................................................... INDEX-1
4. STRINGS

A string represents a sequence of characters. Interlisp strings are a subtype of Common Lisp strings. Medley provides functions for creating strings, concatenating strings, and creating sub-strings of a string; all accepting or producing Common Lisp-acceptable strings.

A string is typed as a double quote ("), followed by a sequence of any characters except double quote and %, terminated by a double quote. To include % or " in a string, type % in front of them:

"A string"
"A string with %" in it, and a %%."
"
; an empty string

Strings are printed by PRINT and PRIN2 with initial and final double quotes, and %s inserted where necessary for it to read back in properly. Strings are printed by PRIN1 without the double quotes and extra %s. The null string is printed by PRINT and PRIN2 as ". (PRIN1 "") doesn’t print anything.

Internally, a string is stored in two parts: a “string header” and the sequence of characters. Several string headers may refer to the same character sequence, so a substring can be made by creating a new string header, without copying any characters. Functions that refer to “strings” actually manipulate string headers. Some functions take an “old string” argument, and re-use the string pointer.

\textbf{(STRINGP X)} \hspace{1cm} \textbf{[Function]}

Returns \texttt{T} if \texttt{X} is a string, \texttt{NIL} otherwise.

\textbf{(STREQUAL X Y)} \hspace{1cm} \textbf{[Function]}

Returns \texttt{T} if \texttt{X} and \texttt{Y} are both strings and they contain the same sequence of characters, otherwise \texttt{NIL}. \texttt{EQUAL} uses \texttt{STREQUAL}. Note that strings may be \texttt{STREQUAL} without being \texttt{EQ}. For instance,

\begin{verbatim}
(STREQUAL "ABC" "ABC") => T
(EQ "ABC" "ABC") => NIL
\end{verbatim}

\texttt{STREQUAL} returns \texttt{T} if \texttt{X} and \texttt{Y} are the same string pointer, or two different string pointers which point to the same character sequence, or two string pointers which point to different character sequences which contain the same characters. Only in the first case would \texttt{X} and \texttt{Y} be \texttt{EQ}.

\textbf{(STRING-EQUAL X Y)} \hspace{1cm} \textbf{[Function]}

Returns \texttt{T} if \texttt{X} and \texttt{Y} are either strings or symbols, and they contain the same sequence of characters, ignoring case. For instance,

\begin{verbatim}
(STRING-EQUAL "FOO" "Foo") => T
(STRING-EQUAL "FOO" 'Foo) => T
\end{verbatim}

This is useful for comparing things that might want to be considered “equal” even though they’re not both symbols in a consistent case, such as file names and user names.
(STRING.EQUAL X Y) [Function]

Returns T if the print names of X and Y contain the same sequence of characters, ignoring case. For instance,

(STRING-EQUAL "320" 320)  =>  T
(STRING-EQUAL "FOO" 'Foo)  =>  T

This is like STRING-EQUAL, but handles numbers, etc., where STRING-EQUAL doesn’t.

(ALLOCSTRING N INITCHAR OLD FATFLG) [Function]

Creates a string of length N characters of INITCHAR (which can be either a character code or something coercible to a character). If INITCHAR is NIL, it defaults to character code 0. If OLD is supplied, it must be a string pointer, which is modified and returned.

If FATFLG is non-NIL, the string is allocated using full 16-bit NS characters (see Chapter 2) instead of 8-bit characters. This can speed up some string operations if NS characters are later inserted into the string. This has no other effect on the operation of the string functions.

(MKSTRING X FLG RDTBL) [Function]

If X is a string, returns X. Otherwise, creates and returns a string containing the print name of X. Examples:

(MKSTRING "ABC")  =>  "ABC"
(MKSTRING '(A B C))  =>  "(A B C)"
(MKSTRING NIL)  =>  "NIL"

Note that the last example returns the string "NIL", not the symbol NIL.

If FLG is T, then the PRIN2-name of X is used, computed with respect to the readtable RDTBL. For example,

(MKSTRING "ABC" T)  =>  "%"ABC%"

(NCHARS X FLG RDTBL) [Function]

Returns the number of characters in the print name of X. If FLG=T, the PRIN2-name is used. For example,

(NCHARS 'ABC)  =>  3
(NCHARS "ABC" T)  =>  5

Note: NCHARS works most efficiently on symbols and strings, but can be given any object.

(SUBSTRING X N M OLDPTR) [Function]

Returns the substring of X consisting of the Nth through Mth characters of X. If M is NIL, the substring contains the Nth character thru the end of X. N and M can be negative numbers, which are interpreted as counts back from the end of the string, as with NTHCHAR (Chapter 2). SUBSTRING returns NIL if the substring is not well defined, (e.g., N or M specify character positions outside of X, or N corresponds to a character in X to the right of the character indicated by M). Examples:
STRINGS

(SUBSTRING "ABCDEFG" 4 6)  =>  "DEF"
(SUBSTRING "ABCDEFG" 3 3)  =>  "C"
(SUBSTRING "ABCDEFG" 3 NIL)  =>  "CDEFG"
(SUBSTRING "ABCDEFG" 4 -2)  =>  "DEF"
(SUBSTRING "ABCDEFG" 6 4)  =>  NIL
(SUBSTRING "ABCDEFG" 4 9)  =>  NIL

If X is not a string, it is converted to one. For example,
(SUBSTRING '(A B C) 4 6)  =>  "B C"

SUBSTRING does not actually copy any characters, but simply creates a new string pointer
to the characters in X. If OLDPTR is a string pointer, it is modified and returned.

(GNC X)  [Function]

"Get Next Character."  Returns the next character of the string X (as a symbol); also
removes the character from the string, by changing the string pointer.  Returns NIL if X is
the null string.  If X isn’t a string, a string is made.  Used for sequential access to characters
of a string.  Example:
← (SETQ FOO "ABCDEFG")
   "ABCDEFG"
← (GNC FOO)    A
← (GNC FOO)    B
← FOO     "CDEFG"

Note that if A is a substring of B, (GNC A) does not remove the character from B.

(GLC X)  [Function]

"Get Last Character."  Returns the last character of the string X (as a symbol); also
removes the character from the string.  Similar to GNC.  Example:
← (SETQ FOO "ABCDEFG")
   "ABCDEFG"
← (GLC FOO)    G
← (GLC FOO)    F
← FOO     "ABCDE"

(CONCAT X1 X2 ... XN)  [NoSpread Function]

Returns a new string which is the concatenation of (copies of) its arguments.  Any
arguments which are not strings are transformed to strings.  Examples:
(CONCAT "ABC" 'DEF "GHI")  =>  "ABCDEFGHI"
(CONCAT '(A B C) "ABC")  =>  "(A B C)ABC"
(CONCAT)  returns the null string, ""

4 - 3
(CONCATLIST L)  

[Function]

L is a list of strings and/or other objects. The objects are transformed to strings if they aren’t strings. Returns a new string which is the concatenation of the strings. Example:

(CONCATLIST '(A B (C D) "EF"))  =>  "AB(C D)EF"

(RPLSTRING X N Y)  

[Function]

Replaces the characters of string X beginning at character position N with string Y. X and Y are converted to strings if they aren’t already. N may be positive or negative, as with SUBSTRING. Characters are smashed into (converted) X. Returns the string X. Examples:

(RPLSTRING "ABCDEFGHIJKLMNOPQRSTUVWXYZ" -3 "END")  =>  "ABCEND"
(RPLSTRING "ABCDEFGHIJKLMNOPQRSTUVWXYZ" 4 '(A B C))  =>  "ABC(A B C)K"

Generates an error if there is not enough room in X for Y, i.e., the new string would be longer than the original. If Y was not a string, X will already have been modified since RPLSTRING does not know whether Y will “fit” without actually attempting the transfer.

Warning: In some implementations of Interlisp, if X is a substring of Z, Z will also be modified by the action of RPLSTRING or RPLCHARCODE. However, this is not guaranteed to be true in all cases, so programmers should not rely on RPLSTRING or RPLCHARCODE altering the characters of any string other than the one directly passed as argument to those functions.

(RPLCHARCODE X N CHAR)  

[Function]

Replaces the Nth character of the string X with the character code CHAR. N may be positive or negative. Returns the new X. Similar to RPLSTRING. Example:

(RPLCHARCODE "ABCDE" 3 (CHARCODE F))  =>  "ABFDE"

(STRPOS PAT STRING START SKIP ANCHOR TAIL CASEARRAY BACKWARDSFLG)  

[Function]

STRPOS is a function for searching one string looking for another. PAT and STRING are both strings (or else they are converted automatically). STRPOS searches STRING beginning at character number START, (or 1 if START is NIL) and looks for a sequence of characters equal to PAT. If a match is found, the character position of the first matching character in STRING is returned, otherwise NIL. Examples:

(STRPOS "ABC" "XYZABCDEF")  =>  4
(STRPOS "ABC" "XYZABCDEF" 5)  =>  NIL
(STRPOS "ABC" "XYZABCDEFABC" 5)  =>  10

SKIP can be used to specify a character in PAT that matches any character in STRING. Examples:

(STRPOS "A&C&C" "XYZABCDEF" NIL '&)  =>  4
(STRPOS "DEF&" "XYZABCDEF" NIL '&)  =>  NIL

If ANCHOR is T, STRPOS compares PAT with the characters beginning at position START (or 1 if START is NIL). If that comparison fails, STRPOS returns NIL without searching any further down STRING. Thus it can be used to compare one string with some portion of another string. Examples:

(STRPOS "ABC" "XYZABCDEF" NIL NIL T)  =>  NIL
STRINGS

(STRPOS "ABC" "XYZABCDEF" 4 NIL T) => 4

If TAIL is T, the value returned by STRPOS if successful is not the starting position of the sequence of characters corresponding to PAT, but the position of the first character after that, i.e., the starting position plus (NCHARS PAT). Examples:

(STRPOS "ABC" "XYZABCDEFABC" NIL NIL NIL T) => 7
(STRPOS "A" "A" NIL NIL NIL T) => 2

If TAIL = NIL, STRPOS returns NIL, or a character position within STRING which can be passed to SUBSTRING. In particular, (STRPOS "**" **) => NIL. However, if TAIL = T, STRPOS may return a character position outside of STRING. For instance, note that the second example above returns 2, even though “A” has only one character.

If CASEARRAY is non-NIL, this should be a casearray like that given to FILEPOS (Chapter 25). The casearray is used to map the string characters before comparing them to the search string.

If BACKWARDSFLG is non-NIL, the search is done backwards from the end of the string.

(STRPOSL A STRING START NEG BACKWARDSFLG)

STRING is a string (or is converted automatically to a string), A is a list of characters or character codes. STRPOSL searches STRING beginning at character number START (or 1 if START = NIL) for one of the characters in A. If one is found, STRPOSL returns as its value the corresponding character position, otherwise NIL. Example:

(STRPOSL '(A B C) "XYZBCD") => 4

If NEG = T, STRPOSL searches for a character not on A. Example:

(STRPOSL '(A B C) "ABCDEF" NIL T) => 4

If any element of A is a number, it is assumed to be a character code. Otherwise, it is converted to a character code via CHCON1. Therefore, it is more efficient to call STRPOSL with A a list of character codes.

If A is a bit table, it is used to specify the characters (see MAKEBITTABLE below)

If BACKWARDSFLG is non-NIL, the search is done backwards from the end of the string.

STRPOSL uses a “bit table” data structure to search efficiently. If A is not a bit table, it is converted to a bit table using MAKEBITTABLE. If STRPOSL is to be called frequently with the same list of characters, a considerable savings can be achieved by converting the list to a bit table once, and then passing the bit table to STRPOSL as its first argument.

(MAKEBITTABLE L NEG A)

Returns a bit table suitable for use by STRPOSL. L is a list of characters or character codes, NEG is the same as described for STRPOSL. If A is a bit table, MAKEBITTABLE modifies and returns it. Otherwise, it will create a new bit table.
Note: If \texttt{NEG = T}, \texttt{STRPOSL} must call \texttt{MAKEBITTABLE} whether \texttt{A} is a list or a bit table. To obtain bit table efficiency with \texttt{NEG=T}, \texttt{MAKEBITTABLE} should be called with \texttt{NEG=T}, and the resulting “inverted” bit table should be given to \texttt{STRPOSL} with \texttt{NEG=NIL}.
An Interlisp array is a one-dimensional vector of objects. Arrays are generally created by the function \texttt{ARRAY}. By contrast, Common Lisp arrays can be multi-dimensional.

Note: Interlisp arrays and Common Lisp arrays are \textbf{not} the same types. Interlisp functions only accept Interlisp arrays and vice versa. There are no functions to convert between the two types.

\begin{verbatim}
(ARRAY SIZE TYPE INIT ORIG ~)
\end{verbatim}

Creates and returns a new array that holds \textit{SIZE} objects of type \textit{TYPE}. If \textit{TYPE} is \texttt{NIL}, the array can contain any arbitrary Lisp datum. In general, \textit{TYPE} may be any of the various field specifications that are legal in \texttt{DATATYPE} declarations (see Chapter 8): \texttt{POINTER}, \texttt{FIXP}, \texttt{FLOATP}, \texttt{(BITS N)}, etc. Medley will, if necessary, choose an “enclosing” type if the given one is not supported; for example, an array of \texttt{(BITS 3)} may be represented by an array of \texttt{(BITS 8)}.

\textit{INIT} is the initial value for each element of the new array. If not specified, the array elements will be initialized with 0 (for number arrays) or \texttt{NIL} (all other types).

Arrays can have either 0-origin or 1-origin indexing, as specified by the \texttt{ORIG} argument; if \texttt{ORIG} is not specified, the default is 1.

Arrays of type \texttt{FLOATP} are stored unboxed. This increases the space and time efficiency of \texttt{FLOATP} arrays. If you want to use boxed floating point numbers, use an array of type \texttt{POINTER} instead of \texttt{FLOATP}.

\begin{verbatim}
(ARRAYP X)
\end{verbatim}

Returns \texttt{X} if \texttt{X} is an array, \texttt{NIL} otherwise.

\begin{verbatim}
(ELT ARRAY N)
\end{verbatim}

Returns the \textit{N}th element of the array \texttt{ARRAY}.

Causes the error, \texttt{Arg not array}, if \texttt{ARRAY} is not an array. Causes the error, \texttt{Illegal Arg}, if \texttt{N} is out of bounds.

\begin{verbatim}
(SETA ARRAY N VAL)
\end{verbatim}

Sets the \textit{N}th element of \texttt{ARRAY} to \texttt{VAL}, and returns \texttt{VAL}.

Causes the error, \texttt{Arg not array}, if \texttt{ARRAY} is not an array. The error, \texttt{Illegal Arg}, if \texttt{N} is out of bounds. Can cause the error, \texttt{Non-numeric arg}, if \texttt{ARRAY} is an array whose \texttt{ARRAYTYP} is \texttt{FIXP} or \texttt{FLOATP} and \texttt{VAL} is non-numeric.

\begin{verbatim}
(ARRAYTYP ARRAY)
\end{verbatim}

Returns the type of the elements in \texttt{ARRAY}, a value corresponding to the second argument to \texttt{ARRAY}.
If ARRAY coerced the array type as described above, ARRAYTYP returns the *new* type. For example, (ARRAYTYP (ARRAY 10 '(BITS 3))) returns BYTE.

(ARRAYSIZE ARRAY) [Function]

Returns the size of ARRAY. Generates the error, Arg not array, if ARRAY is not an array.

(ARRAYORIG ARRAY) [Function]

Returns the origin of ARRAY, which may be 0 or 1. Generates an error, Arg not array, if ARRAY is not an array.

(COPYARRAY ARRAY) [Function]

Returns a new array of the same size and type as ARRAY, and with the same contents as ARRAY. Generates an error, Arg not array, if ARRAY is not an array.
INTERLISP-D REFERENCE MANUAL

[This page intentionally left blank]
Hash arrays let you associate arbitrary Lisp objects ("hash keys") with other objects ("hash values"), so you can get from key to value quickly. There are functions for creating hash arrays, putting a hash key/value pair in a hash array, and quickly retrieving the hash value associated with a given hash key.

By default, the hash array functions use \texttt{EQ} for comparing hash keys. This means that if non-symbols are used as hash keys, the exact same object (not a copy) must be used to retrieve the hash value. However, you can specify the function used to compare hash keys and to "hash" a hash key to a number. You can, for example, create hash arrays where \texttt{EQUAL} but non-\texttt{EQ} strings will hash to the same value. Specifying alternative hashing algorithms is described below.

In the description of the functions below, the argument \texttt{HARRAY} should be a hasharray created by \texttt{HASHARRAY}. For convenience in interactive program development, it may also be \texttt{NIL}, in which case a hash array (\texttt{SYSHASHARRAY}) provided by the system is used; you must watch out for confusions if this form is used to associate more than one kind of value with the same key.

\textbf{Note:} For backwards compatibility, the hash array functions will accept a list whose \texttt{CAR} is a hash array, and whose \texttt{CDR} is the "overflow method" for the hash array (see below). However, hash array functions are guaranteed to perform with maximum efficiency only if a direct value of \texttt{HASHARRAY} is given.

\textbf{Note:} Interlisp hash arrays and Common Lisp hash tables are the same data type, so functions from both may be intermixed. The only difference between the functions may be argument order, as in \texttt{MAPHASH} and \texttt{CL:MAPHASH} (see below).

\begin{verbatim}
(HASHARRAY MINKEYS OVERFLOW HASHBITSFN EQUIVFN RECLAIMABLE REHASH-THRESHOLD)
[Function]

Creates a hash array with space for at least \texttt{MINKEYS} hash keys, with overflow method \texttt{OVERFLOW}. See discussion of overflow behavior below.

If \texttt{HASHBITSFN} and \texttt{EQUIVFN} are non-\texttt{NIL}, they specify the hashing function and comparison function used to interpret hash keys. This is described in the section on user-specified hashing functions below. If \texttt{HASHBITSFN} and \texttt{EQUIVFN} are \texttt{NIL}, the default is to hash \texttt{EQ} hash keys to the same value.

If \texttt{RECLAIMABLE} is \texttt{T}, the entries in the hash table will be removed if the key has a reference count of one and the table is about to be rehashed. This allows the system, in some cases, to reuse keys instead of expanding the table.

\textbf{Note:} \texttt{CL:MAKE-HASH-TABLE} does not allow you to specify your own hashing functions but does provide three built-in types specified by \texttt{Common Lisp, the Language}.

\end{verbatim}

\begin{verbatim}
(HARRAY MINKEYS)
[Function]

Provided for backward compatibility, this is equivalent to \texttt{(HASHARRAY MINKEYS 'ERROR)}, i.e. if the resulting hasarray gets full, an error occurs.

\end{verbatim}
(HARRAYP X) [Function]
Returns X if it is a hash array; otherwise NIL.
HARRAYP returns NIL if X is a list whose CAR is an HARRAYP, even though this is accepted by the hash array functions (see below).

(PUTHASH KEY VAL HARRAY) [Function]
Associates the hash value VAL with the hash key KEY in HARRAY. Replaces the previous hash value, if any. If VAL is NIL, any old association is removed (hence a hash value of NIL is not allowed). If HARRAY is full when PUTHASH is called with a key not already in the hash array, the function HASHOVERFLOW is called, and the PUTHASH is applied to the value returned (see below). Returns VAL.

(GETHASH KEY HARRAY) [Function]
Returns the hash value associated with the hash key KEY in HARRAY. Returns NIL, if KEY is not found.

(CLRHASH HARRAY) [Function]
Clears all hash keys/values from HARRAY. Returns HARRAY.

(HARRAYPROP HARRAY PROP NEWVALUE) [NoSpread Function]
Returns the property PROP of HARRAY; PROP can have the system-defined values SIZE (the maximum occupancy of HARRAY), NUMKEYS (number of occupied slots), OVERFLOW (overflow method), HASHBITSFN (hashing function) and EQUIVFN (comparison function).
Except for SIZE and NUMKEYS, a new value may be specified as NEWVALUE.

By using other values for PROP, the user may also set and get arbitrary property values, to associate additional information with a hash array.

The HASHBITSFN or EQUIVFN properties can only be changed if the hash array is empty.

(HARRAYSIZE HARRAY) [Function]
Returns the number of slots in HARRAY. It’s equivalent to (HARRAYPROP HARRAY ‘SIZE).

(REHASH OLDHARRAY NEWHARRAY) [Function]
Hashes all hash keys and values in OLDHARRAY into NEWHARRAY. The two hash arrays do not have to be (and usually aren’t) the same size. Returns NEWHARRAY.

(MAPHASH HARRAY MAPFHN) [Function]
MAPFHN is a function of two arguments. For each hash key in HARRAY, MAPFHN will be applied to the hash value, and the hash key. For example:

(MAPHASH A
 (FUNCTION (LAMBDA (VAL KEY)
              (if (LISTP KEY) then (PRINT VAL)))]
will print the hash value for all hash keys that are lists. MAPHASH returns HARRAY.
Note: the argument order for CL:MAPHASH is MAPHFN HARRAY.

(DMPHASH HARRAY1 HARRAY2 ... HARRAYN) [NLambda NoSpread Function]

Prints on the primary output file LOADable forms which will restore the hash-arrays contained as the values of the atoms HARRAY1, HARRAY2, ... HARRAYN. Example: (DMPHASH SYSHASHARRAY) will dump the system hash-array.

All EQ identities except symbols and small integers are lost by dumping and loading because READ will create new structure for each item. Thus if two lists contain an EQ substructure, when they are dumped and loaded back in, the corresponding substructures while EQUAL are no longer EQ. The HORRIBLEVARS file package command (Chapter 17) provides a way of dumping hash tables such that these identities are preserved.

Hash Overflow

When a hash array becomes full, trying to add another hash key will cause the function HASHOVERFLOW to be called. This either enlarges the hash array, or causes the error Hash table full. How hash overflow is handled is determined by the value of the OVERFLOW property of the hash array (which can be accessed by HARRAYPROP). The possibilities for the overflow method are:

- the symbol ERROR The error Hash array full is generated when the hash array overflows. This is the default overflow behavior for hash arrays returned by HARRAY.
- NIL The array is automatically enlarged by at least a factor 1.5 every time it overflows. This is the default overflow behavior for hash arrays returned by HASHARRAY.
- a positive integer N The array is enlarged to include at least N more slots than it currently has.
- a floating point number F The array is changed to include F times the number of current slots.
- a function or lambda expression FN Upon hash overflow, FN is called with the hash array as its argument. If FN returns a number, that will become the size of the array. Otherwise, the new size defaults to 1.5 times its previous size. FN could be used to print a message, or perform some monitor function.

Note: For backwards compatibility, the hash array functions accept a list whose CAR is the hash array, and whose CDR is the overflow method. In this case, the overflow method specified in the list overrides the overflow method set in the hash array. Hash array functions perform with maximum efficiency only if a direct value of HASHARRAY is given.

Specifying Your Own Hashing Functions

In general terms, when a key is looked up in a hash array, it is converted to an integer, which is used to index into a linear array. If the key is not the same as the one found at that index, other indices are
tried until it the desired key is found. The value stored with that key is then returned (from GETHASH) or replaced (from PUTHASH).

To customize hash arrays, you’ll need to supply the “hashing function” used to convert a key to an integer and the comparison function used to compare the key found in the array with the key being looked up. For hash arrays to work correctly, any two objects which are equal according to the comparison function must “hash” to equal integers.

By default, Medley uses a hashing function that computes an integer from the internal address of a key, and use EQ for comparing keys. This means that if non-atoms are used as hash keys, the exact same object (not a copy) must be used to retrieve the hash value.

There are some applications for which the EQ constraint is too restrictive. For example, it may be useful to use strings as hash keys, without the restriction that EQUAL but not EQ strings are considered to be different hash keys.

The user can override this default behavior for any hash array by specifying the functions used to compare keys and to “hash” a key to a number. This can be done by giving the HASHBITSFN and EQUIVFN arguments to HASHARRAY (see above).

The EQUIVFN argument is a function of two arguments that returns non-NIL when its arguments are considered equal. The HASHBITSFN argument is a function of one argument that produces a positive small integer (in the range \([0..2^{16} - 1]\)) with the property that objects that are considered equal by the EQUIVFN produce the same hash bits.

For an existing hash array, the function HARRAYPROP (see above) can be used to examine the hashing and equivalence functions as the HASHBITSFN and EQUIVFN hash array properties. These properties are read-only for non-empty hash arrays, as it makes no sense to change the equivalence relationship once some keys have been hashed.

The following function is useful for creating hash arrays that take strings as hash keys:

\[
\begin{align*}
\text{(STRINGHASHBITS STRING)} & \quad \text{[Function]} \\
\text{Hashes the string STRING into an integer that can be used as a HASHBITSFN for a hash array. Strings which are STREQUAL hash to the same integer.} \\
\text{Example:} \\
\text{(HASHARRAY MINKEYS OVERFLOW 'STRINGHASHBITS 'STREQUAL)} \\
\text{creates a hash array where you can use strings as hash keys.}
\end{align*}
\]
INTERLISP-D REFERENCE MANUAL

[This page intentionally left blank]
7. NUMBERS AND ARITHMETIC FUNCTIONS

There are four different types of numbers in Interlisp: small integers, large integers, bignums (arbitrary-size integers), and floating-point numbers. Small integers are in the range -65536 to 65535. Large integers and floating-point numbers are 32-bit quantities that are stored by “boxing” the number (see below). Bignums are “boxed” as a series of words.

Large integers and floating-point numbers can be any full word quantity. To distinguish among the various kinds of numbers, and other Interlisp pointers, these numbers are “boxed.” When a large integer or floating-point number is created (by an arithmetic operation or by \texttt{READ}), Interlisp gets a new word from “number storage” and puts the number into that word. Interlisp then passes around the pointer to that word, i.e., the “boxed number”, rather than the actual quantity itself. When a numeric function needs the actual numeric quantity, it performs the extra level of addressing to obtain the “value” of the number. This latter process is called “unboxing”. Unboxing does not use any storage, but each boxing operation uses one new word of number storage. If a computation creates many large integers or floating-point numbers, i.e., does lots of boxes, it may cause a garbage collection of large integer space, or of floating-point number space.

The following functions can be used to distinguish the different types of numbers:

\begin{itemize}
  \item \texttt{SMALLP X} \hspace{1cm} \textbf{[Function]}
  \begin{itemize}
    \item Returns \( X \), if \( X \) is a small integer; \texttt{NIL} otherwise. Does not generate an error if \( X \) is not a number.
  \end{itemize}

  \item \texttt{FIXP X} \hspace{1cm} \textbf{[Function]}
  \begin{itemize}
    \item Returns \( X \), if \( X \) is an integer; \texttt{NIL} otherwise. Note that \texttt{FIXP} is true for small integers, large integers, and bignums. Does not generate an error if \( X \) is not a number.
  \end{itemize}

  \item \texttt{FLOATP X} \hspace{1cm} \textbf{[Function]}
  \begin{itemize}
    \item Returns \( X \) if \( X \) is a floating-point number; \texttt{NIL} otherwise. Does not give an error if \( X \) is not a number.
  \end{itemize}

  \item \texttt{NUMBERP X} \hspace{1cm} \textbf{[Function]}
  \begin{itemize}
    \item Returns \( X \), if \( X \) is a number of any type; \texttt{NIL} otherwise. Does not generate an error if \( X \) is not a number.
  \end{itemize}

\end{itemize}

\textbf{Note}: In previous releases, \texttt{NUMBERP} was true only if (\texttt{FLOATP X}) or (\texttt{FIXP X}) were true. With the addition of Common Lisp ratios and complex numbers, \texttt{NUMBERP} now returns \texttt{T} for all number types. Code relying on the "old" behavior should be modified.

Each small integer has a unique representation, so \texttt{EQ} may be used to check equality. \texttt{EQ} should not be used for large integers, bignums, or floating-point numbers, \texttt{EQP}, \texttt{IEQP}, or \texttt{EQUAL} must be used instead.

\begin{itemize}
  \item \texttt{EQP X Y} \hspace{1cm} \textbf{[Function]}
  \begin{itemize}
    \item Returns \texttt{T}, if \( X \) and \( Y \) are equal numbers; \texttt{NIL} otherwise. \texttt{EQ} may be used if \( X \) and \( Y \) are known to be small integers. \texttt{EQP} does not convert \( X \) and \( Y \) to integers, e.g., \texttt{(EQP 2000 2000)}
  \end{itemize}
\end{itemize}
2000.3) => NIL, but it can be used to compare an integer and a floating-point number, e.g., (EQP 2000 2000.0) => T. EQP does not generate an error if X or Y are not numbers.

EQP can also be used to compare stack pointers (see Chapter 11) and compiled code objects (see Chapter 10).

The action taken on division by zero and floating-point overflow is determined with the following function:

\[(\text{OVERFLOW } \text{FLG})\]  
[Function]

Sets a flag that determines the system response to arithmetic overflow (for floating-point arithmetic) and division by zero; returns the previous setting.

For integer arithmetic: If \( \text{FLG} = \text{T} \), an error occurs on division by zero. If \( \text{FLG} = \text{NIL} \) or 0, integer division by zero returns zero. Integer overflow cannot occur, because small integers are converted to bignums (see the beginning of this chapter).

For floating-point arithmetic: If \( \text{FLG} = \text{T} \), an error occurs on floating overflow or floating division by zero. If \( \text{FLG} = \text{NIL} \) or 0, the largest (or smallest) floating-point number is returned as the result of the overflowed computation or floating division by zero.

The default value for \( \text{OVERFLOW} \) is \( \text{T} \), meaning an error is generated on division by zero or floating overflow.

**Generic Arithmetic**

The functions in this section are “generic” arithmetic functions. If any of the arguments are floating-point numbers (see the Floating-Point Arithmetic section below), they act exactly like floating-point functions, floating all arguments and returning a floating-point number as their value. Otherwise, they act like the integer functions (see the Integer Arithmetic section below). If given a non-numeric argument, they generate an error, Non-numeric arg. The results of division by zero and floating-point overflow is determined by the function \( \text{OVERFLOW} \) (see the section above).

\[(\text{PLUS } X_1 \ X_2 \ \ldots \ X_n)\]  
[NoSpread Function]

\[X_1 + X_2 + \ldots + X_n\]

\[(\text{MINUS } X)\]  
[Function]

\[-X\]

\[(\text{DIFFERENCE } X \ Y)\]  
[Function]

\[X - Y\]

\[(\text{TIMES } X_1 \ X_2 \ \ldots \ X_n)\]  
[NoSpread Function]

\[X_1 \times X_2 \times \ldots \times X_n\]
NUMBERS AND ARITHMETIC FUNCTIONS

(QUOTIENT X Y) [Function]
If X and Y are both integers, returns the integer division of X and Y. Otherwise, converts both X and Y to floating-point numbers, and does a floating-point division.

(REMAINDER X Y) [Function]
If X and Y are both integers, returns (IREMAINDER X Y), otherwise (FREMAINDER X Y).

(GREATERP X Y) [Function]
T, if X > Y, NIL otherwise.

(LESSP X Y) [Function]
T if X < Y, NIL otherwise.

(GEQ X Y) [Function]
T, if X >= Y, NIL otherwise.

(LEQ X Y) [Function]
T, if X <= Y, NIL otherwise.

(ZEROP X) [Function]
The same as (EQP X 0).

(MINUSP X) [Function]
T, if X is negative; NIL otherwise. Works for both integers and floating-point numbers.

(MIN X1 X2 ... Xn) [NoSpread Function]
Returns the minimum of X1, X2, ..., Xn. (MIN) returns the value of MAX.INTEGER (see the Integer Arithmetic section below).

(MAX X1 X2 ... Xn) [NoSpread Function]
Returns the maximum of X1, X2, ..., Xn. (MAX) returns the value of MIN.INTEGER (see the Integer Arithmetic section below).

(ABS X) [Function]
X if X > 0, otherwise -X. ABS uses GREATERP and MINUS (not IGREATERP and IMINUS).

Integer Arithmetic

The input syntax for an integer is an optional sign (+ or -) followed by a sequence of decimal digits, and terminated by a delimiting character. Integers entered with this syntax are interpreted as decimal integers. Integers in other radices can be entered as follows:

123Q
#o123 If an integer is followed by the letter Q, or preceeded by a pound sign and the letter “o”, the digits are interpreted as an octal (base 8) integer.
If an integer is preceeded by a pound sign and the letter “b”, the digits are interpreted as a binary (base 2) integer.

If an integer is preceeded by a pound sign and the letter “x”, the digits are interpreted as a hexadecimal (base 16) integer.

If an integer is preceeded by a pound sign, a positive decimal integer BASE, and the letter “r”, the digits are interpreted as an integer in the base BASE. For example, #8r123 = 123Q, and #16r12A3 = #x12A3. When typing a number in a radix above ten, the uppercase letters A through Z can be used as the digits after 9 (but there is no digit above Z, so it is not possible to type all base-99 digits).

Medley keeps no record of how you typed a number, so 77Q and 63 both correspond to the same integer, and are indistinguishable internally. The function RADIX (see Chapter 25), sets the radix used to print integers.

PACK and MKATOM create numbers when given a sequence of characters observing the above syntax, e.g. (PACK ‘(1 2 Q)) => 10. Integers are also created as a result of arithmetic operations.

The range of integers of various types is implementation-dependent. This information is accessible to you through the following variables:

- **MIN.SMALLP** [Variable]
- **MAX.SMALLP** [Variable]
  The smallest/largest possible small integer.

- **MIN.FIXP** [Variable]
- **MAX.FIXP** [Variable]
  The smallest/largest possible large integer.

- **MIN.INTEGER** [Variable]
- **MAX.INTEGER** [Variable]
  The value of MAX.INTEGER and MIN.INTEGER are two special system datatypes. For some algorithms, it is useful to have an integer that is larger than any other integer. Therefore, the values of MAX.INTEGER and MIN.INTEGER are two special data types; the value of MAX.INTEGER is greater than any other integer, and the value of MIN.INTEGER is less than any other integer. Trying to do arithmetic using these special bignums, other than comparison, will cause an error.

All of the functions described below work on integers. Unless specified otherwise, if given a floating-point number, they first convert the number to an integer by truncating the fractional bits, e.g., (IPLUS 2.3 3.8) = 5; if given a non-numeric argument, they generate an error, Non-numeric arg.

- **(IPLUS X1 X2 ... Xn)** [NoSpread Function]
  Returns the sum $X_1 + X_2 + \ldots + X_n$. (IPLUS) = 0.

- **(IMINUS X)** [Function]
  - $X$
NUMBERS AND ARITHMETIC FUNCTIONS

(IDIFFERENCE X Y) [Function]

   X - Y

(ADD1 X) [Function]

   X + 1

(SUB1 X) [Function]

   X - 1

(ITIMES X₁ X₂ ... Xₙ) [NoSpread Function]

   Returns the product X₁ * X₂ * ... * Xₙ. (ITIMES) = 1.

(IQUOTIENT X Y) [Function]

   X / Y truncated. Examples:
   (IQUOTIENT 3 2) => 1
   (IQUOTIENT -3 2) => -1

   If Y is zero, the result is determined by the function OVERFLOW.

(IQUOTIENT X Y) [Function]

   Returns the remainder when X is divided by Y. Example:
   (IREMAINDER 5 2) => 1

(IMOD X N) [Function]

   Computes the integer modulus of X mod N; this differs from IREMINDER in that the
   result is always a non-negative integer in the range [0,N).

(IGREATERP X Y) [Function]

   T, if X > Y; NIL otherwise.

(ILESSP X Y) [Function]

   T, if X < Y; NIL otherwise.

(IGEQ X Y) [Function]

   T, if X >= Y; NIL otherwise.

(ILEQ X Y) [Function]

   T, if X <= Y; NIL otherwise.

(IMIN X₁ X₂ ... Xₙ) [NoSpread Function]

   Returns the minimum of X₁, X₂, ..., Xₙ. (IMIN) returns the largest possible large
   integer, the value of MAX_INTEGER.
INTERLISP-D REFERENCE MANUAL

(IMAX X₁ X₂ ... Xₙ) [NoSpread Function]

Returns the maximum of $X₁, X₂, \ldots, Xₙ$. (IMAX) returns the smallest possible large integer, the value of MIN. INTEGER.

(IEQP X Y) [Function]

Returns T if $X$ and $Y$ are equal integers; NIL otherwise. Note that EQ may be used if $X$ and $Y$ are known to be small integers. IEQP converts $X$ and $Y$ to integers, e.g., (IEQP 2000 2000.3) => T.

(FIX N) [Function]

If $N$ is an integer, returns $N$. Otherwise, converts $N$ to an integer by truncating fractional bits. For example, (FIX 2.3) => 2, (FIX -1.7) => -1.

Since FIX is also a programmer’s assistant command (see Chapter 13), typing FIX directly to a Medley executive will not cause the function FIX to be called.

(FIXR N) [Function]

If $N$ is an integer, returns $N$. Otherwise, converts $N$ to an integer by rounding. FIXR will round towards the even number if $N$ is exactly halfway between two integers. For example, (FIXR 2.3) => 2, (FIXR -1.7) => -2, (FIXR 3.5) => 4).

(GCD N₁ N₂) [Function]

Returns the greatest common divisor of $N₁$ and $N₂$. (GCD 72 64) = 8.

Logical Arithmetic Functions

(LOGAND X₁ X₂ ... Xₙ) [NoSpread Function]

Returns the logical AND of all its arguments, as an integer. Example:

(LOGAND 7 5 6) => 4

(LOGOR X₁ X₂ ... Xₙ) [NoSpread Function]

Returns the logical OR of all its arguments, as an integer. Example:

(LOGOR 1 3 9) => 11

(LOGXOR X₁ X₂ ... Xₙ) [NoSpread Function]

Returns the logical exclusive OR of its arguments, as an integer. Example:

(LOGXOR 11 5) => 14

(LOGXOR 11 5 9) = (LOGXOR 14 9) => 7

(LSH X N) [Function]

(Arithmetic) “Left Shift.” Returns $X$ shifted left $N$ places, with the sign bit unaffected. $X$ can be positive or negative. If $N$ is negative, $X$ is shifted right $-N$ places.
NUMBERS AND ARITHMETIC FUNCTIONS

(RSH X N)  [Function]

(Arithmetic) “Right Shift.” Returns X shifted right N places, with the sign bit unaffected, and copies of the sign bit shifted into the leftmost bit. X can be positive or negative. If N is negative, X is shifted left -N places.

Warning: Be careful if using RSH to simulate division; RSHing a negative number isn’t the same as dividing by a power of two.

(LLSH X N)  [Function]
(LRSH X N)  [Function]

“Logical Left Shift” and “Logical Right Shift”. The difference between a logical and arithmetic right shift lies in the treatment of the sign bit. Logical shifting treats it just like any other bit; arithmetic shifting will not change it, and will “propagate” rightward when actually shifting rightwards. Note that shifting (arithmetic) a negative number “all the way” to the right yields -1, not 0.

Note: LLSH and LRSH always operate mod-2^32 arithmetic. Passing a bignum to either of these will cause an error. LRSH of negative numbers will shift 0s into the high bits.

(INTEGERLENGTH X)  [Function]

Returns the number of bits needed to represent X. This is equivalent to: 1+floor[log2[abs[X]]]. (INTEGERLENGTH 0) = 0.

(POWEROFTWOP X)  [Function]

Returns non-NIL if X (coerced to an integer) is a power of two.

(EVENP X Y)  [NoSpread Function]

If Y is not given, equivalent to (ZEROP (IMOD X 2)); otherwise equivalent to (ZEROP (IMOD X Y)).

(ODDP N MODULUS)  [NoSpread Function]

Equivalent to (NOT (EVENP N MODULUS)). MODULUS defaults to 2.

(LOGNOT N)  [Macro]

Logical negation of the bits in N. Equivalent to (LOGXOR N -1).

(BITTEST N MASK)  [Macro]

Returns T if any of the bits in MASK are on in the number N. Equivalent to (NOT (ZEROP (LOGAND N MASK))).

(BITCLEAR N MASK)  [Macro]

Turns off bits from MASK in N. Equivalent to (LOGAND N (LOGNOT MASK)).

(BITSET N MASK)  [Macro]

Turns on the bits from MASK in N. Equivalent to (LOGOR N MASK).
(macro (mask.1's position size))

Returns a bit-mask with SIZE one-bits starting with the bit at POSITION. Equivalent to
(llsh (sub1 (expt 2 size)) position).

(macro (mask.0's position size))

Returns a bit-mask with all one-bits, except for SIZE bits starting at POSITION.
Equivalent to (lognot (mask.1's position size)).

(function (loadbyte n pos size))

Extracts SIZE bits from N, starting at position POS. Equivalent to
(logand (rsh n pos)
(mask.1's 0 size)).

(function (depositbyte n pos size val))

Insert SIZE bits of VAL at position POS into N, returning the result. Equivalent to
(logor (bitclear n (mask.1's pos size))
(lsht (logand val (mask.1's 0 size))
pos))

(function (rot x n fieldsize))

"Rotate bits in field". It performs a bitwise left-rotation of the integer X, by N places,
within a field of FIELDSIZE bits wide. Bits being shifted out of the position selected by
(expt 2 (sub1 fieldsize)) will flow into the "units" position.

The notions of position and size can be combined to make up a “byte specifier”, which is constructed
by the macro BYTE [note reversal of arguments as compared with the above functions]:

(macro (byte size position))

Constructs and returns a “byte specifier” containing SIZE and POSITION.

(macro (bytesize bytespec))

Returns the SIZE componant of the “byte specifier” BYTESPEC.

(macro (byteposition bytespec))

Returns the POSITION componant of the “byte specifier” BYTESPEC.

(macro (ldb bytespec val))

Equivalent to
(loadbyte val (byteposition bytespec) (bytesize bytespec))

(macro (dpb n bytespec val))

Equivalent to
(depositbyte val (byteposition bytespec) (bytesize bytespec) n)
Floating-Point Arithmetic

A floating-point number is input as a signed integer, followed by a decimal point, and another sequence of digits called the fraction, followed by an exponent (represented by E followed by a signed integer) and terminated by a delimiter.

Both signs are optional, and either the fraction following the decimal point, or the integer preceding the decimal point may be omitted. One or the other of the decimal point or exponent may also be omitted, but at least one of them must be present to distinguish a floating-point number from an integer. For example, the following will be recognized as floating-point numbers:

\[ \begin{align*}
5. & \quad 5.00 \quad 5.01 \quad .3 \\
5E2 & \quad 5.1E2 \quad 5E-3 \quad -5.2E+6
\end{align*} \]

Floating-point numbers are printed using the format control specified by the function FLTFMT (see Chapter 25). FLTFMT is initialized to T, or free format. For example, the above floating-point numbers would be printed free format as:

\[ \begin{align*}
5.0 & \quad 5.0 \quad 5.01 \quad .3 \\
500.0 & \quad 510.0 \quad .005 \quad -5.2E6
\end{align*} \]

Floating-point numbers are created by the reader when a "." or an E appears in a number, e.g., 1000 is an integer, 1000. a floating-point number, as are 1E3 and 1.E3. Note that 1000D, 1000F, and 1E3D are perfectly legal literal atoms. Floating-point numbers are also created by PACK and MKATOM, and as a result of arithmetic operations.

PRINTNUM (see Chapter 25) permits greater control over the printed appearance of floating-point numbers, allowing such things as left-justification, suppression of trailing decimals, etc.

The floating-point number range is stored in the following variables:

\[ \begin{align*}
\text{MIN. FLOAT} & \quad \text{Variable} \\
\text{MAX. FLOAT} & \quad \text{Variable}
\end{align*} \]

The smallest possible floating-point number.

The largest possible floating-point number.

All of the functions described below work on floating-point numbers. Unless specified otherwise, if given an integer, they first convert the number to a floating-point number, e.g., \((\text{FPLUS 1 2.3}) \quad <\rightarrow \quad (\text{FPLUS} \ 1.0 \ 2.3) \quad \Rightarrow \quad 3.3\); if given a non-numeric argument, they generate an error, Non-numeric arg.

\[ \begin{align*}
(\text{FPLUS} \ X_1 \ X_2 \ \ldots \ \ldots \ X_n) & \quad \text{[NoSpread Function]} \\
& \quad X_1 + X_2 + \ldots + X_n
\end{align*} \]

\[ \begin{align*}
(\text{FMINUS} \ X) & \quad \text{[Function]} \\
& \quad -X
\end{align*} \]

\[ \begin{align*}
(\text{FDIFFERENCE} \ X \ Y) & \quad \text{[Function]} \\
& \quad X - Y
\end{align*} \]
(FTIMES X₁ X₂ ... Xₙ)  [NoSpread Function]

\[ X₁ \times X₂ \times \ldots \times Xₙ \]

(FQUOTIENT X Y)  [Function]

\[ X / Y. \]

The results of division by zero and floating-point overflow is determined by the function OVERFLOW.

(FREMAINDER X Y)  [Function]

Returns the remainder when \( X \) is divided by \( Y \). Equivalent to:

\[ (FDIFFERENCE X (FTIMES Y (FIX (FQUOTIENT X Y)))) \]

Example:

\[ (FREMAINDER 7.5 2.3) \Rightarrow 0.6 \]

(FGREATERP X Y)  [Function]

T, if \( X > Y \), NIL otherwise.

(FLESSP X Y)  [Function]

T, if \( X < Y \), NIL otherwise.

(FEQP X Y)  [Function]

Returns T if \( X \) and \( Y \) are equal floating-point numbers; NIL otherwise. FEQP converts \( X \) and \( Y \) to floating-point numbers.

(FMIN X₁ X₂ ... Xₙ)  [NoSpread Function]

Returns the minimum of \( X₁, X₂, \ldots, Xₙ \) (FMIN) returns the largest possible floating-point number, the value of MAX.FLOAT.

(FMAX X₁ X₂ ... Xₙ)  [NoSpread Function]

Returns the maximum of \( X₁, X₂, \ldots, Xₙ \) (FMAX) returns the smallest possible floating-point number, the value of MIN.FLOAT.

(FLOAT X)  [Function]

Converts \( X \) to a floating-point number. Example:

\[ (FLOAT 0) \Rightarrow 0.0 \]

Transcendental Arithmetic Functions

(EXPT A N)  [Function]

Returns \( A^N \). If \( A \) is an integer and \( N \) is a positive integer, returns an integer, e.g. (EXPT 3 4) \( \Rightarrow 81 \), otherwise returns a floating-point number. If \( A \) is negative and \( N \) fractional,
generates the error, \textit{Illegal exponentiation}. If \( N \) is floating and either too large or too small, generates the error, \textit{Value out of range expt}.

\begin{itemize}
\item \textbf{(SQRT \( N \))} [Function]
\end{itemize}

Returns the square root of \( N \) as a floating-point number. \( N \) may be fixed or floating-point. Generates an error if \( N \) is negative.

\begin{itemize}
\item \textbf{(LOG \( X \))} [Function]
\end{itemize}

Returns the natural logarithm of \( X \) as a floating-point number. \( X \) can be integer or floating-point.

\begin{itemize}
\item \textbf{(ANTILOG \( X \))} [Function]
\end{itemize}

Returns the floating-point number whose logarithm is \( X \). \( X \) can be integer or floating-point. Example:

\begin{itemize}
\item \textbf{(ANTILOG 1) = e => 2.71828...}
\end{itemize}

\begin{itemize}
\item \textbf{(SIN \( X \) RADIANSFLG)} [Function]
\end{itemize}

Returns the sine of \( X \) as a floating-point number. \( X \) is in degrees unless \textit{RADIANSFLG} = \textit{T}.

\begin{itemize}
\item \textbf{(COS \( X \) RADIANSFLG)} [Function]
\end{itemize}

Similar to \textit{SIN}.

\begin{itemize}
\item \textbf{(TAN \( X \) RADIANSFLG)} [Function]
\end{itemize}

Similar to \textit{SIN}.

\begin{itemize}
\item \textbf{(ARCSIN \( X \) RADIANSFLG)} [Function]
\end{itemize}

The value of \textit{ARCSIN} is a floating-point number, and is in degrees unless \textit{RADIANSFLG} = \textit{T}. In other words, if (ARCSIN \( X \) RADIANSFLG) = \( Z \) then (SIN \( Z \) RADIANSFLG) = \( X \). The range of the value of \textit{ARCSIN} is -90 to +90 for degrees, -\( \pi/2 \) to \( \pi/2 \) for radians. \( X \) must be a number between -1 and 1.

\begin{itemize}
\item \textbf{(ARCCOS \( X \) RADIANSFLG)} [Function]
\end{itemize}

Similar to \textit{ARCSIN}. Range is 0 to 180, 0 to \( \pi \).

\begin{itemize}
\item \textbf{(ARCTAN \( X \) RADIANSFLG)} [Function]
\end{itemize}

Similar to \textit{ARCSIN}. Range is 0 to 180, 0 to \( \pi \).

\begin{itemize}
\item \textbf{(ARCTAN2 \( Y \) \( X \) RADIANSFLG)} [Function]
\end{itemize}

Computes (ARCTAN (FQUOTIENT \( Y \) \( X \)) RADIANSFLG), and returns a corresponding value in the range -180 to 180 (or -\( \pi \) to \( \pi \)), i.e. the result is in the proper quadrant as determined by the signs of \( X \) and \( Y \).
Generating Random Numbers

(RAND LOWER UPPER)  [Function]

Returns a pseudo-random number between LOWER and UPPER inclusive, i.e., RAND can be used to generate a sequence of random numbers. If both limits are integers, the value of RAND is an integer, otherwise it is a floating-point number. The algorithm is completely deterministic, i.e., given the same initial state, RAND produces the same sequence of values. The internal state of RAND is initialized using the function RANDSET.

(RANDSET X)  [Function]

Returns the internal state of RAND. If X = NIL, just returns the current state. If X = T, RAND is initialized using the clocks, and RANDSET returns the new state. Otherwise, X is interpreted as a previous internal state, i.e., a value of RANDSET, and is used to reset RAND. For example,

```
(SETQ OLDSTATE (RANDSET))
...
(for X from 1 to 10 do (PRIN1 (RAND 1 10)))
2847592748NIL
(RANDSET OLDSTATE)
...
(for X from 1 to 10 do (PRIN1 (RAND 1 10)))
2847592748NIL
```
Hiding the details of your code makes it more readable, and lets you program more efficiently. Data structures are a good example: You’re better off if you can say “Fetch me the speed field from this airplane” rather than having to say `(car (cddr (cadr airplane)))`. You can declare data structures used by your programs, then work with field names rather than access details. Using the declarations, Medley performs the access/storage operations you request. If you change a data structure’s declaration, your programs automatically adjust.

You describe the format of a data structure (record) by making a “record declaration” (see the Record Declarations section below). The record declaration is a description of the record, associating names with its various parts, or “fields”. For example, the record declaration

```
(RECORD MSG (FROM TO TEXT))
```

describes a data structure called MSG that has three fields: FROM, TO, and TEXT. You can refer to these fields by name, to get their values or to store new values into them, by using `fetch` and `replace`:

```
(fetch (MSG FROM) of MYMSG)
(replace (MSG TO) of MYMSG with "John Doe")
```

You create new MSGs with `create`:

```
(setq MYMSG (create MSG))
```

and `type?` tells you whether some object is a MSG:

```
(IF (TYPE? MSG THIS-THING) then (SEND-MSG THIS-THING))
```

So far we’ve said nothing about how your MSG is represented—when you’re writing `fetches` and `replaces`, it doesn’t matter. But you can control the representation: The symbol `record` in the declaration above causes each MSG to be represented as a list. There are a number of options, up to creating a completely new Lisp data type; each has its own specifier symbol, and they’re described in detail below.

The record package is implemented using DWIM and CLISP, so it will do spelling correction on field names, record types, etc. Record operations are translated using all CLISP declarations in effect (standard/fast/undoable).

The file manager’s `RECORDS` command lets you give record declarations (see Chapter 17), and `FILES` and `CLEANUP` will tell you about record declarations that need to be dumped.

### FETCH and REPLACE

The fields of a record are accessed and changed with `fetch` and `replace`. If `x` is a MSG data structure, `(fetch FROM of x)` will return the value of the FROM field of `x`, and `(replace FROM of x with y)` will replace this field with the value of `y`. In general, the value of a `replace` operation is the same as the value stored into the field.

Note that `(fetch FROM of x)` assumes that `x` is an instance of the record MSG—the interpretation of `(fetch FROM of x)` never depends on the `value` of `x`. If `x` is not a MSG, this may produce incorrect results.

If there is another record declaration, `(RECORD REPLY (TEXT RESPONSE))`, then `(fetch TEXT of x)` is ambiguous, because `x` could be either a MSG or a REPLY record. In this case, an error will occur, `Ambiguous record field`. To clarify this, give `fetch` and `replace` a list for their “field” argument: `(fetch (MSG TEXT) of x)` will fetch the `TEXT` field of a MSG record. If a field has an `identical` interpretation in two declarations, e.g., if the field
TEXT occurred in the same location within the declarations of MSG and REPLY, then \texttt{(fetch TEXT of X)} would not be ambiguous.

If there's a conflict, “user” record declarations take precedence over “system” record declarations. System records are declared by including \texttt{SYSTEM} in the declaration (see the Record Declarations section below). All of the records defined in the standard Medley system are system records.

Another complication can occur if the fields of a record are themselves records. The fields of a record can be further broken down into sub-fields by a “subdeclaration” within the record declaration. For example,

\begin{verbatim}
(RECORD NODE (POSITION . LABEL) (RECORD POSITION (XLOC . YLOC)))
\end{verbatim}

lets you access the \texttt{POSITION} field with \texttt{(fetch POSITION of X)}, or its subfield \texttt{XLOC} with \texttt{(fetch XLOC of X)}.

You may also declare that field name in a separate record declaration. For instance, the \texttt{TEXT} field in the \texttt{MSG} and \texttt{REPLY} records above may be subdivided with the separate record declaration \texttt{(RECORD TEXT (HEADER TXT))}. You get to fields of subfields (to any level of nesting) by specifying the “data path” as a list of record/field names, where there is some path from each record to the next in the list. For instance,

\begin{verbatim}
(fetch (MSG TEXT HEADER) of X)
\end{verbatim}

treats \texttt{X} as a \texttt{MSG} record, fetches its \texttt{TEXT} field, and fetches its \texttt{HEADER} field. You only need to give enough of the data path to disambiguate it. In this case, \texttt{(fetch (MSG HEADER) of X)} is sufficient: Medley searches among all current record declarations for a path from each name to the next, considering first local declarations (see Chapter 21) and then global ones. Of course, if you had two records with \texttt{HEADER} fields, you get an \texttt{Ambiguous data path} error.

\texttt{FETCH} and \texttt{REPLACE} are translated using the CLISP declarations in effect (see Chapter 21). \texttt{FFETCH} and \texttt{FREPLACE} are fast versions that don't do any type checking. \texttt{/REPLACE} insures undoable declarations.

\section*{Record Declarations}

You define records by evaluating declarations of the form:

\begin{verbatim}
(RECORD-TYPE RECORD-NAME RECORD-FIELDS . RECORD-TAIL)
\end{verbatim}

\texttt{RECORD-TYPE} specifies the “type” of data you’re declaring, and controls how instances will be stored internally. The different record types are described below.

\texttt{RECORD-NAME} is a symbol used to identify the record declaration for \texttt{CREATE}, \texttt{TYPE?}, \texttt{FETCH} and \texttt{REPLACE}, and dumping to files (see Chapter 17). \texttt{DATATYPE} and \texttt{TYPERECORD} declarations also use \texttt{RECORD-NAME} to identify the data structure (as described below).

\texttt{RECORD-FIELDS} describes the structure of the record. Its exact interpretation varies with \texttt{RECORD-TYPE}. Generally, it names the fields within the record that can be accessed with \texttt{FETCH} and \texttt{REPLACE}.

\texttt{RECORD-TAIL} is an optional list where you can specify default values for record fields, special \texttt{CREATE} and \texttt{TYPE?} forms, and subdeclarations (described below).

Record declarations are Lisp programs, and could be included in functions, changing a record declaration at run-time. \textit{Don't do it.} You risk creating a structure with one declaration, and trying to fetch from it with another—complete chaos results. If you need to change record declarations dynamically, consider using association lists or property lists.

\section*{Record Types}

\input{interlisp-d_reference_manual/record_types.tex}
RECORDS AND DATA STRUCTURES

The **RECORD-TYPE** field of the record declaration specifies how the data object is created, and how the various record fields are accessed. Depending on the record type, the record fields may be stored in a list, or in an array, or on a symbol’s property list. The following record types are defined:

### RECORD

The fields of a **RECORD** are kept in a list. **RECORD-FIELDS** is a list; each non-nil symbol is a field-name to be associated with the corresponding element or tail of a list structure. For example, with the declaration `(RECORD MSG (FROM TO . TEXT))`, `(fetch FROM of X)` translates as `(CAR X).`  

NIL can be used as a place marker for an unnamed field, e.g., `(A NIL B)` describes a three element list, with B corresponding to the third element. A number may be used to indicate a sequence of NILs, e.g., `(A 4 B)` is interpreted as `(A NIL NIL NIL NIL B).`

### DATATYPE

Defines a new user data type with type name **RECORD-NAME**. Unlike other record types, the instances of a **DATATYPE** are represented with a completely new Lisp type, and not in terms of other existing types.

**RECORD-FIELDS** is a list of field specifications, where each specification is either a list `(FIELDNAME FIELDTYPE)` or an symbol `FIELDNAME`. If `FIELDTYPE` is omitted, it defaults to **POINTER**. Possible values for `FIELDTYPE` are:

- **POINTER**: Field contains a pointer to any arbitrary Interlisp object.
- **INTEGER** **FIXP**: Field contains a signed integer. Caution: An **INTEGER** field is not capable of holding everything that satisfies **FIXP**, such as bignums.
- **FLOATING** **FLOATP**: Field contains a floating point number.
- **SIGNEDWORD**: Field contains a 16-bit signed integer.
- **FLAG**: Field is a one bit field that “contains” T or NIL.
- **BITS N**: Field contains an N-bit unsigned integer.
- **BYTE**: Equivalent to **BITS 8**.
- **WORD**: Equivalent to **BITS 16**.
- **XPOINTER**: Field contains a pointer like **POINTER**, but the field is *not* reference counted by the garbage collector. **XPOINTER** fields are useful for implementing back-pointers in structures that would be circular and not otherwise collected by the reference-counting garbage collector.

**Warning**: Use **XPOINTER** fields with great care. You can damage the integrity of the storage allocation system by using pointers to objects that have been garbage collected. Code that uses **XPOINTER** fields should be sure that the objects pointed to have not been garbage collected. This can be done in two ways: The first is to maintain the object in a global structure,
so that it is never garbage collected until explicitly deleted from the 
structure, at which point the program must invalidate all the XPOINTER 
fields of other objects pointing at it. The second is to declare the object as 
a DATATYPE beginning with a POINTER field that the program maintains as a 
pointer to an object of another type (e.g., the object containing the XPOINTER 
pointing back at it), and test that field for reasonableness whenever using 
the contents of the XPOINTER field.

For example, the declaration

\[
\text{(DATATYPE FOO (} \text{(FLG BITS 12) TEXT HEAD (DATE BITS 18)} \text{))}
\]

would define a data type FOO with two pointer fields, a floating point number, and fields 
for a 12 and 18 bit unsigned integers, and a flag (one bit). Fields are allocated in such a 
way as to optimize the storage used and not necessarily in the order specified. Generally, 
a DATATYPE record is much more storage compact than the corresponding RECORD structure 
would be; in addition, access is faster.

Since the user data type must be set up at run-time, the RECORDS file package command will 
dump a DECLAREDATATYPE expression as well as the DATATYPE declaration itself. If the record 
declaration is otherwise not needed at runtime, it can be kept out of the compiled file by 
using a (DECLARE: DONTCOPY ...) expression (see Chapter 17), but it is still necessary to ensure 
that the datatype is properly initialized. For this, one can use the INITRECORDS file package 
command (see Chapter 17), which will dump only the DECLAREDATATYPE expression.

Note: When defining a new data type, it is sometimes useful to call the function DEFPRT 
(see Chapter 25) to specify how instances of the new data type should be printed. This 
can be specified in the record declaration by including an INIT record specification (see the 
Optional Record Specifications section below), e.g., (DATATYPE QV.TYPE ... (INIT (DEFPRT 
'QV.TYPE (FUNCTION PRINT.QV.TYPE)))).

DATATYPE declarations cannot be used within local record declarations (see Chapter 21).

TYPERECD [Record Type]

Similar to RECORD, but the record name is added to the front of the list structure to signify 
what “type” of record it is. This type field is used in the translation of TYPE expressions. 
CREATE will insert an extra field containing RECORD-NAME at the beginning of the structure, 
and the translation of the access and storage functions will take this extra field into 
account. For example, for (TYPERECD MSG (FROM TO . TEXT)), (fetch FROM of X) translates as 
(CADR X), not (CAR X).

ASSOCRECD [Record Type]

Describes lists where the fields are stored in association list format:

\[
((\text{FIELDNAME}_1 \ . \ \text{VALUE}_1) \ (\text{FIELDNAME}_2 \ . \ \text{VALUE}_2) \ \ldots)
\]

RECORD-FIELDS is a list of symbols, the permissible field names in the association list. 
Access is done with ASSOC (or FASSOC, if the current CLISP declarations are FAST, see Chapter 
21), storing with PUTASSOC.
RECORDS AND DATA STRUCTURES

PROPRECORD

[Record Type]

Describes lists where the fields are stored in property list format:

\[(FIELDNAME_1 VALUE_1 FIELDNAME_2 VALUE_2 \ldots)\]

RECORD-FIELDS is a list of symbols, the permissable field names in the property list. Access is done with LISTGET, storing with LISTPUT.

Both ASSOCRECORD and PROPRECORD are useful for defining data structures where many of the fields are NIL. Creating one these record types only stores those fields that are non-NIL. Note, however, that with the record declaration \[(PROPRECORD FIE (H I J))] the expression \[(create FIE)] would still construct \[(H NIL)], since a later operation of \[(replace J of X with Y)] could not possibly change the instance of the record if it were NIL.

ARRAYRECORD

[Record Type]

ARRAYRECORDs are stored as arrays. RECORD-FIELDS is a list of field names that are associated with the corresponding elements of an array. NIL can be used as a place marker for an unnamed field (element). Positive integers can be used as abbreviation for the corresponding number of NILs. For example, \[(ARRAYRECORD (ORG DEST NIL ID 3 TEXT))] describes an eight-element array, with ORG corresponding to the first element, ID to the fourth, and TEXT to the eighth.

ARRAYRECORD only creates arrays of pointers. Other kinds of arrays must be implemented with ACCESSFNS (see below).

HASHLINK

[Record Type]

The HASHLINK record type can be used with any type of data object: it specifies that the value of a single field can be accessed by hashing the data object in a given hash array. Since the HASHLINK record type describes an access method, rather than a data structure, CREATE is meaningless for HASHLINK records.

RECORD-FIELDS is either a symbol FIELD-NAME, or a list \[(FIELD-NAME HARRAYNAME HARRAYSIZE)]. HARRAYNAME is a variable whose value is the hash array to be used; if not given, SYSHASHARRAY is used. If the value of the variable HARRAYNAME is not a hash array (at the time of the record declaration), it will be set to a new hash array with a size of HARRAYSIZE. HARRAYSIZE defaults to 100.

The HASHLINK record type is useful as a subdeclaration to other records to add additional fields to already existing data structures (see the Optional Record Specifications section below). For example, suppose that FOO is a record declared with \[(RECORD FOO (A B C))]. To add a new field BAR, without modifying the existing data structures, redefine FOO with:

\[(RECORD FOO (A B C) (HASHLINK FOO (BAR BARHARRAY)))\]

Now, \[(fetch BAR of X)] will translate into \[(GETHASH X BARHARRAY)], hashing off the existing list X.

ATOMRECORD

[Record Type]

ATOMRECORDs are stored on the property lists of symbols. RECORD-FIELDS is a list of property names. Accessing is performed with GETPROP, storing with PUTPROP. The CREATE expression is not initially defined for ATOMRECORD records.
BLOCKRECORD [Record Type]

BLOCKRECORD is used in low-level system programming to “overlay” an organized structure over an arbitrary piece of raw storage. RECORD-FIELDS is interpreted exactly as with a DATATYPE declaration, except that fields are not automatically rearranged to maximize storage efficiency. Like an ACCESSFNS record, a BLOCKRECORD does not have concrete instances; it merely provides a way of interpreting some existing block of storage. So you can’t create an instance of a BLOCKRECORD (unless the declaration includes an explicit CREATE expression), nor is there a default type? expression for a BLOCKRECORD.

Warning: Exercise caution in using BLOCKRECORD declarations, as they let you fetch and store arbitrary data in arbitrary locations, thereby evading Medley’s normal type system. Except in very specialized situations, a BLOCKRECORD should never contain POINTER or XPOINTER fields, nor be used to overlay an area of storage that contains pointers. Such use could compromise the garbage collector and storage allocation system. You are responsible for ensuring that all FETCH and REPLACE expressions are performed only on suitable objects, as no type testing is performed.

A typical use for a BLOCKRECORD in user code is to overlay a non-pointer portion of an existing DATATYPE. For this use, the LOCF macro is useful. (LOCF (fetch FIELD of DATUM)) can be used to refer to the storage that begins at the first word that contains FIELD of DATUM. For example, to define a new kind of Ethernet packet, you could overlay the “body” portion of the ETHERPACKET datatype declaration as follows:

```
(ACCESSFNS MYPACKET
  ((MYBASE (LOCF (fetch (ETHERPACKET EPBODY) of DATUM)))))
(BLOCKRECORD MYBASE
  ((MYTYPE WORD) (MYLENGTH WORD) (MYSTATUS BYTE)
   (MYERRORCODE BYTE) (MYDATA INTEGER)))
(TYPE? (type? ETHERPACKET DATUM)))
```

With this declaration in effect, the expression (fetch MYLENGTH of PACKET) would retrieve the second 16-bit field beyond the place inside PACKET where the EPBODY field starts.

ACCESSFNS [Record Type]

ACCESSFNS lets you specify arbitrary functions to fetch and store data. For each field name, you specify how it is to be accessed and set. This lets you use arbitrary data structures, with complex access methods. Most often, ACCESSFNS are useful when you can compute one field’s value from other fields. If you’re representing a time period by its start and duration, you could add an ACCESSFNS definition for the ending time that did the obvious addition.

RECORD-FIELDS is a list of elements of the form (FIELD-NAME ACCESSDEF SETDEF). ACCESSDEF should be a function of one argument, the datum, and will be used for accessing the value of the field. SETDEF should be a function of two arguments, the datum and the new value, and will be used for storing a new value in a field. SETDEF may be omitted, in which case, no storing operations are allowed.

ACCESSDEF and/or SETDEF may also be a form written in terms of variables DATUM and (in SETDEF) NEWVALUE. For example, given the declaration

```
[ACCESSFNS FOO
  ((FIRSTCHAR (NTHCHAR DATUM 1) (RPLSTRING DATUM 1 NEWVALUE)))
  (RESTCHARS (SUBSTRING DATUM 2))]
```
[replace (FOO FIRSTCHAR) of X with Y] would translate to (RPLSTRING X 1 Y). Since no SETDEF is given for the RESTCHARS field, attempting to perform [replace (FOO RESTCHARS) of X with Y] would generate an error, Replace undefined for field. Note that ACCESSFNS do not have a CREATE definition. However, you may supply one in the defaults or subdeclarations of the declaration, as described below. Attempting to CREATE an ACCESSFNS record without specifying a create definition will cause an error: Create not defined for this record.

ACCESSDEF and SETDEF can also be a property list which specify FAST, STANDARD and UNDOABLE versions of the ACCESSFNS forms, e.g.

```
[ACCESSFNS LITATOM
  [(DEF [STANDARD GETD FAST FGETD]
    [STANDARD PUTD UNDOABLE /PUTD]
]
```

means if FAST declaration is in effect, use FGETD for fetching, if UNDOABLE, use /PUTD for saving (see CLISP declarations, see Chapter 21).

SETDEF forms should be written so that they return the new value, to be consisitant with REPLACE operations for other record types. The REPLACE does not enforce this, though.

ACCESSFNS let you use data structures not specified by one of the built-in record types. For example, one possible representation of a data structure is to store the fields in parallel arrays, especially if the number of instances required is known, and they needn’t be garbage collected. To implement LINK with two fields FROM and TO, you’d have two arrays FROMARRAY and TOARRAY. The representation of an “instance” of LINK would be an integer, used to index into the arrays. This can be accomplished with the declaration:

```
[ACCESSFNS LINK
  [(FROM (ELT FROMARRAY DATUM)
    (SETA FROMARRAY DATUM NEWVALUE))
  (TO (ELT TOARRAY DATUM)
    (SETA TOARRAY DATUM NEWVALUE))]
  (CREATE (PROG1 (SETQ LINKCNT (ADD1 LINKCNT))
    (SETA FROMARRAY LINKCNT FROM)
    (SETA TOARRAY LINKCNT TO))]
  (INIT (PROGN
    (SETQ FROMARRAY (ARRAY 100))
    (SETQ TOARRAY (ARRAY 100))
    (SETQ LINKCNT 0))]
```

To create a new LINK, a counter is incremented and the new elements stored. (Note: The CREATE form given the declaration probably should include a test for overflow.)

Optional Record Specifications

After the RECORD-FIELDS item in a record declaration expression there can be an arbitrary number of additional expressions in RECORD-TAIL. These expressions can be used to specify default values for record fields, special CREATE and TYPE? forms, and subdeclarations. The following expressions are permitted:

FIELD-NAME ← FORM Allows you to specify within the record declaration the default value to be stored in FIELD-NAME by a CREATE (if no value is given within the CREATE expression itself). Note that FORM is evaluated at CREATE time, not when the declaration is made.

Create the manner in which CREATE of this record should be performed. This provides a way of specifying how ACCESSFNS should be created or overriding the usual definition of CREATE. If FORM contains the field-names of the declaration as variables, the forms given in the
CREATE operation will be substituted in. If the word DATUM appears in the
create form, the original CREATE definition is inserted. This effectively
allows you to "advise" the create.

(INIT FORM) Specifies that FORM should be evaluated when the record is declared.
FORM will also be dumped by the INITRECORDS file package command
(see Chapter 17).

For example, see the example of an ACCESSFNS record declaration above.
In this example, PROMARRAY and T OMAPARRAY are initialized with an INIT form.

(TYPE? FORM) Defines the manner in which TYPE? expressions are to be translated.
FORM may either be an expression in terms of DATUM or a function of one
argument.

(SUBRECORD NAME .
  DEFAULTS) NAME must be a field that appears in the current declaration and the
name of another record. This says that, for the purposes of translating
CREATE expressions, substitute the top-level declaration of NAME for the
SUBRECORD form, adding on any defaults specified.

For example: Given (RECORD B (E F G)), (RECORD A (B C D) (SUBRECORD B))
would be treated like (RECORD A (B C D) (RECORD B (E F G))) for the
purposes of translating CREATE expressions.

a subdeclaration If a record declaration expression occurs among the record
specifications of another record declaration, it is known as a
"subdeclaration." Subdeclarations are used to declare that fields of a
record are to be interpreted as another type of record, or that the
record data object is to be interpreted in more than one way.

The RECORD-NAME of a subdeclaration must be either the RECORD-
NAME of its immediately superior declaration or one of the superior's
field-names. Instead of identifying the declaration as with top level
declarations, the record-name of a subdeclaration identifies the parent
field or record that is being described by the subdeclaration.
Subdeclarations can be nested to an arbitrary depth.

Giving a subdeclaration (RECORD NAME1 NAME2) is a simple way of
defining a synonym for the field NAME1.

It is possible for a given field to have more than one subdeclaration.
For example, in

(RECORD FOO (A B) (RECORD A (C D)) (RECORD A (Q R))

(Q R) and (C D) are "overlayered," i.e. (fetch Q of X) and (fetch C of X)
would be equivalent. In such cases, the first subdeclaration is the one
used by CREATE.

(SYNONYM FIELD
RECORDS AND DATA STRUCTURES

(SYN₁ ... SYNₙ) FIELD must be a field that appears in the current declaration. This defines SYN₁ ... SYNₙ all as synonyms of FIELD. If there is only one synonym, this can be written as (SYNONYM FIELD SYN).

(SYSTEM) If (SYSTEM) is included in a record declaration, this indicates that the record is a “system” record rather than a “user” record. The only distinction between the two types of records is that “user” record declarations take precedence over “system” record declarations, in cases where an unqualified field name would be considered ambiguous. All of the records defined in the standard Medley system are defined as system records.

CREATE

You can create RECORDs by hand if you like, using CONS, LIST, etc. But that defeats the whole point of hiding implementation details. So much easier to use:

(create RECORD-NAME , ASSIGNMENTS)

CREATE translates into an appropriate Interlisp form that uses CONS, LIST, PUTHASH, ARRAY, etc., to create the new datum with the its fields initialized to the values you specify. ASSIGNMENTS is optional and may contain expressions of the following form:

FIELD-NAME ← FORM Specifies initial value for FIELD-NAME.

USING FORM FORM is an existing instance of RECORD-NAME. If you don’t specify a value for some field, the value of the corresponding field in FORM is to be used.

COPYING FORM Like USING, but the corresponding values are copied (with COPYALL).

REUSING FORM Like USING, but wherever possible, the corresponding structure in FORM is used.

SMASHING FORM A new instance of the record is not created at all; rather, new field values are smashed into FORM, which CREATE then returns.

When it makes a difference, Medley goes to great pains to make its translation do things in the same order as the original CREATE expression. For example, given the declaration (RECORD CONS (CAR . CDR)), the expression (create CONS CAR=X CDR=V) will translate to (CONS Y X), but (create CONS CDR=(FOO) CAR=(FIE)) will translate to ((LAMBDA ($$1) (CONS (PROGN (SETQ $$1 (FOO)) (FIE)) $$1))) because FOO might set some variables used by FIE.

How are USING and REUSING different? (create RECORD using FORM ...) doesn’t do any destructive operations on the value of FORM, but will incorporate as much as possible of the old data structure into the new one. On the other hand, (create RECORD using FORM ...) will create a completely new data structure, with only the contents of the fields re-used. For example, REUSING a PROPRECORD just copies the new property names and values onto the list, while USING copies the top level of the list. Another example of this distinction occurs when a field is elaborated by a subdeclaration: USING will create a new instance of the sub-record, while REUSING will use the old contents of the field (unless some field of the subdeclaration is assigned in the CREATE expression.)
If the value of a field is neither explicitly specified, nor implicitly specified via using, copying or reusing, the default value in the declaration is used, if any, otherwise NIL. (For between fields in DATATYPE records, $N_2$ is used; for other non-pointer fields zero is used.) For example, following (RECORD A (B C D) D ← 3)

```
(create A B ← T) ==> (LIST T NIL 3)
(create A B ← T using X) ==> (LIST T (CADR X) (CADDR X))
(create A B ← T copying X)) ==> (LIST T (COPYALL (CADR X)) (COPYALL (CADDR X])
(create A B ← T reusing X) ==> (CONS T (CDR X))
```

**TYPE?**

The record package allows you to test if a given datum “looks like” an instance of a record. This can be done via an expression of the form `(TYPE? RECORD-NAME FORM)`.

**TYPE?** is mainly intended for records with a record type of DATATYPE or TYPERCORED. For DATATYPES, the **TYPE?** check is exact; i.e. the **TYPE?** expression will return non-NIL only if the value of FORM is an instance of the record named by RECORD-NAME. For TYPERCOREDS, the **TYPE?** expression will check that the value of FORM is a list beginning with RECORD-NAME. For ARRAYRECORDS, it checks that the value is an array of the correct size. For PROPRECORDS and ASSOCRECORDS, a **TYPE?** expression will make sure that the value of FORM is a property/association list with property names among the field-names of the declaration.

There is no built-in type test for records of type ACCESSFNS, HASHLINK or RECORD. Type tests can be defined for these kinds of records, or redefined for the other kinds, by including an expression of the form `(TYPE? COM)` in the record declaration (see the Record Declarations section below). Attempting to execute a **TYPE?** expression for a record that has no type test causes an error, **TYPE? not implemented for this record**.

**WITH**

Often one wants to write a complex expression that manipulates several fields of a single record. The *WITH* construct can make it easier to write such expressions by allowing one to refer to the fields of a record as if they were variables within a lexical scope:

```
(with RECORD-NAME RECORD-INSTANCE FORM1 ... FORMN)
```

**RECORD-NAME** is the name of a record, and **RECORD-INSTANCE** is an expression which evaluates to an instance of that record. The expressions **FORM1** ... **FORMN** are evaluated so that references to variables which are field-names of **RECORD-NAME** are implemented via **FETCH** and **SETQ**s of those variables are implemented via **REPLACE**.

For example, given

```
(RECORD RECN (FLD1 FLD2))
(SETQ INST (create RECN FLD1 ← 10 FLD2 ← 20))
```

Then the construct

```
(with RECN INST (SETQ FLD2 (PLUS FLD1 FLD2))
```

is equivalent to

```
(replace FLD2 of INST with (PLUS (fetch FLD1 of INST) (fetch FLD2 of INST))
```

**Warning**: *WITH* is implemented by doing simple substitutions in the body of the forms, without regard for how the record fields are used. This means, for example, if the record **POO** is defined by *(RECORD POO (POINTER1 POINTER2))*, then the form

```
(with POO X (SELECTQ Y (POINTER1 POINTER1) NIL)
```
RECORDS AND DATA STRUCTURES

will be translated as

```lisp
(SELECTQ Y ((CAR X) (CAR X)) NIL)
```

Be careful that record field names are not used except as variables in the WITH forms.

**Defining New Record Types**

In addition to the built-in record types, you can declare your own record types by performing the following steps:

1. Add the new record-type to the value of `CLISPRECORDTYPES`.
2. Perform `(MOVQ 'RECORD RECORD-TYPE)`.
3. Put the name of a function which will return the translation on the property list of `RECORD-TYPE`, as the value of the property `USERRECORDTYPE`. Whenever a record declaration of type `RECORD-TYPE` is encountered, this function will be passed the record declaration as its argument, and should return a new record declaration which the record package will then use in its place.

**Manipulating Record Declarations**

```lisp
(EDITREC NAME COM1 ... COMN)
```

```
[NLambda NoSpread Function]
```

EDITREC calls the editor on a copy of all declarations in which `NAME` is the record name or a field name. On exit, it redeclares those that have changed and undeclares any that have been deleted. If `NAME` is `NIL`, all declarations are edited.

`COM1 ... COMN` are (optional) edit commands.

When you redefine a global record, the translations of all expressions involving that record or any of its fields are automatically deleted from `CLISPARRAY`, and thus will be recomputed using the new information. If you change a local record declaration (see Chapter 21), or change some other CLISP declaration (see Chapter 21), e.g., `STANDARD` to `FAST`, and wish the new information to affect record expressions already translated, you must make sure the corresponding translations are removed, usually either by `CLISPIFYing` or using the `DW` edit macro.

```lisp
(RECLOOK RECDATA) ->
```

```
[Function]
```

Returns the entire declaration for the record named `RECDATA`; `NIL` if there is no record declaration with name `RECDATA`. Note that the record package maintains internal state about current record declarations, so performing destructive operations (e.g. `MODIFY`) on the value of `RECLOOK` may leave the record package in an inconsistent state. To change a record declaration, use EDITREC.

```lisp
(FIELDLOOK FIELDNAME) ->
```

```
[Function]
```

Returns the list of declarations in which `FIELDNAME` is the name of a field.

```lisp
(RECORDFIELDNAMES RECORDNAME) ->
```

```
[Function]
```

Returns the list of fields declared in record `RECORDNAME`. `RECORDNAME` may either be a name or an entire declaration.
INTERLISP-D REFERENCE MANUAL

(RECORDACCESS FIELD DATUM DEC TYPE NEWVALUE)

[Function]

TYPE is one of FETCH, REPLACE, FFETCH, FREPLACE, /REPLACE or their lowercase equivalents. TYPE=NIL means FETCH. If TYPE corresponds to a fetch operation, i.e. is FETCH or FFETCH, RECORDACCESS performs (TYPE FIELD of DATUM). If TYPE corresponds to a replace, RECORDACCESS performs (TYPE FIELD of DATUM with NEWVALUE). DEC is an optional declaration; if given, FIELD is interpreted as a field name of that declaration.

Note that RECORDACCESS is relatively inefficient, although it is better than constructing the equivalent form and performing an EVAL.

(RECORDACCESSFORM FIELD DATUM TYPE NEWVALUE)

[Function]

Returns the form that would be compiled as a result of a record access. TYPE is one of FETCH, REPLACE, FFETCH, FREPLACE, /REPLACE or their lowercase equivalents. TYPE=NIL means FETCH.

Changetran

Often, you’ll want to assign a new value to some datum that is a function of its current value:

Incrementing a counter:  (SETQ X (+X 1))

Pushing an item on the front of a list:  (SETQ X (CONS Y X))

Popping an item off a list:  (PROG1 (CAR X) (SETQ X (CDR X)))

Those are simple when you’re working with a variable; it gets complicated when you’re working with structured data. For example, if you want to modify (CAR X), the above examples would be:

(CAR (RPLACA X (+ (CAR X) 1)))
(CAR (RPLACA X (CONS Y (CAR X))))
(nth 1 (RPLACA X (CAR X)))

and if you’re changing an element in an array, (ELT A N), the examples would be:

(SETQ A N (+ (ELT A N) 1))
(SETQ A N (CONS Y (ELT A N)))
(SETQ A N (CDR (ELT A N)))

Changetran is designed to provide a simpler way to express these common (but user-extensible) structure modifications. Changetran defines a set of CLISP words that encode the kind of modification to take place—pushing on a list, adding to a number, etc. More important, you only indicate the item to be modified once. Thus, the “change word” ADD is used to increase the value of a datum by the sum of a set of numbers. Its arguments are the datum, and a set of numbers to be added to it. The datum must be a variable or an accessing expression (envolving FETCH, CAR, LAST, ELT, etc) that can be translated to the appropriate setting expression.

For example, (ADD X 1) is equivalent to:

(SETQ X (+ X 1))

and (ADD (CADDR X) (FOO)) is equivalent to:

(CAR (RPLACA (CDR X) (+ FOO (CADDR X))))

If the datum is a complicated form involving function calls, such as (ELT (POO X) (PIE Y)), Changetran goes to some lengths to make sure that those subsidiary functions are evaluated only once, even though they are used in both the setting and accessing parts of the translation. You can rely on the fact that the forms will be evaluated only as often as they appear in your expression.
For `ADD` and all other changewords, the lowercase version (`add`, etc.) may also be specified. Like other CLISP words, change words are translated using all CLISP declarations in effect (see Chapter 21).

The following is a list of those change words recognized by Changetran. Except for POP, the value of all built-in changeword forms is defined to be the new value of the datum.

- **ADD** `DATUM ITEM1 ITEM2 ...` [Change Word]
  
  Adds the specified items to the current value of the datum, stores the result back in the datum location. The translation will use `IPPLUS`, `PLUS`, or `FPLUS` according to the CLISP declarations in effect (see Chapter 21).

- **PUSH** `DATUM ITEM1 ITEM2 ...` [Change Word]
  
  CONSes the items onto the front of the current value of the datum, and stores the result back in the datum location. For example, `(PUSH X A B)` would translate as `(SETQ X (CONS A (CONS B X)))`.

- **PUSHNEW** `DATUM ITEM1` [Change Word]
  
  Like `PUSH` (with only one item) except that the item is not added if it is already `FMEMB` of the datum's value.

  Note that, whereas `(CAR (PUSH X 'FOO))` will always be `FOO`, `(CAR (PUSHNEW X 'FOO))` might be something else if `FOO` already existed in the middle of the list.

- **PUSHLIST** `DATUM ITEM1 ITEM2 ...` [Change Word]
  
  Similar to `PUSH`, except that the items are `APPEND`ed in front of the current value of the datum. For example, `(PUSHLIST X A B)` translates as `(SETQ X (APPEND A B X))`.

- **POP** `DATUM` [Change Word]
  
  Returns `CAR` of the current value of the datum after storing its `CDR` into the datum. The current value is computed only once even though it is referenced twice. Note that this is the only built-in changeword for which the value of the form is not the new value of the datum.

- **SWAP** `DATUM1 DATUM2` [Change Word]
  
  Sets `DATUM1` to `DATUM2` and vice versa.

- **CHANGE** `DATUM FORM` [Change Word]
  
  This is the most flexible of all change words: You give an arbitrary form describing what the new value should be. But it still highlights the fact that structure modification is happening, and still lets the datum appear only once. `CHANGE` sets `DATUM` to the value of `FORM`, where `FORM` is constructed from `FORM` by substituting the datum expression for every occurrence of the symbol `DATUM`. For example,

  `(CHANGE (CAR X) (ITIMES DATUM 5))` translates as
CHANGE is useful for expressing modifications that are not built-in and are not common enough to justify defining a user-changeword.

You can define new change words. To define a change word, say \textit{sub}, that subtracts items from the current value of the datum, you must put the property \textit{CLISPWORD}, value (\textit{CHANGETRAN} . \textit{sub}) on both the upper- and lower-case versions of \textit{sub}:

\begin{verbatim}
(PUTPROP 'SUB 'CLISPWORD '((CHANGETRAN . sub))
(PUTPROP 'sub 'CLISPWORD '((CHANGETRAN . sub))
\end{verbatim}

Then, you must put (on the lower-case version of \textit{sub} only) the property \textit{CHANGETRAN}, with value \textit{FN}. \textit{FN} is a function that will be applied to a single argument, the whole \textit{sub} form, and must return a form that Changetran can translate into an appropriate expression. This form should be a list structure with the symbol \textit{DATUM} used whenever you want an accessing expression for the current value of the datum to appear. The form \texttt{(DATUM- FORM)} (note that \texttt{DATUM-} is a single symbol) should occur once in the expression; this specifies that an appropriate storing expression into the datum should occur at that point. For example, \textit{sub} could be defined as:

\begin{verbatim}
(PUTPROP 'sub 'CHANGETRAN (LAMBDA (FORM)
  (LIST 'DATUM-
   (LIST 'IDIFFERENCE 'DATUM
    (CONS 'IPLUS (CDR FORM))))))
\end{verbatim}

If the expression \texttt{(sub (CAR X) A B)} were encountered, the arguments to \textsc{sub} would first be dwimified, and then the \textit{CHANGETRAN} function would be passed the list \texttt{(sub (CAR X) A B)}, and return \texttt{(DATUM- (IDIFFERENCE DATUM (IPLUS A B)))}, which Changetran would convert to \texttt{(CAR (RPLACA X (IDIFFERENCE (CAR X) (IPLUS A B))))}.

\textbf{Note}: The \textit{sub} changeword as defined above will always use \textit{IDIFFERENCE} and \textit{IPLUS}; \textit{add} uses the correct addition operation depending on the current CLISP declarations (see Chapter 21).

\section*{Built-In and User Data Types}

Medley is a system for manipulating various kinds of data; it comes with a large set of built-in data types, which you can use to represent a variety of abstract objects; you can also define additional “user data types” that you can manipulate exactly like built-in data types.

Each data type in Medley has an associated “type name,” a symbol. Some of the type names of built-in data types are: \texttt{LITATOM}, \texttt{LISTP}, \texttt{STRINGP}, \texttt{ARRAYP}, \texttt{STACKP}, \texttt{SMALLP}, \texttt{FIXP}, and \texttt{FLOATP}. For user data types, the type name is specified when the data type is created.

\begin{verbatim}
(DATATYPES —)
\end{verbatim} [Function]

Returns a list of all type names currently defined.

\begin{verbatim}
(USERDATATYPES)
\end{verbatim} [Function]

Returns list of names of currently declared user data types.

\begin{verbatim}
(TYPENAME DATUM)
\end{verbatim} [Function]

Returns the type name for the data type of \texttt{DATUM}.
RECORDS AND DATA STRUCTURES

\[(\text{TYPENAMEP DATUM TYPE})\]  
[Function]  
Returns \(\text{T}\) if \(\text{DATUM}\) is an object with type name equal to \(\text{TYPE}\), otherwise \(\text{NIL}\).

In addition to built-in data-types like symbols, lists, arrays, etc., Medley provides a way to define completely new classes of objects, with a fixed number of fields determined by the definition of the data type. To define a new class of objects, you must supply a name for the new data type and specifications for each of its fields. Each field may contain either a pointer (i.e., any arbitrary Interlisp datum), an integer, a floating point number, or an \(N\)-bit integer.

\textbf{Note:} The most convenient way to define new user data types is via \textsc{datatypes} record declarations (see Chapter 8) which call the following functions.

\[(\text{DECLREDATATYPE TYPENAME FIELDSPECS -- --})\]  
[Function]  
Defines a new user data type, with the name \(\text{TYPENAME}\). \(\text{FIELDSPECS}\) is a list of “field specifications.” Each field specification may be one of the following:

\begin{itemize}
  \item \text{POINTER} Field may contain any Interlisp datum.
  \item \text{FIXP} Field contains an integer.
  \item \text{FLOATP} Field contains a floating point number.
  \item \{(\text{BITS} \text{N})\} Field contains a non-negative integer less than \(2^N\).
  \item \text{BYTE} Equivalent to \{(\text{BITS} 8)\}.
  \item \text{WORD} Equivalent to \{(\text{BITS} 16)\}.
  \item \text{SIGNEDWORD} Field contains a 16 bit signed integer.
\end{itemize}

\textsc{declaredatatype} returns a list of “field descriptors,” one for each element of \(\text{FIELDSPECS}\). A field descriptor contains information about where within the datum the field is actually stored.

If \(\text{FIELDSPECS}\) is \(\text{NIL}\), \(\text{TYPENAME}\) is “undeclared.” If \(\text{TYPENAME}\) is already declared as a data type, it is undeclared, and then re-declared with the new \(\text{FIELDSPECS}\). An instance of a data type that has been undeclared has a type name of \(*\text{DEALLOC}\*\).

\[(\text{FETCHFIELD DESCRIPTR DATUM})\]  
[Function]  
Returns the contents of the field described by \(\text{DESCRIPTR}\) from \(\text{DATUM}\). \(\text{DESCRIPTR}\) must be a “field descriptor” as returned by \textsc{declaredatatype} or \textsc{getdescriptors}. If \(\text{DATUM}\) is not an instance of the datatype of which \(\text{DESCRIPTR}\) is a descriptor, causes error \(\text{Datum of incorrect type}\).

\[(\text{REPLACEFIELD DESCRIPTR DATUM NEWVALUE})\]  
[Function]  
Store \(\text{NEWVALUE}\) into the field of \(\text{DATUM}\) described by \(\text{DESCRIPTR}\). \(\text{DESCRIPTR}\) must be a field descriptor as returned by \textsc{declaredatatype}. If \(\text{DATUM}\) is not an instance of the
The datatype of which DESCRIPTOR is a descriptor, causes error Datum of incorrect type. Value is NEWVALUE.

**NCREATE TYPE OLDOBJ**  
[Function]  
Creates and returns a new instance of datatype TYPE.  
If OLDOBJ is also a datum of datatype TYPE, the fields of the new object are initialized to the values of the corresponding fields in OLDOBJ.  
NCREATE will not work for built-in datatypes, such as ARRAYP, STRINGP, etc. If TYPE is not the type name of a previously declared user data type, generates an error, Illegal data type.

**GETFIELDSPECS TYPENAME**  
[Function]  
Returns a list which is EQUAL to the FIELDSPECS argument given to DECLAREDATATYPE for TYPENAME; if TYPENAME is not a currently declared data-type, returns NIL.

**GETDESCRIPTORS TYPENAME**  
[Function]  
Returns a list of field descriptors, EQUAL to the value of DECLAREDATATYPE for TYPENAME. If TYPENAME is not an atom, (TYPENAME TYPENAME) is used.

You can define how a user data type prints, using DEFPRINT (see Chapter 25), how they are to be evaluated by the interpreter via DEFEVAL (see Chapter 10), and how they are to be compiled by the compiler via COMPILETYPELST (see Chapter 18).
9. LISTS AND ITERATIVE STATEMENTS

Medley gives you a large number of predicates, conditional functions, and control functions. Also, there is a complex “iterative statement” facility which allows you to easily create complex loops and iterative constructs.

**Data Type Predicates**

Medley provides separate functions for testing whether objects are of certain commonly-used types:

- **(LITATOM X)**
  - [Function]
  - Returns T if X is a symbol; NIL otherwise. Note that a number is not a symbol.

- **(SMALLP X)**
  - [Function]
  - Returns X if X is a small integer; NIL otherwise. (The range of small integers is -65536 to +65535.)

- **(FIXP X)**
  - [Function]
  - Returns X if X is a small or large integer; NIL otherwise.

- **(FLOATP X)**
  - [Function]
  - Returns X if X is a floating point number; NIL otherwise.

- **(NUMBERP X)**
  - [Function]
  - Returns X if X is a number of any type, NIL otherwise.

- **(ATOM X)**
  - [Function]
  - Returns T if X is an atom (i.e. a symbol or a number); NIL otherwise.

- **(LISTP X)**
  - [Function]
  - Returns X if X is a list cell (something created by CONS); NIL otherwise.

- **(NLISTP X)**
  - [Function]
  - (NOT (LISTP X)). Returns T if X is not a list cell, NIL otherwise.

- **(STRINGP X)**
  - [Function]
  - Returns X if X is a string, NIL otherwise.

- **(ARRAYP X)**
  - [Function]
  - Returns X if X is an array, NIL otherwise.

- **(HARRAYP X)**
  - [Function]
  - Returns X if it is a hash array object; otherwise NIL.
HARRAYP returns NIL if \( X \) is a list whose CAR is an HARRAYP, even though this is accepted by the hash array functions.

**Note:** The empty list, () or NIL, is considered to be a symbol, rather than a list. Therefore, \((LITATOM\ NIL) = (ATOM\ NIL) = \text{T}\) and \((LISTP\ NIL) = \text{NIL}\). Take care when using these functions if the object may be the empty list NIL.

### Equality Predicates

Sometimes, there is more than one type of equality. For instance, given two lists, you can ask whether they are exactly the same object, or whether they are two distinct lists that contain the same elements. Confusion between these two types of equality is often the source of program errors.

\[
\text{(EQ} X Y) \quad \text{[Function]}
\]

Returns \text{T} if \( X \) and \( Y \) are identical pointers; \text{NIL} otherwise. EQ should not be used to compare two numbers, unless they are small integers; use \text{EQP} instead.

\[
\text{(NEQ} X Y) \quad \text{[Function]}
\]

The same as \((\text{NOT} (\text{EQ} X Y))\)

\[
\text{(NULL} X) \quad \text{[Function]}
\]

\[
\text{(NOT} X) \quad \text{[Function]}
\]

The same as \((\text{EQ} X \text{NIL})\)

\[
\text{(EQP} X Y) \quad \text{[Function]}
\]

Returns \text{T} if \( X \) and \( Y \) are EQ, or if \( X \) and \( Y \) are numbers and are equal in value; \text{NIL} otherwise. For more discussion of EQP and other number functions, see Chapter 7.

EQP also can be used to compare stack pointers (Section 11) and compiled code (Chapter 10).

\[
\text{(EQUAL} X Y) \quad \text{[Function]}
\]

EQUAL returns \text{T} if \( X \) and \( Y \) are one of the following:

1. EQ
2. EQP, i.e., numbers with equal value
3. STREQUAL, i.e., strings containing the same sequence of characters
4. Lists and CAR of \( X \) is EQUAL to CAR of \( Y \), and CDR of \( X \) is EQUAL to CDR of \( Y \)

EQUAL returns \text{NIL} otherwise. Note that EQUAL can be significantly slower than EQ.

A loose description of EQUAL might be to say that \( X \) and \( Y \) are EQUAL if they print out the same way.

\[
\text{(EQUALALL} X Y) \quad \text{[Function]}
\]

Like EQUAL, except it descends into the contents of arrays, hash arrays, user data types, etc. Two non-EQ arrays may be EQUALALL if their respective components are EQUALALL.
Note: In general, EQUALALL descends all the way into all datatypes, both those you’ve defined and those built into the system. If you have a data structure with fonts and pointers to windows, EQUALALL will descend those also. If the data structures are circular, as windows are, EQUALALL can cause stack overflow.

Logical Predicates

\[ \text{(AND } X_1 X_2 \ldots X_n \text{)} \]  

Takes an indefinite number of arguments (including zero), that are evaluated in order. If any argument evaluates to NIL, AND immediately returns NIL, without evaluating the remaining arguments. If all of the arguments evaluate to non-NIL, the value of the last argument is returned. \((\text{AND}) \Rightarrow T.\)

\[ \text{(OR } X_1 X_2 \ldots X_n \text{)} \]  

Takes an indefinite number of arguments (including zero), that are evaluated in order. If any argument is non-NIL, the value of that argument is returned by OR (without evaluating the remaining arguments). If all of the arguments evaluate to NIL, NIL is returned. \((\text{OR}) \Rightarrow \text{NIL.}\)

AND and OR can be used as simple logical connectives, but note that they may not evaluate all of their arguments. This makes a difference if some of the arguments cause side-effects. This also means you can use AND and OR as simple conditional statements. For example: \((\text{AND } (\text{LISTP } X) (\text{CDR } X))\) returns the value of \((\text{CDR } X)\) if \(X\) is a list cell; otherwise it returns NIL without evaluating \((\text{CDR } X)\).

In general, you should avoid this use of AND and OR in favor of more explicit conditional statements in order to make programs more readable.

COND Conditional Function

\[ \text{(COND } \text{CLAUSE}_1 \text{ CLAUSE}_2 \ldots \text{ CLAUSE}_k \text{)} \]  

COND takes an indefinite number of arguments, called clauses. Each \text{CLAUSE}_i is a list of the form \((P_i \ C_{i1} \ldots \ C_{iN})\), where \(P_i\) is the predicate, and \(C_{i1} \ldots \ C_{iN}\) are the consequents. The operation of COND can be paraphrased as:

\[
\text{IF } P_1 \text{ THEN } C_{11} \ldots \ C_{1N} \text{ ELSEIF } P_2 \text{ THEN } C_{21} \ldots \ C_{2N} \text{ ELSEIF } P_3 \ldots
\]

The clauses are considered in sequence as follows: The predicate \(P_i\) of the clause \text{CLAUSE}_i is evaluated. If the value of \(P_i\) is “true” (non-NIL), the consequents \(C_{i1} \ldots \ C_{iN}\) are evaluated in order, and the value of the COND is the value of the last expression in the clause. If \(P_i\) is “false” (EQ to NIL), then the remainder of \text{CLAUSE}_i is ignored, and the next clause, \text{CLAUSE}_{i+1}, is considered. If no \(P_i\) is true for any clause, the value of the COND is NIL.

If a clause has no consequents, and has the form \((P_i)\), then if \(P_i\) evaluates to non-NIL, it is returned as the value of the COND. It is only evaluated once.

Example:

\[
\text{← (DEFINEQ (DOUBLE } X) \\
\text{ (COND } ((\text{NUMBERP } X) (\text{PLUS } X X))
\]
A few points about this example: Notice that 5 is both a number and an atom, but it is “caught” by the NUMBERP clause before the ATOM clause. Also notice the predicate T, which is always true. This is the normal way to indicate a COND clause which will always be executed (if none of the preceding clauses are true). (HORRIBLE-ERROR) will never be executed.

The IF Statement

The IF statement lets you write conditional expressions that are easier to read than using COND directly. CLISP translates expressions using IF, THEN, ELSEIF, or ELSE (or their lowercase versions) into equivalent CONDs. In general, statements of the form:

(if AAA then BBB elseif CCC then DDD else EEE)

are translated to:

(COND (AAA BBB) (CCC DDD) (T EEE))

The segment between IF or ELSEIF and the next THEN corresponds to the predicate of a COND clause, and the segment between THEN and the next ELSE or ELSEIF as the consequent(s). ELSE is the same as ELSEIF T THEN. These words are spelling corrected using the spelling list CLISPIFWORDSPLST. You may also use lower-case versions (if, then, elseif, else).

If there is nothing following a THEN, or THEN is omitted entirely, the resulting COND clause has a predicate but no consequent. For example, (if X then elseif ...) and (if X elseif ...) both translate to (COND (X) ...)—if X is not NIL, it is returned as the value of the COND.

Each predicate must be a single expression, but multiple expressions are allowed as the consequents after THEN or ELSE. Multiple consequent expressions are implicitly wrapped in a PROGN, and the value of the last one is returned as the value of the consequent. For example:

(if X then (PRINT "FOO") (PRINT "BAR") elseif Y then (PRINT "BAZ"))
Selection Functions

\[(\text{SELECTQ } X \text{ CLAUSE}_1 \text{ CLAUSE}_2 \ldots \text{ CLAUSE}_k \text{ DEFAULT})\]  

[ NLambda NoSpread Function ]

Selects a form or sequence of forms based on the value of \(X\). Each clause \(\text{CLAUSE}_i\) is a list of the form \(\langle S_i, C_{i1}, \ldots, C_{iN} \rangle\), where \(S_i\) is the selection key. Think of \(\text{SELECTQ}\) as:

\[
\begin{align*}
\text{IF } X = S_1 & \text{ THEN } C_{11} \ldots C_{1N} \text{ ELSEIF } X = S_2 \\
\text{THEN } & \ldots \text{ ELSE DEFAULT}
\end{align*}
\]

If \(S_i\) is a symbol, the value of \(X\) is tested to see if it is \(\text{EQ}\) to \(S_i\) (which is \text{not} evaluated). If so, the expressions \(C_{i1}, \ldots, C_{iN}\) are evaluated in sequence, and the value of the \(\text{SELECTQ}\) is the value of the last expression.

If \(S_i\) is a list, the value of \(X\) is compared with each element (not evaluated) of \(S_i\), and if \(X\) is \(\text{EQ}\) to any one of them, then \(C_{i1}, \ldots, C_{iN}\) are evaluated as above.

If \(\text{CLAUSE}_i\) is not selected in one of the two ways described, \(\text{CLAUSE}_{i+1}\) is tested, etc., until all the clauses have been tested. If none is selected, \(\text{DEFAULT}\) is evaluated, and its value is returned as the value of the \(\text{SELECTQ}\). \(\text{DEFAULT}\) must be present.

An example of the form of a \(\text{SELECTQ}\) is:

\[
\begin{align*}
\text{[SELECTQ MONTH} \\
\text{ (FEBRUARY (if (LEAPYEAR) then 29 else 28)) (SEPTEMBER APRIL JUNE NOVEMBER) 30} \text{ 31}]\end{align*}
\]

If the value of \(\text{MONTH}\) is the symbol \(\text{FEBRUARY}\), the \(\text{SELECTQ}\) returns \(28\) or \(29\) (depending on \(\text{LEAPYEAR}\)); otherwise if \(\text{MONTH}\) is \(\text{APRIL, JUNE, SEPTEMBER, or NOVEMBER}\), the \(\text{SELECTQ}\) returns \(30\); otherwise it returns \(31\).

\(\text{SELECTQ}\) compiles open, and is therefore very fast; however, it will not work if the value of \(X\) is a list, a large integer, or floating point number, since \(\text{SELECTQ}\) uses \(\text{EQ}\) for all comparisons.

\(\text{SELCHARQ}\) (Chapter 2) is a version of \(\text{SELECTQ}\) that recognizes \text{CHARCODE} symbols.

\[(\text{SELECTC } X \text{ CLAUSE}_1 \text{ CLAUSE}_2 \ldots \text{ CLAUSE}_k \text{ DEFAULT})\]  

[ NLambda NoSpread Function ]

“\(\text{SELECTQ}\)-on-
Constant.” Like \(\text{SELECTQ}\), but the selection keys are evaluated, and the result used as a \(\text{SELECTQ}\)-style selection key.

\(\text{SELECTC}\) is compiled as a \(\text{SELECTQ}\), with the selection keys evaluated at compile-time. Therefore, the selection keys act like compile-time constants (see Chapter 18).

For example:

\[
\begin{align*}
\text{[SELECTC NUM} \\
\text{ ((for X from 1 to 9 collect (TIMES X X)) "SQUARE") "HIP"}]\end{align*}
\]

compiles as:

\[
\begin{align*}
\text{(SELECTQ NUM} \\
\text{ ((1 4 9 16 25 36 49 64 81) "SQUARE") "HIP")}\end{align*}
\]
**INTERLISP-D REFERENCE MANUAL**

**PROG and Associated Control Functions**

((PROG1 \(X_1, X_2, \ldots, X_n\)) ...)  
[NoSpread Function]

Evaluates its arguments in order, and returns the value of its first argument \(X_1\). For example, \((\text{PROG1} \ X \ \text{SETQ} \ X \ Y)\) sets \(X\) to \(Y\), and returns \(X\)’s original value.

((PROG2 \(X_1, X_2, \ldots, X_n\)) ...)  
[NoSpread Function]

Like PROG1. Evaluates its arguments in order, and returns the value of its second argument \(X_2\).

(\(\text{PROGN} \ X_1 \ X_2 \ \ldots \ X_n\))  
[NoSpread Function]

\(\text{PROGN}\) evaluates each of its arguments in order, and returns the value of its last argument. \(\text{PROGN}\) is used to specify more than one computation where the syntax allows only one, e.g., \((\text{SELECTQ} \ \ldots \ \text{PROGN} \ \ldots))\) allows evaluation of several expressions as the default condition for a \(\text{SELECTQ}\).

((PROG \VARLIST \(E_1, E_2, \ldots, E_n\)) ...)  
[NoSpread Function]

Lets you bind some variables while you execute a series of expressions. \VARLIST is a list of local variables (must be NIL if no variables are used). Each symbol in \VARLIST is treated as the name of a local variable and bound to NIL. \VARLIST can also contain lists of the form \((\text{NAME} \ \text{FORM})\). In this case, \text{NAME} is the name of the variable and is bound to the value of \text{FORM}. The evaluation takes place before any of the bindings are performed, e.g., \((\text{PROG} \ ((X \ Y) \ (Y \ X)) \ \ldots)\) will bind local variable \(X\) to the value of \(Y\) (evaluated outside the \text{PROG}) and local variable \(Y\) to the value of \(X\) (outside the \text{PROG}). An attempt to use anything other than a symbol as a \text{PROG} variable will cause an error, Arg not symbol. An attempt to use NIL or T as a \text{PROG} variable will cause an error, Attempt to bind NIL or T.

The rest of the \text{PROG} is a sequence of forms and symbols (labels). The forms are evaluated sequentially; the labels serve only as markers. The two special functions, \text{GO} and \text{RETURN}, alter this flow of control as described below. The value of the \text{PROG} is usually specified by the function \text{RETURN}. If no \text{RETURN} is executed before the \text{PROG} “falls off the end,” the value of the \text{PROG} is NIL.

((GO \L) ...)  
[NoSpread Function]

\text{GO} is used to cause a transfer in a \text{PROG}. \((\text{GO} \ L)\) will cause the \text{PROG} to evaluate forms starting at the label \(L\) (\text{GO} does not evaluate its argument). A \text{GO} can be used at any level in a \text{PROG}. If the label is not found, \text{GO} will search higher progs within the same function, e.g., \((\text{PROG} \ \ldots \ A \ \ldots \ (\text{PROG} \ \ldots \ (\text{GO} \ A))\)). If the label is not found in the function in which the \text{PROG} appears, an error is generated, Undefined or illegal GO.

((RETURN \X) ...)  
[Function]

A \text{RETURN} is the normal exit for a \text{PROG}. Its argument is evaluated and is immediately returned the value of the \text{PROG} in which it appears.
Note: If a GO or RETURN is executed in an interpreted function which is not a PROG, the GO or RETURN will be executed in the last interpreted PROG entered if any, otherwise cause an error.

GO or RETURN inside of a compiled function that is not a PROG is not allowed, and will cause an error at compile time.

As a corollary, GO or RETURN in a functional argument, e.g., to SORT, will not work compiled. Also, since NLSETQ’s and ERSETQ’s compile as separate functions, a GO or RETURN cannot be used inside of a compiled NLSETQ or ERSETQ if the corresponding PROG is outside, i.e., above, the NLSETQ or ERSETQ.

\[
\text{(LET VARLST E1 E2 \ldots EN)} \quad \text{[Macro]}
\]

LET is essentially a PROG that can’t contain GO’s or RETURN’s, and whose last form is the returned value.

\[
\text{(LET* VARLST E1 E2 \ldots EN)} \quad \text{[Macro]}
\]

\[
\text{(PROG* VARLST E1 E2 \ldots EN)} \quad \text{[Macro]}
\]

LET* and PROG* differ from LET and PROG only in that the binding of the bound variables is done “sequentially.” Thus

\[
\text{(LET* ((A (LIST 5)) (B (LIST A A))) (EQ A (CADR B)))}
\]

would evaluate to T; whereas the same form with LET might find A an unbound variable when evaluating (LIST A A).

The Iterative Statement

The various forms of the iterative statement (i.s.) let you write complex loops easily. Rather than writing PROG, MAPC, MAPCAR, etc., let Medley do it for you.

An iterative statement is a form consisting of a number of special words (known as i.s. operators or i.s.oprs), followed by operands. Many i.s.oprs (FOR, DO, WHILE, etc.) act like loops in other programming languages; others (COLLECT, JOIN, IN, etc.) do things useful in Lisp. You can also use lower-case versions of i.s.oprs (do, collect, etc.).

\[
\text{← (for X from 1 to 5 do (PRINT 'FOO))}
\]

FOO

\[
\text{← (for X from 2 to 10 by 2 collect (TIMES X X))}
\]

(4 16 36 64 100)

\[
\text{← (for X in '(A B 1 C 6.5 NIL (45)) count (NUMBERP X))}
\]

2

Iterative statements are implemented using CLISP, which translates them into the appropriate PROGs, MAPCARS, etc. They’re are translated using all CLISP declarations in effect (standard/fast/undoable/
etc.; see Chapter 21. Misspelled i.s.ops are recognized and corrected using the spelling list CLISPFORWORDSPLST. Operators can appear in any order; CLISP scans the entire statement before it begins to translate.

If you define a function with the same name as an i.s.opr (WHILE, TO, etc.), that i.s.opr will no longer cause looping when it appears as CAR of a form, although it will continue to be treated as an i.s.opr if it appears in the interior of an iterative statement. To alert you, a warning message is printed, e.g., (While defined, therefore disabled in CLISP).

I.S. Types

Every iterative statement must have exactly one of the following operators in it (its “is.stype”), to specify what happens on each iteration. Its operand is called the “body” of the iterative statement.

- **DO FORMS** [I.S. Operator]
  
  Evaluate FORMS at each iteration. DO with no other operator specifies an infinite loop. If some explicit or implicit terminating condition is specified, the value of the loop is NIL. Translates to MAPC or MAP whenever possible.

- **COLLECT FORM** [I.S. Operator]
  
  The value of FORM at each iteration is collected in a list, which is returned as the value of the loop when it terminates. Translates to MAPCAR, MAPLIST or SUBSET whenever possible.

  When COLLECT translates to a PROG (if UNTIL, WHILE, etc. appear in the loop), the translation employs an open TCONC using two pointers similar to that used by the compiler for compiling MAPCAR. To disable this translation, perform (CLDISABLE 'FCOLLECT).

- **JOIN FORM** [I.S. Operator]
  
  FORM returns a list; the lists from each iteration are concatenated using NCONC, forming one long list. Translates to MAPCONC or MAPCON whenever possible. /NCONC, /MAPCONC, and /MAPCON are used when the CLISP declaration UNDOABLE is in effect.

- **SUM FORM** [I.S. Operator]
  
  The values of FORM from each iteration are added together and returned as the value of the loop, e.g., (for I from 1 to 5 sum (TIMES I I)) returns 1+4+9+16+25 = 55. IPLUS, FPLUS, or PLUS will be used in the translation depending on the CLISP declarations in effect.

- **COUNT FORM** [I.S. Operator]
  
  Counts the number of times that FORM is true, and returns that count as the loop’s value.

- **ALWAYS FORM** [I.S. Operator]
  
  Returns T if the value of FORM is non-NIL for all iterations. Note: Returns NIL as soon as the value of FORM is NIL).
NEVER FORM

Like ALWAYS, but returns T if the value of FORM is never true. **Note:** Returns NIL as soon as the value of FORM is non-NIL.

Often, you’ll want to set a variable each time through the loop; that’s called the “iteration variable”, or i.v. for short. The following i.s.types explicitly refer to the i.v. This is explained below under FOR.

THEREIS FORM

Returns the first value of the i.v. for which FORM is non-NIL, e.g., (for X in Y thereis (NUMBERP X)) returns the first number in Y.

**Note:** Returns the value of the i.v. as soon as the value of FORM is non-NIL.

LARGEST FORM

SMALLEST FORM

Returns the value of the i.v. that provides the largest/smallest value of FORM. $\$$EXTREME is always bound to the current greatest/smallest value, $\$$VAL to the value of the i.v. from which it came.

**Iteration Variable I.s.ops**

You’ll want to bind variables to use during the loop. Rather than putting the loop inside a PROG or LET, you can specify bindings like so:

BIND VAR

BIND VARS

Used to specify dummy variables, which are bound locally within the i.s.

**Note:** You can initialize a variable VAR by saying VAR←FORM:

(bind HEIGHT ← 0 WEIGHT ← 0 for SOLDIER in ...) 

To specify iteration variables, use these operators:

FOR VAR

Specifies the iteration variable (i.v.) that is used in conjunction with IN, ON, FROM, TO, and BY. The variable is rebound within the loop, so the value of the variable outside the loop is not affected. Example:

← (SETQ X 55) 
55
← (for X from 1 to 5 collect (TIMES X X)) 
(1 4 9 16 25)
←X
55

FOR OLD VAR

Like FOR, but VAR is not rebound, so its value outside the loop is changed. Example:

← (SETQ X 55) 
55
INTERLISP-D REFERENCE MANUAL

←(for old X from 1 to 5 collect (TIMES X X))
      (1 4 9 16 25)
←X
      6

FOR VARS [I.S. Operator]

VARS a list of variables, e.g., (for (X Y Z) in ...). The first variable is the i.v., the
rest are dummy variables. See BIND above.

IN FORM [I.S. Operator]

FORM must evaluate to a list. The i.v. is set to successive elements of the list, one per
iteration. For example, (for X in Y do ...) corresponds to (MAPC Y (FUNCTION
(LAMBDA (X) ...))). If no i.v. has been specified, a dummy is supplied, e.g., (in Y
collect CDR) is equivalent to (MAPCAR Y (FUNCTION CDR)).

ON FORM [I.S. Operator]

Same as IN, but the i.v. is reset to the corresponding tail at each iteration. Thus IN
corresponds to MAP, MAPCAR, and MAPCONC, while ON corresponds to MAP, MAPLIST,
and MAPCON.

←(for X on '(A B C) do (PRINT X))
      (A B C)
      (B C)
      (C)
      NIL

Note: For both IN and ON, FORM is evaluated before the main part of the i.s. is entered, i.e.
outside of the scope of any of the bound variables of the i.s. For example, (for X bind
(Y←'(1 2 3)) in Y ...) will map down the list which is the value of Y evaluated
outside of the i.s., not (1 2 3).

IN OLD VAR [I.S. Operator]

Specifies that the i.s. is to iterate down VAR, with VAR itself being reset to the
corresponding tail at each iteration, e.g., after (for X in old L do ... until ...
finishes, L will be some tail of its original value.

IN OLD (VAR←FORM) [I.S. Operator]

Same as IN OLD VAR, except VAR is first set to value of FORM.

ON OLD VAR [I.S. Operator]

Same as IN OLD VAR except the i.v. is reset to the current value of VAR at each iteration,
instead of to (CAR VAR).

ON OLD (VAR←FORM) [I.S. Operator]

Same as ON OLD VAR, except VAR is first set to value of FORM.
CONDITIONALS AND ITERATIVE STATEMENTS

**INSIDE FORM**

Like IN, but treats first non-list, non-NIL tail as the last element of the iteration, e.g.,
INSIDE '(A B C D . E) iterates five times with the i.v. set to E on the last iteration.
INSIDE 'A is equivalent to INSIDE '(A), which will iterate once.

**FROM FORM**

Specifies the initial value for a numerical i.v.  The i.v. is automatically incremented by 1
after each iteration (unless BY is specified).  If no i.v. has been specified, a dummy i.v. is
supplied and initialized, e.g., (from 2 to 5 collect SQRT) returns (1.414 1.732
2.0 2.236).

**TO FORM**

Specifies the final value for a numerical i.v.  If FROM is not specified, the i.v. is initialized
to 1.  If no i.v. has been specified, a dummy i.v. is supplied and initialized.  If BY is not
specified, the i.v. is known to be numerical, so the new i.v. is computed by
adding the value of FORM (which is reevaluated each iteration) to the current value of the
i.v., e.g., (for N from 1 to 10 by 2 collect N) makes a list of the first five odd
numbers.

**BY FORM** (without IN or ON)

If you aren't using IN or ON, BY specifies how the i.v. itself is reset at each iteration.  If
you're using FROM or TO, the i.v. is known to be numerical, so the new i.v. is computed by
adding the value of FORM (which is reevaluated each iteration) to the current value of the
i.v., e.g., (for N from 1 to 10 by 2 collect N) makes a list of the first five odd
numbers.

If FORM is a positive number (FORM itself, not its value, which in general CLISP would
have no way of knowing in advance), the loop stops when the value of the i.v. exceeds the
value of TO's operand.  If FORM is a negative number, the loop stops when the value of the
i.v. becomes less than TO's operand, e.g., (for I from N to M by -2 until
(LESSP I M) ...).  Otherwise, the terminating condition for each iteration depends on
the value of FORM for that iteration: if FORM<0, the test is whether the i.v. is less than TO's
operand, if FORM>0 the test is whether the i.v. exceeds TO's operand; if FORM = 0, the
loop terminates unconditionally.
If you didn’t use FROM or TO and FORM is not a number, the i.v. is simply reset to the value of FORM after each iteration, e.g., (for I from N by (FOO) ...) sets I to the value of (FOO) on each loop after the first.

**BY FORM** (with IN or ON)

If you did use IN or ON, FORM’s value determines the tail for the next iteration, which in turn determines the value for the i.v. as described earlier, i.e., the new i.v. is CAR of the tail for IN, the tail itself for ON. In conjunction with IN, you can refer to the current tail within FORM by using the i.v. or the operand for IN/ON, e.g., (for Z in L by (CDDR Z) ...) or (for Z in L by (CDDR L) ...). At translation time, the name of the internal variable which holds the value of the current tail is substituted for the i.v. throughout FORM. For example, (for X in Y by (CDR (MEMB ‘FOO (CDR X))) collect X) specifies that after each iteration, CDR of the current tail is to be searched for the atom FOO, and (CDR of) this latter tail to be used for the next iteration.

**AS VAR**

Lets you have more than one i.v. for a single loop, e.g., (for X in Y as U in V do ...) moves through the lisps Y and V in parallel (see MAP2C). The loop ends when any of the terminating conditions is met, e.g., (for X in Y as I from 1 to 10 collect X) makes a list of the first ten elements of Y, or however many elements there are on Y if less than 10.

The operand to AS, VAR, specifies the new i.v. For the remainder of the i.s., or until another AS is encountered, all operators refer to the new i.v. For example, (for I from 1 to N1 as J from 1 to N2 by 2 as K from N3 to 1 by -1 ...) terminates when I exceeds N1, or J exceeds N2, or K becomes less than 1. After each iteration, I is incremented by 1, J by 2, and K by -1.

**OUTOF FORM**

For use with generators. On each iteration, the i.v. is set to successive values returned by the generator. The loop ends when the generator runs out.

**Condition I.S. Oprs**

What if you want to do things only on certain times through the loop? You could make the loop body a big COND, but it’s much more readable to use one of these:

**WHEN FORM**

Only run the loop body when FORM’s value is non-NIL. For example, (for X in Y collect X when (NUMBERP X)) collects only the elements of Y that are numbers.

**UNLESS FORM**

Opposite of WHEN: WHEN Z is the same as UNLESS (NOT Z).

**WHILE FORM**

WHILE FORM evaluates FORM before each iteration, and if the value is NIL, exits.
CONDITIONALS AND ITERATIVE STATEMENTS

UNTIL FORM [I.S. Operator]
Opposite of WHILE: Evaluates FORM before each iteration, and if the value is not NIL, exits.

REPEATWHILE FORM [I.S. Operator]
Same as WHILE except the test is performed after the loop body, but before the i.v. is reset for the next iteration.

REPEATUNTIL FORM [I.S. Operator]
Same as UNTIL, except the test is performed after the loop body.

Other I.S. Operators

FIRST FORM [I.S. Operator]
FORM is evaluated once before the first iteration, e.g., (for X Y Z in L first (FOO Y Z) ...), and FOO could be used to initialize Y and Z.

FINALLY FORM [I.S. Operator]
FORM is evaluated after the loop terminates. For example, (for X in L bind Y_0 do (if (ATOM X) then (SETQ Y (PLUS Y 1))) finally (RETURN Y)) will return the number of atoms in L.

EACHTIME FORM [I.S. Operator]
FORM is evaluated at the beginning of each iteration before, and regardless of, any testing. For example, consider,

(for I from 1 to N
do (... (FOO I) ...)
unless (... (FOO I) ...)
until (... (FOO I) ...)"

You might want to set a temporary variable to the value of (FOO I) in order to avoid computing it three times each iteration. However, without knowing the translation, you can't know whether to put the assignment in the operand to DO, UNLESS, or UNTIL. You can avoid this problem by simply writing EACHTIME (SETQ J (FOO I)).

DECLARE DECL [I.S. Operator]
Inserts the form (DECLARE DECL) immediately following the PROG variable list in the translation, or, in the case that the translation is a mapping function rather than a PROG, immediately following the argument list of the lambda expression in the translation. This can be used to declare variables bound in the iterative statement to be compiled as local or special variables. For example (for X in Y declare: (LOCALVARS X) ...). Several DECLARE:s can apppear in the same i.s.; the declarations are inserted in the order they appear.

DECLARE DECL [I.S. Operator]
Same as DECLARE::.
Since DECLARE is also the name of a function, DECLARE cannot be used as an i.s. operator when it appears as CAR of a form, i.e. as the first i.s. operator in an iterative statement. However, declare (lowercase version) can be the first i.s. operator.

**ORIGINAL I.S.OPR OPERAND**

**I.S. OPR** will be translated using its original, built-in interpretation, independent of any user defined i.s. operators.

There are also a number of i.s.ops that make it easier to create iterative statements that use the clock, looping for a given period of time. See timers, Chapter 12.

### Miscellaneous Hints For Using I.S.Oprs

Lowercase versions of all i.s. operators are equivalent to the uppercase, e.g., \( \texttt{(for X in Y ...)} \) is equivalent to \( \texttt{(FOR X IN Y ...)} \).

Each i.s. operator is of lower precedence than all Interlisp forms, so parentheses around the operands can be omitted, and will be supplied where necessary, e.g., \( \texttt{BIND (X Y Z)} \) can be written \( \texttt{BIND X Y Z, OLD (X FORM)} \) as \( \texttt{OLD X FORM} \), etc.

RETURN or GO may be used in any operand. (In this case, the translation of the iterative statement will always be in the form of a PROG, never a mapping function.) RETURN means return from the loop (with the indicated value), not from the function in which the loop appears. GO refers to a label elsewhere in the function in which the loop appears, except for the labels \( \$$LP, \$$ITERATE, and \( \$$OUT \) which are reserved, as described below.

In the case of FIRST, FINALLY, EACHTIME, DECLARE: or one of the i.s.types, e.g., DO, COLLECT, SUM, etc., the operand can consist of more than one form, e.g., \( \texttt{COLLECT (PRINT (CAR X)) (CDR X)} \), in which case a \( \texttt{PROGN} \) is supplied.

Each operand can be the name of a function, in which case it is applied to the (last) i.v., e.g., \( \texttt{(for X in Y do PRINT when NUMBERP)} \) is the same as \( \texttt{(for X in Y do (PRINT X) when (NUMBERP X))} \). Note that the i.v. need not be explicitly specified, e.g., \( \texttt{(in Y as I from 1 to 10 do PRINT)} \) will work.

For i.s.types, e.g., DO, COLLECT, JOIN, the function is always applied to the first i.v. in the i.s., whether explicitly named or not. For example, \( \texttt{(in Y as I from 1 to 10 do PRINT)} \) prints elements on \( Y \), not integers between 1 and 10.

Note that this feature does not make much sense for FOR, OLD, BIND, IN, or ON, since they “operate” before the loop starts, when the i.v. may not even be bound.

In the case of BY in conjunction with IN, the function is applied to the current tail e.g., \( \texttt{(for X in Y by CDDR ...)} \) is the same as \( \texttt{(for X in Y by (CDDR X) ...)} \).

While the exact translation of a loop depends on which operators are present, a PROG will always be used whenever the loop specifies dummy variables—if BIND appears, or there is more than one variable specified by a FOR, or a GO, RETURN, or a reference to the variable \( \$$VAL \) appears in any of the operands. When PROG is used, the form of the translation is:

\[
\texttt{(PROG VARIABLES \{initialize\})}
\]
CONDITIONALS AND ITERATIVE STATEMENTS

$$LP{\text{eachtime}}\{test\}\{body\}$$
$$ITERATE\{aftertest\}\{update\}(GO\ \$$LP$$)$$
$$OUT\{finalize\}(RETURN\ $$VAL))$$

where \{test\} corresponds to that part of the loop that tests for termination and also for those iterations for which \{body\} is not going to be executed, (as indicated by a \textit{WHEN} or \textit{UNLESS}); \{body\} corresponds to the operand of the i.s.type, e.g., DO, COLLECT, etc.; \{aftertest\} corresponds to those tests for termination specified by \textit{REPEATWHILE} or \textit{REPEATUNTIL}; and \{update\} corresponds to that part that resets the tail, increments the counter, etc. in preparation for the next iteration. \{initialize\}, \{finalize\}, and \{eachtime\} correspond to the operands of FIRST, FINALLY, and EACHTIME, if any.

Since \{body\} always appears at the top level of the \texttt{PROG}, you can insert labels in \{body\}, and \texttt{GO} to them from within \{body\} or from other i.s. operands, e.g., \texttt{(for X in Y first (GO A) do (FOO) A (FIE))}. However, since \{body\} is dwimified as a list of forms, the label(s) should be added to the dummy variables for the iterative statement in order to prevent their being dwimified and possibly “corrected”, e.g., \texttt{(for X in Y bind A first (GO A) do (FOO) A (FIE))}. You can also \texttt{GO} to $$LP$$, $$ITERATE$$, or $$OUT$$, or explicitly set $$VAL$$.

Errors in Iterative Statements

An error will be generated and an appropriate diagnostic printed if any of the following conditions hold:

1. Operator with null operand, i.e., two adjacent operators, as in \(\texttt{(for X in Y until do ...)}\)

2. Operand consisting of more than one form (except as operand to \textit{FIRST}, \textit{FINALLY}, or one of the i.s.types), e.g., \texttt{(for X in Y \{PRINT X\} collect ...)}.

3. \texttt{IN}, \texttt{ON}, \texttt{FROM}, \texttt{TO}, or \texttt{BY} appear twice in same i.s.

4. Both \texttt{IN} and \texttt{ON} used on same i.v.

5. \texttt{FROM} or \texttt{TO} used with \texttt{IN} or \texttt{ON} on same i.v.

6. More than one i.s.type, e.g., a \texttt{DO} and a \texttt{SUM}.

In 3, 4, or 5, an error is not generated if an intervening \texttt{AS} occurs.

If an error occurs, the i.s. is left unchanged.

If no \texttt{DO}, \texttt{COLLECT}, \texttt{JOIN} or any of the other i.s.types are specified, \texttt{CLISP} will first attempt to find an operand consisting of more than one form, e.g., \texttt{(for X in Y \{PRINT X\} when \texttt{ATOM X ...})}, and in this case will insert a \texttt{DO} after the first form. (In this case, condition 2 is not considered to be met, and an error is not generated.) If \texttt{CLISP} cannot find such an operand, and no \texttt{WHILE} or \texttt{UNTIL} appears in the i.s., a warning message is printed: NO \texttt{DO}, \texttt{COLLECT}, OR \texttt{JOIN}: followed by the i.s.
Similarly, if no terminating condition is detected, i.e., no **IN**, **ON**, **WHILE**, **UNTIL**, **TO**, or a **RETURN** or **GO**, a warning message is printed: Possible non-terminating iterative statement: followed by the iterative statement. However, since the user may be planning to terminate the i.s. via an error, Control-E, or a **RETFROM** from a lower function, the i.s. is still translated.

**Note:** The error message is not printed if the value of **CLISPI.S.GAG** is **T** (initially **NIL**).

### Defining New Iterative Statement Operators

The following function is available for defining new or redefining existing iterative statement operators:

```
(I.S.OPR NAME FORM OTHERS EVALFLG)
```

**NAME** is the name of the new i.s.opr. If **FORM** is a list, **NAME** will be a new **i.s.type**, and **FORM** its body.

**OTHERS** is an (optional) list of additional i.s. operators and operands which will be added to the i.s. at the place where **NAME** appears. If **FORM** is **NIL**, **NAME** is a new i.s.opr defined entirely by **OTHERS**.

In both **FORM** and **OTHERS**, the atom $$VAL$$ can be used to reference the value to be returned by the i.s., **I.V**. to reference the current i.v., and **BODY** to reference **NAME**'s operand. In other words, the current i.v. will be substituted for all instances of **I.V**. and **NAME**'s operand will be substituted for all instances of **BODY** throughout **FORM** and **OTHERS**.

If **EVALFLG** is **T**, **FORM** and **OTHERS** are evaluated at translation time, and their values used as described above. A dummy variable for use in translation that does not clash with a dummy variable already used by some other i.s. operators can be obtained by calling **(GETDUMMYVAR)**. **(GETDUMMYVAR T)** will return a dummy variable and also insure that it is bound as a **PROG** variable in the translation.

If **NAME** was previously an i.s.opr and is being redefined, the message **(NAME REDEFINED)** will be printed (unless **DFNFLG=T**), and all expressions using the i.s.opr **NAME** that have been translated will have their translations discarded.

The following are some examples of how **I.S.OPR** could be called to define some existing i.s.oprs, and create some new ones:

```
COLLECT (I.S.OPR 'COLLECT ' (SETQ $$VAL (NCONC1 $$VAL BODY)))
```

```
SUM (I.S.OPR 'SUM ' (SETQ $$VAL (PLUS $$VAL BODY) ' (FIRST (SETQ $$VAL0)))
```

```
NEVER (I.S.OPR 'NEVER ' (if BODY then (SETQ $$VAL NIL) (GO $$OUT)))
```

**Note:** **(if BODY then (RETURN NIL))** would exit from the i.s. immediately and therefore not execute the operations specified via a **FINALLY** (if any).
CONDITIONALS AND ITERATIVE STATEMENTS

THEREIS  (I.S.OPR 'THEREIS
    '(if BODY then
        (SETQ $$VAL I.V.) (GO $$OUT))))

RCOLLECT To define RCOLLECT, a version of COLLECT which uses CONS instead of NCONC1 and then reverses the list of values:

(I.S.OPR 'RCOLLECT
    '(FINALLY (RETURN
                (DREVERSE $$VAL)))))

TCOLLECT To define TCOLLECT, a version of COLLECT which uses TCONC:

(I.S.OPR 'TCOLLECT
    '(TCONC $$VAL BODY)
    '(FIRST (SETQ $$VAL (CONS))
               FINALLY (RETURN
                        (CAR $$VAL)))))

PRODUCT (I.S.OPR 'PRODUCT
    '(SETQ $$VAL $$VAL*BODY)
    '(FIRST ($$VAL 1))]

UPTO To define UPTO, a version of TO whose operand is evaluated only once:

(I.S.OPR 'UPTO
    NIL
    '(BIND $$FOO←BODY TO $$FOO)]

TO To redefine TO so that instead of recomputing FORM each iteration, a variable is bound to the value of FORM, and then that variable is used:

(I.S.OPR 'TO
    NIL
    '(BIND $$END FIRST
        (SETQ $$END BODY)
        ORIGINALETTO $$END))]

Note the use of ORIGINAL to redefine TO in terms of its original definition. ORIGINAL is intended for use in redefining built-in operators, since their definitions are not accessible, and hence not directly modifiable. Thus if the operator had been defined by the user via I.S.OPR, ORIGINAL would not obtain its original definition. In this case, one presumably would simply modify the i.s.opr definition.

I.S.OPR can also be used to define synonyms for already defined i.s. operators by calling I.S.OPR with FORM an atom, e.g., (I.S.OPR 'WHERE 'WHEN) makes WHERE be the same as WHEN. Similarly, following (I.S.OPR 'ISTHERE 'THEREIS), one can write (ISTHERE ATOM IN Y), and following (I.S.OPR 'FIND 'FOR) and (I.S.OPR 'SUCHTHAT 'THEREIS), one can write (find X in Y suchthat X member Z). In the current system, WHERE is synonymous with WHEN, SUCHTHAT and ISTHERE with THEREIS, FIND with FOR, and THRU with TO.
If FORM is the atom MODIFIER, then NAME is defined as an i.s.opr which can immediately follow another i.s. operator (i.e., an error will not be generated, as described previously). NAME will not terminate the scope of the previous operator, and will be stripped off when DWIMIFY is called on its operand. OLD is an example of a MODIFIER type of operator. The MODIFIER feature allows the user to define i.s. operators similar to OLD, for use in conjunction with some other user defined i.s.opr which will produce the appropriate translation.

The file package command I.S.OPRS (Chapter 17) will dump the definition of i.s.oprs. (I.S.OPRS PRODUCT UPTO) as a file package command will print suitable expressions so that these iterative statement operators will be (re)defined when the file is loaded.
INTERLISP-D REFERENCE MANUAL

[This page intentionally left blank]
Medley is designed to help you define and debug functions. Developing an applications program with Medley involves defining a number of functions in terms of the system primitives and other user-defined functions. Once defined, your functions may be used exactly like Interlisp primitive functions, so the programming process can be viewed as extending the Interlisp language to include the required functionality.

A function’s definition specifies if the function has a fixed or variable number of arguments, whether these arguments are evaluated or not, the function argument names, and a series of forms which define the behavior of the function. For example:

```
(LAMBDA (X Y) (PRINT X) (PRINT Y))
```

This function has two evaluated arguments, \textit{X} and \textit{Y}, and it will execute (PRINT \textit{X}) and (PRINT \textit{Y}) when evaluated. Other types of function definitions are described below.

A function is defined by putting an expr definition in the function definition cell of a symbol. There are a number of functions for accessing and setting function definition cells, but one usually defines a function with \texttt{DEFINEQ} (see the Defining Functions section below). For example:

```
(DEFINEQ (FOO (LAMBDA (X Y) (PRINT X) (PRINT Y))))
```

The above expression will define the function \textit{FOO} to have the expr definition (LAMBDA (X Y) (PRINT X) (PRINT Y)). After being defined, this function may be evaluated just like any system function:

```
(FOO 3 (IPLUS 3 4))
```

Not all function definition cells contain expr definitions. The compiler (see the first page of Chapter 18) translates expr definitions into compiled code objects, which execute much faster. Interlisp provides a number of “function type functions” which determine how a given function is defined, the number and names of function arguments, etc. See the Function Type Functions section below.

Usually, functions are evaluated automatically when they appear within another function or when typed into Interlisp. However, sometimes it is useful to invoke the Interlisp interpreter explicitly to apply a given “functional argument” to some data. There are a number of functions which will apply a given function repeatedly. For example, \texttt{MAPCAR} will apply a function (or an expr definition) to all of the elements of a list, and return the values returned by the function:

```
(MAPCAR '(1 2 3 4 5) '(LAMBDA (X) (ITIMES X X)))
```

When using functional arguments, there are a number of problems which can arise, related to accessing free variables from within a function argument. Many times these problems can be solved using the function \texttt{FUNCTION} to create a \texttt{FUNARG} object.

The macro facility provides another way of specifying the behavior of a function (see the Macros section below). Macros are very useful when developing code which should run very quickly, which should be compiled differently than when it is interpreted, or which should run differently in different implementations of Interlisp.
Function Types

Interlisp functions are defined using list expressions called “expr definitions.” An expr definition is a list of the form \( \text{LAMBDA-WORD ARG-LIST FORM}_{1} \ldots \text{FORM}_{n} \). \text{LAMBDA-WORD} determines whether the arguments to this function will be evaluated or not. \text{ARG-LIST} determines the number and names of arguments. \text{FORM}_{1} \ldots \text{FORM}_{n} are a series of forms to be evaluated after the arguments are bound to the local variables in \text{ARG-LIST}.

If \text{LAMBDA-WORD} is the symbol \text{LAMBDA}, then the arguments to the function are evaluated. If \text{LAMBDA-WORD} is the symbol \text{NLAMBDA}, then the arguments to the function are not evaluated. Functions which evaluate or don’t evaluate their arguments are therefore known as “lambda” or “nlambda” functions, respectively.

If \text{ARG-LIST} is \text{NIL} or a list of symbols, this indicates a function with a fixed number of arguments. Each symbol is the name of an argument for the function defined by this expression. The process of binding these symbols to the individual arguments is called “spreading” the arguments, and the function is called a “spread” function. If the argument list is any symbol other than \text{NIL}, this indicates a function with a variable number of arguments, known as a “nospread” function.

If \text{ARG-LIST} is anything other than a symbol or a list of symbols, such as \( \text{(LAMBDA ’FOO’ ...) \) attempting to use this expr definition will generate an \text{Arg not symbol} error. In addition, if \text{NIL} or \text{T} is used as an argument name, the error \text{Attempt to bind NIL or T} is generated.

These two parameters (lambda/nlambda and spread/nospread) may be specified independently, so there are four main function types, known as lambda-spread, nlambda-spread, lambda-nospread, and nlambda-nospread functions. Each one has a different form and is used for a different purpose. These four function types are described more fully below.

For lambda-spread, lambda-nospread, or nlambda-spread functions, there is an upper limit to the number of arguments that a function can have, based on the number of arguments that can be stored on the stack on any one function call. Currently, the limit is 80 arguments. If a function is called with more than that many arguments, the error \text{Too many arguments} occurs. However, nlambda-nospread functions can be called with an arbitrary number of arguments, since the arguments are not individually saved on the stack.

Lambda-Spread Functions

Lambda-spread functions take a fixed number of evaluated arguments. This is the most common function type. A lambda-spread expr definition has the form:

\[
\text{LAMBDA (ARG}_{1} \ldots \text{ARG}_{n} \text{ FORM}_{1} \ldots \text{FORM}_{n})
\]

The argument list \( \text{ARG}_{1} \ldots \text{ARG}_{n} \) is a list of symbols that gives the number and names of the formal arguments to the function. If the argument list is \( () \) or \text{NIL}, this indicates that the function takes no arguments. When a lambda-spread function is applied to some arguments, the arguments are evaluated, and bound to the local variables \text{ARG}_{1} \ldots \text{ARG}_{n}. Then, \text{FORM}_{1} \ldots \text{FORM}_{n} are evaluated in order, and the value of the function is the value of \text{FORM}_{n}.

\[
\begin{align*}
\text{DEFINEQ (FOO (LAMBDA (X Y) (LIST X Y)))} \\
\text{FOO} \\
\text{FOO 99 (PLUS 3 4)} \\
\text{99 7}
\end{align*}
\]
FUNCTION DEFINITION, MANIPULATION AND EVALUATION

In the above example, the function FOO defined by \((\text{LAMBDA} (X \ Y) (\text{LIST} X \ Y))\) is applied to the arguments 99 and \((\text{PLUS} 3 \ 4)\). These arguments are evaluated (giving 99 and 7), the local variable \(x\) is bound to 99 and \(y\) to 7, \((\text{LIST} X \ Y)\) is evaluated, returning \((99 \ 7)\), and this is returned as the value of the function.

A standard feature of the Interlisp system is that no error occurs if a spread function is called with too many or too few arguments. If a function is called with too many arguments, the extra arguments are evaluated but ignored. If a function is called with too few arguments, the unsupplied ones will be delivered as \(\text{NIL}\). In fact, a spread function cannot distinguish between being given \(\text{NIL}\) as an argument, and not being given that argument, e.g., \((\text{FOO})\) and \((\text{FOO} \ \text{NIL})\) are exactly the same for spread functions. If it is necessary to distinguish between these two cases, use an nlambda function and explicitly evaluate the arguments with the \(\text{EVAL}\) function.

Nlambda-Spread Functions

Nlambda-spread functions take a fixed number of unevaluated arguments. An nlambda-spread expr definition has the form:

\[
(\text{NLAMBDA} \ (\text{ARG}_1 \ \ldots \ \text{ARG}_n) \ \text{FORM}_1 \ \ldots \ \text{FORM}_n)
\]

Nlambda-spread functions are evaluated similarly to lambda-spread functions, except that the arguments are not evaluated before being bound to the variables \(\text{ARG}_1 \ \ldots \ \text{ARG}_n\).

\[
\text{←} \ (\text{DEFINEQ} \ \text{FOO} \ (\text{NLAMBDA} \ (X \ Y) \ (\text{LIST} X \ Y)))
\]

\[
\text{←} \ (\text{FOO} \ 99 \ (\text{PLUS} 3 \ 4))
\]

\[
(\text{NLAMBDA} \ (\text{ARG}_1 \ \ldots \ \text{ARG}_n) \ \text{FORM}_1 \ \ldots \ \text{FORM}_n)
\]

In the above example, the function FOO defined by \((\text{NLAMBDA} (X \ Y) (\text{LIST} X \ Y))\) is applied to the arguments 99 and \((\text{PLUS} 3 \ 4)\). These arguments are unevaluated, \((\text{LIST} X \ Y)\) is evaluated, returning \((99 \ (\text{PLUS} 3 \ 4))\), and this is returned as the value of the function.

Functions can be defined so that all of their arguments are evaluated (lambda functions) or none are evaluated (nlambda functions). If it is desirable to write a function which only evaluates some of its arguments (e.g., \(\text{SETQ}\)), the functions should be defined as an nlambda, with some arguments explicitly evaluated using the function \(\text{EVAL}\). If this is done, the user should put the symbol \(\text{EVAL}\) on the property list of the function under the property \(\text{INFO}\). This informs various system packages, such as DWIM, CLISP, and Masterscope, that this function in fact does evaluate its arguments, even though it is an nlambda.

Warning: A frequent problem that occurs when evaluating arguments to nlambda functions with \(\text{EVAL}\) is that the form being evaluated may reference variables that are not accessible within the nlambda function. This is usually not a problem when interpreting code, but when the code is compiled, the values of "local" variables may not be accessible on the stack (see Chapter 18). The system nlambda functions that evaluate their arguments (such as \(\text{SETQ}\)) are expanded in-line by the compiler, so this is not a problem. Using the macro facility is recommended in cases where it is necessary to evaluate some arguments to an nlambda function.

Lambda-Nospread Functions

Lambda-nospread functions take a variable number of evaluated arguments. A lambda-nospread expr definition has the form:

\[
(\text{LAMBDA} \ \text{VAR} \ \text{FORM}_1 \ \ldots \ \text{FORM}_n)
\]
VAR may be any symbol, except NIL and T. When a lambda-nospread function is applied to some arguments, each of these arguments is evaluated and the values stored on the stack. VAR is then bound to the number of arguments which have been evaluated. For example, if FOO is defined by (LAMBDA X ...), when (FOO A B C) is evaluated, A, B, and C are evaluated and X is bound to 3. VAR should never be reset.

The following functions are used for accessing the arguments of lambda-nospread functions.

\[ \text{ARG \ VAR \ M} \]  
[NLambda Function]

Returns the \( M \)th argument for the lambda-nospread function whose argument list is VAR. VAR is the name of the atomic argument list to a lambda-nospread function, and is not evaluated. \( M \) is the number of the desired argument, and is evaluated. The value of ARG is undefined for \( M \) less than or equal to 0 or greater than the value of VAR.

\[ \text{SETARG \ VAR \ M \ X} \]  
[NLambda Function]

Sets the \( M \)th argument for the lambda-nospread function whose argument list is VAR to X. VAR is not evaluated; \( M \) and \( X \) are evaluated. \( M \) should be between 1 and the value of VAR.

In the example below, the function FOO is defined to collect and return a list of all of the evaluated arguments it is given (the value of the for statement).

\[
\begin{align*}
\text{←} & \quad \text{[DEFINEQ \ (FOO (LAMBDA X (for ARGNUM from 1 to X collect (ARG X ARGNUM)))]} \\
\text{←} & \quad \text{[FOO 99 (PLUS 3 4)]} \\
\text{←} & \quad \text{[FOO 99 (PLUS 3 4) (TIMES 3 4)]}
\end{align*}
\]

**Nlambda-Nospread Functions**

Nlambda-nospread functions take a variable number of unevaluated arguments. An nlambda-nospread expr definition has the form:

\[
\text{(NLAMBDA \ VAR \ FORM_1 \ ... \ FORM_n)}
\]

VAR may be any symbol, except NIL and T. Though similar in form to lambda-nospread expr definitions, an nlambda-nospread is evaluated quite differently. When an nlambda-nospread function is applied to some arguments, VAR is simply bound to a list of the unevaluated arguments. The user may pick apart this list, and evaluate different arguments.

In the example below, FOO is defined to return the reverse of the list of arguments it is given (unevaluated):

\[
\begin{align*}
\text{←} & \quad \text{[DEFINEQ \ (FOO (NLAMBDA X (REVERSE X)))]} \\
\text{←} & \quad \text{[FOO 99 (PLUS 3 4)]} \\
\text{←} & \quad \text{[FOO 99 (PLUS 3 4) (TIMES 3 4)]}
\end{align*}
\]

The warning about evaluating arguments to nlambda functions also applies to nlambda-nospread function.
Compiled Functions

Functions defined by expr definitions can be compiled by the Interlisp compiler (see Chapter 18). The compiler produces compiled code objects (of data type CCODEP) which execute more quickly than the corresponding expr definition code. Functions defined by compiled code objects may have the same four types as expr definitions (lambda/nlambda, spread/nospread). Functions created by the compiler are referred to as compiled functions.

Function Type Functions

There are a variety of functions used for examining the type, argument list, etc. of functions. These functions may be given either a symbol (in which case they obtain the function definition from the definition cell), or a function definition itself.

\( \text{FNTYP} \, \text{FN} \)  

[Function]

Returns nil if \( \text{FN} \) is not a function definition or the name of a defined function. Otherwise, \( \text{FNTYP} \) returns one of the following symbols, depending on the type of function definition.

- \( \text{EXPR} \) : Lambda-spread expr definition
- \( \text{CEXPR} \) : Lambda-spread compiled definition
- \( \text{FEXPR} \) : Nlambda-spread expr definition
- \( \text{CFEXPR} \) : Nlambda-spread compiled definition
- \( \text{EXPR*} \) : Lambda-nospread expr definition
- \( \text{CEXPR*} \) : Lambda-nospread compiled definition
- \( \text{FEXPR*} \) : Nlambda-nospread expr definition
- \( \text{CFEXPR*} \) : Nlambda-nospread compiled definition

\( \text{FUNARG \ FNTYP} \) returns the symbol \( \text{FUNARG} \) if \( \text{FN} \) is a \( \text{FUNARG} \) expression.

\( \text{EXPRP} \, \text{FN} \)  

[Function]

Returns true if \( \text{FNTYP} \, \text{FN} \) is \( \text{EXPR} \), \( \text{FEXPR} \), \( \text{EXPR*} \), or \( \text{FEXPR*} \); nil otherwise. However, \( \text{EXPRP} \, \text{FN} \) is also true if \( \text{FN} \) is (has) a list definition, even if it does not begin with \( \text{LAMBDA} \) or \( \text{NLAMBDA} \). In other words, \( \text{EXPRP} \) is not quite as selective as \( \text{FNTYP} \).

\( \text{CCODEP} \, \text{FN} \)  

[Function]

Returns true if \( \text{FNTYP} \, \text{FN} \) is either \( \text{CEXPR} \), \( \text{CFEXPR} \), \( \text{CEXPR*} \), or \( \text{CFEXPR*} \); nil otherwise.

\( \text{ARGTYPE} \, \text{FN} \)  

[Function]

\( \text{FN} \) is the name of a function or its definition. \( \text{ARGTYPE} \) returns 0, 1, 2, or 3, or nil if \( \text{FN} \) is not a function. \( \text{ARGTYPE} \) corresponds to the rows of \( \text{FNTYP} \). The interpretation of this value is as follows:

0  Lambda-spread function \( \text{EXPR}, \text{CEXPR} \)  
1  Nlambda-spread function \( \text{FEXPR}, \text{CFEXPR} \)
2 Lambda-nospread function \((EXPR\ast, CEXPR\ast)\)

3 Nlambda-nospread function \((FEXPR\ast, CFEXPR\ast)\)

**\(\text{NARGS } FN\)**

[Function]

Returns the number of arguments of \(FN\), or \(NIL\) if \(FN\) is not a function. If \(FN\) is a nospread function, the value of \(\text{NARGS}\) is 1.

**\(\text{ARGLIST } FN\)**

[Function]

Returns the “argument list” for \(FN\). Note that the “argument list” is a symbol for nospread functions. Since \(NIL\) is a possible value for \(\text{ARGLIST}\), the error \text{Args not available} is generated if \(FN\) is not a function.

If \(FN\) is a compiled function, the argument list is constructed, i.e., each call to \(\text{ARGLIST}\) requires making a new list. For functions defined by expr definitions, lists beginning with \(\text{LAMBDA}\) or \(\text{NLAMBDA}\), the argument list is simply \(\text{CADR}\) of \(\text{GETD}\). If \(FN\) has an expr definition, and \(\text{CAR}\) of the definition is not \(\text{LAMBDA}\) or \(\text{NLAMBDA}\), \(\text{ARGLIST}\) will check to see if \(\text{CAR}\) of the definition is a member of \(\text{LAMBDASPLST}\) (see Chapter 20). If it is, \(\text{ARGLIST}\) presumes this is a function object the user is defining via \(\text{DWIMUSERFORMS}\), and simply returns \(\text{CADR}\) of the definition as its argument list. Otherwise \(\text{ARGLIST}\) generates an error as described above.

**\(\text{SMARTARGLIST } FN \ EXPLAINFLG \ TAIL\)**

[Function]

A “smart” version of \(\text{ARGLIST}\) that tries various strategies to get the arglist of \(FN\).

First \(\text{SMARTARGLIST}\) checks the property list of \(FN\) under the property \(\text{ARGNAMES}\). For spread functions, the argument list itself is stored. For nospread functions, the form is \((\text{NIL ARGLIST}_1, \text{ARGLIST}_2)\), where \(\text{ARGLIST}_1\) is the value \(\text{SMARTARGLIST}\) should return when \(\text{EXPLAINFLG} = T\), and \(\text{ARGLIST}_2\) the value when \(\text{EXPLAINFLG} = \text{NIL}\). For example, \((\text{GETPROP} '\text{DEFINED} '\text{ARGNAMES}) = (\text{NIL} \ X_1 \ X_1 \ldots \ X_n) \ . \ X)\). This allows the user to specify special argument lists.

Second, if \(FN\) is not defined as a function, \(\text{SMARTARGLIST}\) attempts spelling correction on \(FN\) by calling \(\text{FNCHECK}\) (see Chapter 20), passing \(TAIL\) to be used for the call to \(\text{FIXSPELL}\). If unsuccessful, the \text{FN Not a function} error will be generated.

Third, if \(FN\) is known to the file package (see Chapter 17) but not loaded in, \(\text{SMARTARGLIST}\) will obtain the arglist information from the file.

Otherwise, \(\text{SMARTARGLIST}\) simply returns \(\text{ARGLIST } FN\).

\(\text{SMARTARGLIST}\) is used by \(\text{BREAK}\) (see Chapter 15) and \(\text{ADVISE}\) with \(\text{EXPLAINFLG} = \text{NIL}\) for constructing equivalent expr definitions, and by the \(\text{TTYIN}\) in-line command \(?=\) (see Chapter 26), with \(\text{EXPLAINFLG} = T\).

**Defining Functions**

Function definitions are stored in a “function definition cell” associated with each symbol. This cell is directly accessible via the two functions \(\text{PUTD}\) and \(\text{GETD}\) (see below), but it is usually easier to define functions with \(\text{DEFINEN}\).
FUNCTION DEFINITION, MANIPULATION AND EVALUATION

\texttt{{\bf DEFINEQ} } \texttt{X_1, X_2 \ldots X_N} \quad \texttt{[NLambda NoSpread Function]}

\texttt{DEFINEQ} is the function normally used for defining functions. It takes an indefinite number of arguments which are not evaluated. Each \texttt{X_i} must be a list defining one function, of the form \texttt{(NAME DEFINITION)}. For example:

\begin{verbatim}
(DEFINEQ (DOUBLE (LAMBDA (X) (IPLUS X X)))
\end{verbatim}

The above expression will define the function \texttt{DOUBLE} with the expr definition \texttt{(LAMBDA (X) (IPLUS X X))}. \texttt{X_i} may also have the form \texttt{(NAME ARGS . DEF-BODY)}, in which case an appropriate lambda expr definition will be constructed. Therefore, the above expression is exactly the same as:

\begin{verbatim}
(DEFINEQ (DOUBLE (X) (IPLUS X X)))
\end{verbatim}

Note that this alternate form can only be used for lambda functions. The first form must be used to define an nlambda function.

\texttt{DEFINEQ} returns a list of the names of the functions defined.

\texttt{{\bf DEFINE} } \texttt{X —} \quad \texttt{[Function]}

Lambda-spread version of \texttt{DEFINEQ}. Each element of the list \texttt{X} is itself a list either of the form \texttt{(NAME DEFINITION)} or \texttt{(NAME ARGS . DEF-BODY)}. \texttt{DEFINE} will generate an error, Incorrect defining form on encountering an atom where a defining list is expected.

\texttt{DEFINE} and \texttt{DEFINEQ} operate correctly if the function is already defined and \texttt{BROKEN, ADVISED, or BROKEN-IN}.

For expressions involving type-in only, if the time stamp facility is enabled (see the Time Stamps section of Chapter 16), both \texttt{DEFINE} and \texttt{DEFINEQ} stamp the definition with your initials and date.

\texttt{UNSAFE.TO.MODIFY.FNS} \quad \texttt{[Variable]}

Value is a list of functions that should not be redefined, because doing so may cause unusual bugs (or crash the system!). If you try to modify a function on this list (using \texttt{DEFINEQ, TRACE, etc}), the system prints Warning: XXX may be unsafe to modify -- continue? If you type \texttt{Yes}, the function is modified, otherwise an error occurs. This provides a measure of safety for novices who may accidently redefine important system functions. You can add your own functions onto this list.

By convention, all functions starting with the character backslash ("\") are system internal functions, which you should never redefine or modify. Backslash functions are not on \texttt{UNSAFE.TO.MODIFY.FNS}, so trying to redefine them will not cause a warning.

\texttt{DFNFLG} \quad \texttt{[Variable]}

\texttt{DFNFLG} is a global variable that affects the operation of \texttt{DEFINEQ} and \texttt{DEFINE}. If \texttt{DFNFLG=NIL}, an attempt to redefine a function \texttt{FN} will cause \texttt{DEFINE} to print the message \texttt{(FN REDEFINED)} and to save the old definition of \texttt{FN} using \texttt{SAVEDEF} (see the Functions for Manipulating Typed Definitions section of Chapter 17) before redefining it (except if the old and new definitions are \texttt{EQUAL}, in which case the effect is simply a no-op). If \texttt{DFNFLG=T}, the function is simply redefined. If \texttt{DFNFLG=PROP} or \texttt{ALLPROP}, the new definition is stored on the property list under the property \texttt{EXPR}. \texttt{ALLPROP} also affects the operation of \texttt{RPAQ} and \texttt{RPAQ} (see the Functions Used Within Source Files section of Chapter 17). \texttt{DFNFLG} is initially \texttt{NIL}. 

10 - 7
DFNFLG is reset by LOAD (see the Loading Files section of Chapter 17) to enable various ways of handling the defining of functions and setting of variables when loading a file. For most applications, the user will not reset DFNFLG directly.

**Note:** The compiler does not respect the value of DFNFLG when it redefines functions to their compiled definitions (see the first page of Chapter 18). Therefore, if you set DFNFLG to PROP to completely avoid inadvertently redefining something in your running system, you must use compile mode $F$, not $ST$.

Note that the functions SAVEDEF and UNSAVEDEF (see the Functions for Manipulating Typed Definitions section of Chapter 17) can be useful for “saving” and restoring function definitions from property lists.

### (GETD FN)

**[Function]**

Returns the function definition of FN. Returns NIL if FN is not a symbol, or has no definition.

GETD of a compiled function constructs a pointer to the definition, with the result that two successive calls do not necessarily produce EQ results. EQP or EQUAL must be used to compare compiled definitions.

### (PUTD FN DEF -)

**[Function]**

Puts DEF into FN’s function cell, and returns DEF. Generates an error, Arg not symbol, if FN is not a symbol. Generates an error, Illegal arg, if DEF is a string, number, or a symbol other than NIL.

### (MOVD FROM TO COPYFLG -)

**[Function]**

Moves the definition of FROM to TO, i.e., redefines TO. If COPYFLG = T, a COPY of the definition of FROM is used. COPYFLG =T is only meaningful for expr definitions, although MOVD works for compiled functions as well. MOVD returns TO.

COPYDEF (see the Functions for Manipulating Typed Definitions section of Chapter 17) is a higher-level function that not only moves expr definitions, but works also for variables, records, etc.

### (MOVD? FROM TO COPYFLG -)

**[Function]**

If TO is not defined, same as (MOVD FROM TO COPYFLG). Otherwise, does nothing and returns NIL.

---

### Function Evaluation

Usually, function application is done automatically by the Interlisp interpreter. If a form is typed into Interlisp whose CAR is a function, this function is applied to the arguments in the CDR of the form. These arguments are evaluated or not, and bound to the function parameters, as determined by the type of the function, and the body of the function is evaluated. This sequence is repeated as each form in the body of the function is evaluated.

There are some situations where it is necessary to explicitly call the evaluator, and Interlisp supplies a number of functions that will do this. These functions take “functional arguments,” which may either
be symbols with function definitions, or expr definition forms such as \( \text{(LAMBDA } (X) \ldots) \), or \text{FUNARG} expressions.

\textbf{APPLY} \textit{FN} \textit{ARGLIST} \textit{⇒} \hspace{100pt} \text{[Function]}

Applies the function \textit{FN} to the arguments in the list \textit{ARGLIST}, and returns its value. \text{APPLY} is a lambda function, so its arguments are evaluated, but the individual elements of \textit{ARGLIST} are not evaluated. Therefore, lambda and nlambda functions are treated the same by \text{APPLY}—lambda functions take their arguments from \textit{ARGLIST} without evaluating them. For example:

\begin{verbatim}
  (APPLY 'APPEND '((PLUS 1 2 3)(4 5 6)))
\end{verbatim}

Note that \textit{FN} may explicitly evaluate one or more of its arguments itself. For example, the system function \text{SETQ} is an nlambda function that explicitly evaluates its second argument. Therefore, \text{(APPLY \text{'}\text{SETQ}' \text{'}\text{FOO} \text{'}\text{ADD1 3})\text{)}\text{)} will set \text{FOO} to 4, instead of setting it to the expression \text{(ADD1 3)}.

\text{APPLY} can be used for manipulating expr definitions. For example:

\begin{verbatim}
  (APPLY '(LAMBDA (X Y) (ITIMES X Y)) '(3 4))
\end{verbatim}

\textbf{APPLY*} \textit{FN} \textit{ARG1} \textit{ARG2} \ldots \textit{ARGN} \hspace{100pt} \text{[NoSpread Function]}

Nospread version of \text{APPLY}. Applies the function \textit{FN} to the arguments \textit{ARG1} \textit{ARG2} \ldots \textit{ARGN}. For example:

\begin{verbatim}
  (APPLY 'APPEND '(PLUS 1 2 3)(4 5 6))
\end{verbatim}

\textbf{EVAL} \textit{X} \textit{⇒} \hspace{100pt} \text{[Function]}

\text{EVAL} evaluates the expression \textit{X} and returns this value, i.e., \text{EVAL} provides a way of calling the Interlisp interpreter. Note that \text{EVAL} is itself a lambda function, so its argument is first evaluated, e.g.:

\begin{verbatim}
  (SETQ FOO 'ADD1 3))
\end{verbatim}

\begin{verbatim}
  (EVAL FOO)
\end{verbatim}

\begin{verbatim}
  (QUOTE FOO)
\end{verbatim}

\textbf{QUOTE} \textit{X} \hspace{100pt} \text{[Nlambda NoSpread Function]}

\text{QUOTE} prevents its arguments from being evaluated. Its value is \textit{X} itself, e.g., \text{(QUOTE FOO)} is \text{FOO}.

Interlisp functions can either evaluate or not evaluate their arguments. \text{QUOTE} can be used in those cases where it is desirable to specify arguments unevaluated.

The single-quote character (‘) is defined with a read macro so it returns the next expression, wrapped in a call to \text{QUOTE} (see Chapter 25). For example, ‘\text{FOO} reads as \text{(QUOTE FOO)}. This is the form used for examples in this manual.

Since giving \text{QUOTE} more than one argument is almost always a parenthese error, and one that would otherwise go undetected, \text{QUOTE} itself generates an error in this case, \text{Parenthesis error}.\hfill\text{10-9}
**KWOTE X**

Value is an expression which, when evaluated, yields X. If X is NIL or a number, this is X itself. Otherwise (LIST (QUOTE QUOTE) X). For example:

(KWOTE 5) => 5
(KWOTE (CONS 'A 'B)) => (QUOTE (A.B))

**NLAMBDA.ARGS X**

This function interprets its argument as a list of unevaluated nlambda arguments. If any of the elements in this list are of the form (QUOTE...), the enclosing QUOTE is stripped off. Actually, NLAMBDA.ARGS stops processing the list after the first non-quoted argument. Therefore, whereas (NLAMBDA.ARGS '((QUOTE FOO) BAR)) -> (FOO BAR), (NLAMBDA.ARGS '(FOO (QUOTE BAR))) -> (FOO (QUOTE BAR)).

NLAMBDA.ARGS is called by a number of nlambda functions in the system, to interpret their arguments. For instance, the function BREAK calls NLAMBDA.ARGS so that (BREAK 'FOO) will break the function FOO, rather than the function QUOTE.

**EVALA X A**

Simulates association list variable lookup. X is a form, A is a list of the form:

((NAME1 . VAL1) (NAME2 . VAL2) ... (NAMEN . VALN))

The variable names and values in A are “spread” on the stack, and then X is evaluated. Therefore, any variables appearing free in X that also appears as CAR of an element of A will be given the value on the CDR of that element.

**DEFEVAL TYPE FN**

Specifies how a datum of a particular type is to be evaluated. Intended primarily for user-defined data types, but works for all data types except lists, literal atoms, and numbers. TYPE is a type name. FN is a function object, i.e., name of a function or a lambda expression. Whenever the interpreter encounters a datum of the indicated type, FN is applied to the datum and its value returned as the result of the evaluation. DEFEVAL returns the previous evaling function for this type. If FN = NIL, DEFEVAL returns the current evaling function without changing it. If FN = T, the evaling functions is set back to the system default (which for all data types except lists is to return the datum itself).

COMPILETYPELST (see Chapter 18) permits the user to specify how a datum of a particular type is to be compiled.

**EVALHOOK FORM EVALHOOKFN**

EVALHOOK evaluates the expression FORM, and returns its value. While evaluating FORM, the function EVAL behaves in a special way. Whenever a list other than FORM itself is to be evaluated, whether implicitly or via an explicit call to EVAL, EVALHOOKFN is invoked (it should be a function), with the form to be evaluated as its argument. EVALHOOKFN is then responsible for evaluating the form. Whatever is returned is assume to be the result of evaluating the form. During the execution of EVALHOOKFN, this special evaluation is turned off. (Note that EVALHOOK does not affect the evaluations of variables, only of lists).

Here is an example of a simple tracing routine that uses the EVALHOOK feature:
FUNCTION DEFINITION, MANIPULATION AND EVALUATION

≡ (DEFINEQ (PRINTHOOK (FORM)
(printout T "eval: "FORM T)
(EVALHOOK FORM (FUNCTION PRINTHOOK)
(PRINTHOOK))

Using PRINTHOOK, one might see the following interaction:
≡ (EVALHOOK '(LIST (CONS 1 2) (CONS 3 4)) 'PRINTHOOK)
eval: (CONS 1 2)
eval: (CONS 3 4)
{(1.2) (3.4)}

Iterating and Mapping Functions

The functions below are used to evaluate a form or apply a function repeatedly. RPT, RPTQ, and FRPTQ evaluate an expression a specified number of times. MAP, MAPCAR, MAPLIST, etc., apply a given function repeatedly to different elements of a list, possibly constructing another list.

These functions allow efficient iterative computations, but they are difficult to use. For programming iterative computations, it is usually better to use the CLISP Iterative Statement facility (see Chapter 9), which provides a more general and complete facility for expressing iterative statements. Whenever possible, CLISP translates iterative statements into expressions using the functions below, so there is no efficiency loss.

(RPT N FORM) [Function]
Evaluates the expression FORM, N times. Returns the value of the last evaluation. If N is less than or equal to 0, FORM is not evaluated, and RPT returns NIL.

Before each evaluation, the local variable RPTN is bound to the number of evaluations yet to take place. This variable can be referenced within FORM. For example, (RPT 10 'PRINT RPTN) will print the numbers 10, 9..., 1, and return 1.

(RPTQ N FORM1 FORM2 ... FORMN) [NLambda NoSpread Function]
Nlambda-nospread version of RPT: N is evaluated, FORMi are not. Returns the value of the last evaluation of FORMN.

(FRPTQ N FORM1 FORM2 ... FORMN) [NLambda NoSpread Function]
Faster version of RPTQ. Does not bind RPTN.

(MAP MAPX MAPFN1 MAPFN2) [Function]
If MAPFN2 is NIL, MAP applies the function MAPFN1 to successive tails of the list MAPX. That is, first it computes (MAPFN1 MAPX), and then (MAPFN1 (CDR MAPX)), etc., until MAPX becomes a non-list. If MAPFN2 is provided, (MAPFN2 MAPX) is used instead of (CDR MAPX) for the next call for MAPFN1, e.g., if MAPFN2 were CDIR, alternate elements of the list would be skipped. MAP returns NIL.

(MAPC MAPX MAPFN1 MAPFN2) [Function]
Identical to MAP, except that (MAPFN1 (CDR MAPX)) is computed at each iteration instead of (MAPFN1 MAPX), i.e., MAPC works on elements, MAP on tails. MAPC returns NIL.
([\textit{MAPLIST} \textit{MAP} \textit{MAPFN}_1 \textit{MAPFN}_2]) \quad \text{[Function]}

Successively computes the same values that \textit{MAP} would compute, and returns a list consisting of those values.

([\textit{MAPCAR} \textit{MAP} \textit{MAPFN}_1 \textit{MAPFN}_2]) \quad \text{[Function]}

Computes the same values that \textit{MAPC} would compute, and returns a list consisting of those values, e.g., ([\textit{MAPCAR} \textit{X} \textit{\textprime{FNTYP}}]) is a list of \textit{FNTYP}s for each element on \textit{X}.

([\textit{MAPCON} \textit{MAP} \textit{MAPFN}_1 \textit{MAPFN}_2]) \quad \text{[Function]}

Computes the same values that \textit{MAP} and \textit{MAPLIST} but \textit{nconc}s these values to form a list which it returns.

([\textit{MAPCONC} \textit{MAP} \textit{MAPFN}_1 \textit{MAPFN}_2]) \quad \text{[Function]}

Computes the same values that \textit{MAPC} and \textit{MAPCAR}, but \textit{nconc}s the values to form a list which it returns.

Note that \textit{MAPCAR} creates a new list which is a mapping of the old list in that each element of the new list is the result of applying a function to the corresponding element on the original list. \textit{MAPCONC} is used when there are a variable number of elements (including none) to be inserted at each iteration.

Examples:

([\textit{MAPCONC} '(A B C NIL D NIL) '(LAMBDA (Y) (if (NULL Y) then NIL else (LISP Y)))) = > (A B C D)

This \textit{MAPCONC} returns a list consisting of \textit{MAP} with all \textit{NIL}s removed.

([\textit{MAPCONC} '((A B C) (D E F G) G) H I) '(LAMBDA (Y) (if (LISP Y) then Y else NIL))) = > ((A B C) D E F G)

This \textit{MAPCONC} returns a linear list consisting of all the lists on \textit{MAP}.

Since \textit{MAPCONC} uses \textit{nconc} to string the corresponding lists together, in this example the original list will be altered to be ((A B C D E F G) C (D E F G) G) H I). If this is an undesirable side effect, the functional argument to \textit{MAPCONC} should return instead a top level copy of the lists, i.e., (LAMBDA (Y) (if (LISP Y) then (\textit{APPEND} Y) else NIL))).

([\textit{MAP2C} \textit{MAP} \textit{MAP}_1 \textit{MAPFN}_1 \textit{MAPFN}_2]) \quad \text{[Function]}

Identical to \textit{MAPC} except \textit{MAPFN}_2 is a function of two arguments, and ([\textit{MAPFN}_1 (\textbf{CAR} \textit{MAP}_2) (\textbf{CAR} \textit{MAP}_1)]) is computed at each iteration. Terminates when either \textit{MAP} or \textit{MAP}_1 is a non-list.

\textit{MAPFN}_2 is still a function of one argument, and is applied twice on each iteration; ([\textit{MAPFN}_1 \textit{MAP}_2]) gives the new \textit{MAP}_2. (\textit{MAPFN}_2 \textit{MAP}_1) the new \textit{MAP}_2. \textit{Cdr} is used if \textit{MAPFN}_2 is not supplied, i.e., is \textit{NIL}.

([\textit{MAP2CAR} \textit{MAP} \textit{MAP}_1 \textit{MAPFN}_1 \textit{MAPFN}_2]) \quad \text{[Function]}

Identical to \textit{MAPCAR} except \textit{MAPFN}_2 is a function of two arguments, and ([\textit{MAPFN}_1 (\textbf{CAR} \textit{MAP}_2) (\textbf{CAR} \textit{MAP}_1)]) is used to assemble the new list. Terminates when either \textit{MAP} or \textit{MAP}_1 is a non-list.
FUNCTION DEFINITION, MANIPULATION AND EVALUATION

SUBSET MAPX MAPFN1 MAPFN2

Applies MAPFN1 to elements of MAPX and returns a list of those elements for which this application is non-NIL, e.g.:

(SUBSET 'A B 3 C 4 'NUMBERP) = (3 4)

MAPFN2 plays the same role as with MAP, MAPC, et al.

EVERY EVERYX EVERYFN1 EVERYFN2

Returns T if the result of applying EVERYFN1 to each element in EVERYX is true, otherwise NIL. For example, (EVERY '(X Y Z) 'ATOM) => T.

EVERY operates by evaluating (EVERYFN1 (CAR EVERYX) EVERYX). The second argument is passed to EVERYFN1 so that it can look at the next element on EVERYX if necessary. If EVERYFN1 yields NIL, EVERY immediately returns NIL. Otherwise, EVERY computes (EVERYFN2 EVERYX) or (CDR EVERYX) if EVERYFN2 = NIL and uses this as the "new" EVERYX and the process continues. For example (EVERY X 'ATOM 'CDDR) is true if every other element of X is atomic.

SOME SOMEX SOMEFN1 SOMEFN2

Returns the tail of SOMEX beginning with the first element that satisfies SOMEFN1, i.e., for which SOMEFN1 applied to that element is true. Value is NIL if no such element exists. (SOME X '(LAMBDA (Z) (EQUAL Z Y))) is equivalent to (MEMBER Y X). SOME operates analogously to EVERY. At each stage, (SOMEFN1 (CAR SOMEX) SOMEX) is computed, and if this not NIL, SOMEX is returned as the value of SOME. Otherwise, (SOMEFN2 SOMEX) is computed, or (CDR SOMEX) if SOMEFN2 = NIL, and used for the next SOMEX.

NOTANY SOMEX SOMEFN1 SOMEFN2

(NOT (SOME SOMEX SOMEFN1 SOMEFN2)).

NOTEVERY EVERYX EVERYFN1 EVERYFN2

(NOT (EVERY EVERYX EVERYFN1 EVERYFN2)).

MAPPRINT LST FILE LEFT RIGHT SEP PFN LISPXPRINTFLG

A general printing function. For each element of the list LST, applies PFN to the element, and FILE. If PFN is NIL, PRIN1 is used. Between each application MAPPRINT performs PRIN1 of SEP (or "" if SEP = NIL). If LEFT is given, it is printed (using PRIN1) initially; if RIGHT is given, it is printed (using PRIN1) at the end.

For example, (MAPPRINT X NIL '( ( ')) ) is equivalent to PRIN1 for lists. To print a list with commas between each element and a final ",", one could use (MAPPRINT X X NIL ', ', ,).

If LISPXPRINTFLG = T, LISPXPRIN1 (see Chapter 13) is used instead of PRIN1.
Functional Arguments

The functions that call the Interlisp-D evaluator take “functional arguments,” which may be symbols with function definitions, or expr definition forms such as `(LAMBDA (X) ...)`. The following functions are useful when one wants to supply a functional argument which will always return `NIL`, `T`, or `0`. Note that the arguments `X_1 ... X_N` to these functions are evaluated, though they are not used.

- `(NILL X_1 ... X_N)` [NoSpread Function]
  Returns `NIL`.

- `(TRUE X_1 ... X_N)` [NoSpread Function]
  Returns `T`.

- `(ZERO X_1 ... X_N)` [NoSpread Function]
  Returns `0`.

When using expr definitions as function arguments, they should be enclosed within the function `FUNCTION` rather than `QUOTE`, so that they will be compiled as separate functions.

- `(FUNCTION FN ENV)` [NLambda Function]
  If `ENV = NIL`, `FUNCTION` is the same as `QUOTE`, except that it is treated differently when compiled. Consider the function definition:
  ```lisp
  (DEFINEQ (FOO (LST)(FIE LST (FUNCTION (LAMBDA (Z)(ITIMES Z Z)))))
  ```
  FOO calls the function FIE with the value of LST and the expr definition `(LAMBDA (Z)(LIST (CAR Z)))`.

  If FOO is run interpreted, it does not make any difference whether `FUNCTION` or `QUOTE` is used. However, when FOO is compiled, if `FUNCTION` is used the compiler will define and compile the expr definition as an auxiliary function (see Chapter 18). The compiled expr definition will run considerably faster, which can make a big difference if it is applied repeatedly.

  Compiling `FUNCTION` will not create an auxiliary function if it is a functional argument to a function that compiles open, such as most of the mapping functions (`MAPCAR`, `MAPLIST`, etc.).

  If `ENV` is not `NIL`, it can be a list of variables that are (presumably) used freely by `FN`. `ENV` can also be an atom, in which case it is evaluated, and the value interpreted as described above.

Macros

Macros provide an alternative way of specifying the action of a function. Whereas function definitions are evaluated with a “function call”, which involves binding variables and other housekeeping tasks, macros are evaluated by translating one Interlisp form into another, which is then evaluated.

A symbol may have both a function definition and a macro definition. When a form is evaluated by the interpreter, if the CAR has a function definition, it is used (with a function call), otherwise if it has a
FUNCTION DEFINITION, MANIPULATION AND EVALUATION

macro definition, then that is used. However, when a form is compiled, the CAR is checked for a macro definition first, and only if there isn’t one is the function definition compiled. This allows functions that behave differently when compiled and interpreted. For example, it is possible to define a function that, when interpreted, has a function definition that is slow and has a lot of error checks, for use when debugging a system. This function could also have a macro definition that defines a fast version of the function, which is used when the debugged system is compiled.

Macro definitions are represented by lists that are stored on the property list of a symbol. Macros are often used for functions that should be compiled differently in different Interlisp implementations, and the exact property name a macro definition is stored under determines whether it should be used in a particular implementation. The global variable MACROPROPS contains a list of all possible macro property names which should be saved by the MACROS file package command. Typical macro property names are DMACRO for Interlisp-D, 10MACRO for Interlisp-10, VAXMACRO for Interlisp-VAX, JMACRO for Interlisp-Jerico, and MACRO for “implementation independent” macros. The global variable COMPILERMACROPROPS is a list of macro property names. Interlisp determines whether a symbol has a macro definition by checking these property names, in order, and using the first non-nil property value as the macro definition. In Interlisp-D this list contains DMACRO and MACRO in that order so that DMACROs will override the implementation-independent MACRO properties. In general, use a DMACRO property for macros that are to be used only in Interlisp-D, use 10MACRO for macros that are to be used only in Interlisp-10, and use MACRO for macros that are to affect both systems.

Macro definitions can take the following forms:

(LAMBDA ...)
(NLAMBDA ...)

A function can be made to compile open by giving it a macro definition of the form (LAMBDA ...) or (NLAMBDA ...), e.g., (LAMBDA (X) (COND ((GREATERP X 0) X) (T (MINUS X)))) for ABS. The effect is as if the macro definition were written in place of the function wherever it appears in a function being compiled, i.e., it compiles as a lambda or nlambda expression. This saves the time necessary to call the function at the price of more compiled code generated in-line.

(NIL EXPRESSION)
(LIST EXPRESSION)

“Substitution” macro. Each argument in the form being evaluated or compiled is substituted for the corresponding atom in LIST, and the result of the substitution is used instead of the form. For example, if the macro definition of ADD1 is ((X) (IPLUS X 1)), then, (ADD1 (CAR Y)) is compiled as (IPLUS (CAR Y) 1).

Note that ABS could be defined by the substitution macro ((X) (COND ((GREATERP X 0) X) (T (MINUS X))))). In this case, however, (ABS (FOO X)) would compile as

(COND ((GREATERP (FOO X) 0)
    (FOO X))
    (T (MINUS (FOO X))))

and (FOO X) would be evaluated two times. (Code to evaluate (FOO X) would be generated three times.)

(OPENLAMBDA ARGS BODY)

This is a cross between substitution and LAMBDA macros. When the compiler processes an OPENLAMBDA, it attempts to substitute the actual arguments for the formals wherever this preserves the frequency and
order of evaluation that would have resulted from a LAMBDA expression, and produces a LAMBDA binding only for those that require it.

Note: OPENLAMBDA assumes that it can substitute literally the actual arguments for the formal arguments in the body of the macro if the actual is side-effect free or a constant. Thus, you should be careful to use names in ARGS which don’t occur in BODY (except as variable references). For example, if FOO has a macro definition of

```
(OPENLAMBDA (ENV) (FETCH (MY-RECORD-TYPE ENV) OF BAR))
```

then (FOO NIL) will expand to

```
(FETCH (MY-RECORD-TYPE NIL) OF BAR)
```

T When a macro definition is the atom T, it means that the compiler should ignore the macro, and compile the function definition; this is a simple way of turning off other macros. For example, the user may have a function that runs in both Interlisp-D and Interlisp-10, but has a macro definition that should only be used when compiling in Interlisp-10. If the MACRO property has the macro specification, a DMACRO of T will cause it to be ignored by the Interlisp-D compiler. This DMACRO would not be necessary if the macro were specified by a 10MACRO instead of a MACRO.

(= . OTHER-FUNCTION;) A simple way to tell the compiler to compile one function exactly as it would compile another. For example, when compiling in Interlisp-D, FRPLACA’s are treated as RPLACA’s. This is achieved by having FRPLACA have a DMACRO of (= . RPLACA).

(LITATOM EXPRESSION;) If a macro definition begins with a symbol other than those given above, this allows computation of the Interlisp expression to be evaluated or compiled in place of the form. LITATOM is bound to the CDR of the calling form, EXPRESSION is evaluated, and the result of this evaluation is evaluated or compiled in place of the form. For example, LIST could be compiled using the computed macro:

```
[X (LIST ‘CONS (CAR X) (AND (CDR X) (CONS ‘LIST (CDR X)))]
```

This would cause (LIST X Y Z) to compile as (CONS X (CONS Y (CONS Z NIL))). Note the recursion in the macro expansion.

If the result of the evaluation is the symbol IGNOREMACRO, the macro is ignored and the compilation of the expression proceeds as if there were no macro definition. If the symbol in question is normally treated specially by the compiler (CAR, CDR, COND, AND, etc.), and also has a macro, if the macro expansion returns IGNOREMACRO, the symbol will still be treated specially.

In Interlisp-10, if the result of the evaluation is the atom INSTRUCTIONS, no code will be generated by the compiler. It is then assumed the evaluation was done for effect and the necessary code, if any, has been added. This is a way of giving direct instructions to the compiler if you understand it.
FUNCTION DEFINITION, MANIPULATION AND EVALUATION

It is often useful, when constructing complex macro expressions, to use the \texttt{quote} facility (see the Read Macros section of Chapter 25).

The following function is quite useful for debugging macro definitions:

\begin{verbatim}
(DEFMACRO EXP QUIETFLG — —)
\end{verbatim}

\texttt{EXPANDMACRO} \texttt{EXP} \texttt{QUIETFLG \texttt{— —}} \hspace{1cm} [Function]

Takes a form whose \texttt{CAR} has a macro definition and expands the form as it would be compiled. The result is prettyprinted, unless \texttt{QUIETFLG} = \texttt{T}, in which case the result is simply returned.

\textbf{Note:} \texttt{EXPANDMACRO} only works on Interlisp macros. Use \texttt{CL:MACROEXPAND-1} to expand Interlisp macros visible to the Common Lisp interpreter and compiler.

\textbf{DEFMACRO}

Macros defined with the function \texttt{DEFMACRO} are much like "computed" macros (see the above section), in that they are defined with a form that is evaluated, and the result of the evaluation is used (evaluated or compiled) in place of the macro call. However, \texttt{DEFMACRO} macros support complex argument lists with optional arguments, default values, and keyword arguments as well as argument list destructuring.

\begin{verbatim}
(DEFMACRO NAME ARGS FORM)
\end{verbatim}

\texttt{DEFMACRO \texttt{NAME} \texttt{ARGS} \texttt{FORM}} \hspace{1cm} [NLambda NoSpread Function]

Defines \texttt{NAME} as a macro with the arguments \texttt{ARGS} and the definition form \texttt{FORM} (\texttt{NAME}, \texttt{ARGS}, and \texttt{FORM} are unevaluated). If an expression starting with \texttt{NAME} is evaluated or compiled, arguments are bound according to \texttt{ARGS}, \texttt{FORM} is evaluated, and the value of \texttt{FORM} is evaluated or compiled instead. The interpretation of \texttt{ARGS} is described below.

\textbf{Note:} Like the function \texttt{DEFMACRO} in Common Lisp, this function currently removes any function definition for \texttt{NAME}.

\texttt{ARGS} is a list that defines how the argument list passed to the macro \texttt{NAME} is interpreted. Specifically, \texttt{ARGS} defines a set of variables that are set to various arguments in the macro call (unevaluated), that \texttt{FORM} can reference to construct the macro form.

In the simplest case, \texttt{ARGS} is a simple list of variable names that are set to the corresponding elements of the macro call (unevaluated). For example, given:

\begin{verbatim}
(DEFMACRO FOO (A B) (LIST `PLUS A B B))
\end{verbatim}

The macro call \texttt{(FOO X (BAR Y Z))} will expand to \texttt{(PLUS X (BAR Y Z) (BAR Y Z))}.

"$\&$-keywords" (beginning with the character "$\&$") that are used to set variables to particular items from the macro call form, as follows:

\begin{verbatim}
&OPTIONAL
\end{verbatim}

Used to define optional arguments, possibly with default values. Each element on \texttt{ARGS} after \texttt{OPTIONAL} until the next "$\&$"-keyword or the end of the list defines an optional argument, which can either be a symbol or a list, interpreted as follows:

\begin{verbatim}
VAR
\end{verbatim}

If an optional argument is specified as a symbol, that variable is set to the corresponding element of the macro call (unevaluated).
(VAR DEFAULT)
If an optional argument is specified as a two element list, VAR is the variable to be set, and DEFAULT is a form that is evaluated and used as the default if there is no corresponding element in the macro call.

(VAR DEFAULT VARSETP)
If an optional argument is specified as a three element list, VAR and DEFAULT are the variable to be set and the default form, and VARSETP is a variable that is set to T if the optional argument is given in the macro call, NIL otherwise. This can be used to determine whether the argument was not given, or whether it was specified with the default value.

For example, after (DEFMACRO FOO (OPTIONAL A (B 5) (C 6 CSET)) FORM) expanding the macro call (FOO) would cause FORM to be evaluated with A set to NIL, B set to 5, C set to 6, and CSET set to NIL. (FOO 4 5 6) would be the same, except that A would be set to 4 and CSET would be set to T.

&REST &BODY
Used to get a list of all additional arguments from the macro call. Either &REST or &BODY should be followed by a single symbol, which is set to a list of all arguments to the macro after the position of the &-keyword. For example, given

(DEFMACRO FOO (A B &REST C) FORM)

expanding the macro call (FOO 1 2 3 4 5) would cause FORM to be evaluated with A set to 1, B set to 2, and C set to (3 4 5).

If the macro calling form contains keyword arguments (see &KEY below), these are included in the &REST list.

&KEY
Used to define keyword arguments, that are specified in the macro call by including a “keyword” (a symbol starting with the character “:”) followed by a value.

Each element on ARGS after &KEY until the next &-keyword or the end of the list defines a keyword argument, which can either be a symbol or a list, interpreted as follows:

VAR
(VAR)
((KEYWORD VAR))

If a keyword argument is specified by a single symbol VAR, or a one-element list containing VAR, it is set to the value of a keyword argument, where the keyword used is created by adding the character “:” to the front of VAR. If a keyword argument is specified by a single-element list containing a two-element list, KEYWORD is interpreted as the keyword (which should start with the letter “:”), and VAR is the variable to set.

(VAR DEFAULT)
((KEYWORD VAR) DEFAULT)
FUNCTION DEFINITION, MANIPULATION AND EVALUATION

(\textsc{var} \textsc{default} \textsc{varsetp})
(\textsc{keyword} \textsc{var}; \textsc{default} \textsc{varsetp})

If a keyword argument is specified by a two- or three-element list, the first element of the list specifies the keyword and variable to set as above. Similar to \textsc{optional} (above), the second element \textsc{default} is a form that is evaluated and used as the default if there is no corresponding element in the macro call, and the third element \textsc{varsetp} is a variable that is set to \texttt{T} if the optional argument is given in the macro call, \texttt{NIL} otherwise.

For example, the form
\begin{verbatim}
(defform macro (\textsc{key} \textsc{a} \textsc{b} \textsc{varsetp}) \textsc{form})
\end{verbatim}

Defines a macro with keys \textsc{a}, \textsc{b} (defaulting to \texttt{5}), and \textsc{bar}. Expanding the macro call \begin{verbatim}(macro \textsc{a} \textsc{b} 2 \textsc{form})\end{verbatim} would cause \textsc{form} to be evaluated with \textsc{a} set to \texttt{1}, \textsc{b} set to \texttt{5}, \textsc{var} set to \texttt{NIL}, \textsc{c} set to \texttt{2}, and \textsc{varsetp} set to \texttt{T}.

\textbf{&allow-other-keys}

It is an error for any keywords to be supplied in a macro call that are not defined as keywords in the macro argument list, unless either the \texttt{&}-keyword \texttt{&allow-other-keys} appears in \texttt{args}, or the keyword \texttt{:allow-other-keys} (with a non-\texttt{NIL} value) appears in the macro call.

\textbf{&aux}

Used to bind and initialize auxiliary variables, using a syntax similar to \texttt{prog} (see the \texttt{prog} and Associated Control Functions section of Chapter 9). Any elements after \texttt{&aux} should be either symbols or lists, interpreted as follows:

\begin{enumerate}
\item \textsc{var}
Single symbols are interpreted as auxiliary variables that are initially bound to \texttt{NIL}.
\item \texttt{(\textsc{var} \textsc{exp})}
If an auxiliary variable is specified as a two element list, \textsc{var} is a variable initially bound to the result of evaluating the form \textsc{exp}.
\end{enumerate}

For example, given
\begin{verbatim}
(defform macro (\textsc{a} \textsc{b} \textsc{c} \textsc{d} \textsc{varsetp}) \textsc{form})
\end{verbatim}
\begin{verbatim}
\textsc{c} will be bound to \texttt{NIL} and \textsc{d} to \texttt{5} when \textsc{form} is evaluated.
\end{verbatim}

\textbf{&whole}

Used to get the whole macro calling form. Should be the first element of \texttt{args}, and should be followed by a single symbol, which is set to the entire macro calling form. Other \texttt{&}-keywords or arguments can follow. For example, given
\begin{verbatim}
(defform macro (\textsc{whole} \textsc{x} \textsc{a} \textsc{b}) \textsc{form})
\end{verbatim}

Expanding the macro call \begin{verbatim}(macro \texttt{1} \texttt{2})\end{verbatim} would cause \textsc{form} to be evaluated with \textsc{x} set to \begin{verbatim}(macro \texttt{1} \texttt{2})\end{verbatim}, \textsc{a} set to \texttt{1}, and \textsc{b} set to \texttt{2}.

Defform macros also support argument list “destructuring,” a facility for accessing the structure of individual arguments to a macro. Any place
in an argument list where a symbol is expected, an argument list (in the form described above) can appear instead. Such an embedded argument list is used to match the corresponding parts of that particular argument, which should be a list structure in the same form. In the simplest case, where the embedded argument list does not include &-keywords, this provides a simple way of picking apart list structures passed as arguments to a macro. For example, given

```
(DEFMACRO FOO (A (B (C . D)) E) FORM)
```

Expanding the macro call `(FOO 1 (2 (3 4 5)) 6)` would cause FORM to be evaluated with with A set to 1, B set to 2, C set to 3, D set to (4 5), and E set to 6. Note that the embedded argument list `(B (C . D))` has an embedded argument list `(C . D)`. Also notice that if an argument list ends in a dotted pair, that the final symbol matches the rest of the arguments in the macro call.

An embedded argument list can also include &-keywords, for interpreting parts of embedded list structures as if they appeared in a top-level macro call. For example, given

```
(DEFMACRO FOO (A (B &OPTIONAL (C 6)) D) FORM)
```

Expanding the macro call `(FOO 1 (2) 3)` would cause FORM to be evaluated with with A set to 1, B set to 2, C set to 6 (because of the default value), and D set to 3.

**Warning:** Embedded argument lists can only appear in positions in an argument list where a list is otherwise not accepted. In the above example, it would not be possible to specify an embedded argument list after the &OPTIONAL keyword, because it would be interpreted as an optional argument specification (with variable name, default value, set variable). However, it would be possible to specify an embedded argument list as the first element of an optional argument specification list, as so:

```
(DEFMACRO FOO (A (B &OPTIONAL ((X (Y) Z) '(1 (2) 3))) D) FORM)
```

In this case, X, Y, and Z default to 1, 2, and 3, respectively. Note that the “default” value has to be an appropriate list structure. Also, in this case either the whole structure `(X (Y) Z)` can be supplied, or it can be defaulted (i.e., is not possible to specify Z while letting Y default).

**Interpreting Macros**

When the interpreter encounters a form CAR of which is an undefined function, it tries interpreting it as a macro. If CAR of the form has a macro definition, the macro is expanded, and the result of this expansion is evaluated in place of the original form. CLISPTRAN (see the Miscellaneous Functions and Variables section of Chapter 21) is used to save the result of this expansion so that the expansion only has to be done once. On subsequent occasions, the translation (expansion) is retrieved from CLISPARRAY the same as for other CLISP constructs.

**Note:** Because of the way that the evaluator processes macros, if you have a macro on FOO, then typing `(FOO 'A 'B)` will work, but `FOO(A B)` will not work.
11. VARIABLE BINDINGS AND THE STACK

Medley uses “deep binding.” Every time a function is entered, a basic frame containing the new variables is put on top of the stack. Therefore, any variable reference requires searching the stack for the first instance of that variable, which makes free variable use somewhat more expensive than in a shallow binding scheme. On the other hand, spaghetti stack operations are considerably faster. Some other tricks involving copying freely-referenced variables to higher frames on the stack are also used to speed up the search.

The basic frames are allocated on a stack; for most user purposes, these frames should be thought of as containing the variable names associated with the function call, and the current values for that frame. The descriptions of the stack functions in below are presented from this viewpoint. Both interpreted and compiled functions store both the names and values of variables so that interpreted and compiled functions are compatible and can be freely intermixed, i.e., free variables can be used with no SPECVAR declarations necessary. However, it is possible to suppress storing of names in compiled functions, either for efficiency or to avoid a clash, via a LOCALVAR declaration (see the Local Variables and Special Variables section of Chapter 18). The names are also very useful in debugging, for they make possible a complete symbolic backtrace in case of error.

In addition to the binding information, additional information is associated with each function call: access information indicating the path to search the basic frames for variable bindings, control information, and temporary results are also stored on the stack in a block called the frame extension. The interpreter also stores information about partially evaluated expressions as described in the Stack and Interpreter section of Chapter 11.

Spaghetti Stack

The Bobrow/Wegbreit paper, “A Model and Stack Implementation for Multiple Environments” (Communications of the ACM, Vol. 16, 10, October 1973.), describes an access and control mechanism more general than a simple linear stack. The access and control mechanism used by Interlisp is a slightly modified version of the one proposed by Bobrow and Wegbreit. This mechanism is called the “spaghetti stack.”

The spaghetti system presents the access and control stack as a data structure composed of “frames.” The functions described below operate on this structure. These primitives allow user functions to manipulate the stack in a machine independent way. Backtracking, coroutines, and more sophisticated control schemes can be easily implemented with these primitives.

The evaluation of a function requires the allocation of storage to hold the values of its local variables during the computation. In addition to variable bindings, an activation of a function requires a return link (indicating where control is to go after the completion of the computation) and room for temporaries needed during the computation. In the spaghetti system, one “stack” is used for storing all this information, but it is best to view this stack as a tree of linked objects called frame extensions (or simply frames).

A frame extension is a variable sized block of storage containing a frame name, a pointer to some variable bindings (the BLINK), and two pointers to other frame extensions (the ALINK and CLINK). In addition to these components, a frame extension contains other information (such as temporaries and reference counts) that does not interest us here.
The block of storage holding the variable bindings is called a basic frame. A basic frame is essentially an array of pairs, each of which contains a variable name and its value. The reason frame extensions point to basic frames (rather than just having them “built in”) is so that two frame extensions can share a common basic frame. This allows two processes to communicate via shared variable bindings.

The chain of frame extensions which can be reached via the successive \textit{ALINK}s from a given frame is called the “access chain” of the frame. The first frame in the access chain is the starting frame. The chain through successive \textit{CLINK}s is called the “control chain”.

A frame extension completely specifies the variable bindings and control information necessary for the evaluation of a function. Whenever a function (or in fact, any form which generally binds local variables) is evaluated, it is associated with some frame extension.

In the beginning there is precisely one frame extension in existence. This is the frame in which the top-level call to the interpreter is being run. This frame is called the “top-level” frame.

Since precisely one function is being executed at any instant, exactly one frame is distinguished as having the “control bubble” in it. This frame is called the active frame. Initially, the top-level frame is the active frame. If the computation in the active frame invokes another function, a new basic frame and frame extension are built. The frame name of this basic frame will be the name of the function being called. The \textit{ALINK}, \textit{BLINK}, and \textit{CLINK} of the new frame all depend on precisely how the function is invoked. The new function is then run in this new frame by passing control to that frame, i.e., it is made the active frame.

Once the active computation has been completed, control normally returns to the frame pointed to by the \textit{CLINK} of the active frame. That is, the frame in the \textit{CLINK} becomes the active frame.

In most cases, the storage associated with the basic frame and frame extension just abandoned can be reclaimed. However, it is possible to obtain a pointer to a frame extension and to “hold on” to this frame even after it has been exited. This pointer can be used later to run another computation in that environment, or even “continue” the exited computation.

A separate data type, called a stack pointer, is used for this purpose. A stack pointer is just a cell that literally points to a frame extension. Stack pointers print as \#ADR/\textit{FRAMENAME}, e.g., \#1,13636/\textit{COND}. Stack pointers are returned by many of the stack manipulating functions described below. Except for certain abbreviations (such as “the frame with such-and-such a name”), stack pointers are the only way you can reference a frame extension. As long as you have a stack pointer which references a frame extension, that frame extension (and all those that can be reached from it) will not be garbage collected.

Two stack pointers referencing the same frame extension are \textit{not} necessarily \textit{EQ}, i.e., \( \text{EQ} \left( \text{STKPOS 'FOO} \right) \left( \text{STKPOS 'FOO} \right) = \text{NIL} \). However, \textit{EQP} can be used to test if two different stack pointers reference the same frame extension (see the Equality Predicates section of Chapter 9).

It is possible to evaluate a form with respect to an access chain other than the current one by using a stack pointer to refer to the head of the access chain desired. Note, however, that this can be very expensive when using a shallow binding scheme such as that in Interlisp-10. When evaluating the form, since all references to variables under the shallow binding scheme go through the variable’s value cell, the values in the value cells must be adjusted to reflect the values appropriate to the desired access chain. This is done by changing all the bindings on the current access chain (all the name-value pairs) so that they contain the value current at the time of the call. Then along the new access path, all
VARIABLE BINDINGS AND THE STACK

bindings are made to contain the previous value of the variable, and the current value is placed in the value cell. For that part of the access path which is shared by the old and new chain, no work has to be done. The context switching time, i.e. the overhead in switching from the current, active, access chain to another one, is directly proportional to the size of the two branches that are not shared between the access contexts. This cost should be remembered in using generators and coroutines (see the Generators section below).

Stack Functions

In the descriptions of the stack functions below, when we refer to an argument as a stack descriptor, we mean that it is one of the following:

A stack pointer  An object that points to a frame on the stack. Stack pointers are returned by many of the stack manipulating functions described below.

NIL  Specifies the active frame; that is, the frame of the stack function itself.

T  Specifies the top-level frame.

A symbol  Specifies the first frame (along the control chain from the active frame) that has the frame name LITATOM. Equivalent to (STKPOS LITATOM -1).

A list of symbols  Specifies the first frame (along the control chain from the active frame) whose frame name is included in the list.

A number $N$  Specifies the $N$th frame back from the active frame. If $N$ is negative, the control chain is followed, otherwise the access chain is followed. Equivalent to (STKNTH N).

In the stack functions described below, the following errors can occur: The error Illegal stack arg occurs when a stack descriptor is expected and the supplied argument is either not a legal stack descriptor (i.e., not a stack pointer, symbol, or number), or is a symbol or number for which there is no corresponding stack frame, e.g., (STKNTH -1 'FOO) where there is no frame named FOO in the active control chain or (STKNTH -10 'EVALQT). The error Stack pointer has been released occurs whenever a released stack pointer is supplied as a stack descriptor argument for any purpose other than as a stack pointer to re-use.

Note: The creation of a single stack pointer can result in the retention of a large amount of stack space. Therefore, one should try to release stack pointers when they are no longer needed (see the Releasing and Reusing Stack Pointers section below).

In Lisp there is a fixed amount of space allocated for the stack. When most of this space is exhausted, the STACK OVERFLOW error occurs and the debugger will be invoked. You will still have a little room on the stack to use inside the debugger. If you use up this last little bit of stack you will encounter a “hard” stack overflow. A “hard” stack overflow will put you into URaid (see the documentation on URaid).
Searching the Stack

\[(\text{STKPOS FRAMENAME N POS OLDPOS})\]  
[Function]  
Returns a stack pointer to the \(N\)th frame with frame name \(\text{FRAMENAME}\). The search begins with (and includes) the frame specified by the stack descriptor \(\text{POS}\). The search proceeds along the control chain from \(\text{POS}\) if \(N\) is negative, or along the access chain if \(N\) is positive. If \(N\) is \(\text{NIL}\), -1 is used. Returns a stack pointer to the frame if such a frame exists, otherwise returns \(\text{NIL}\). If \(\text{OLDPOS}\) is supplied and is a stack pointer, it is reused. If \(\text{OLDPOS}\) is supplied and is a stack pointer and \(\text{STKPOS}\) returns \(\text{NIL}\), \(\text{OLDPOS}\) is released. If \(\text{OLDPOS}\) is not a stack pointer it is ignored.

\[(\text{STKNTH N POS OLDPOS})\]  
[Function]  
Returns a stack pointer to the \(N\)th frame back from the frame specified by the stack descriptor \(\text{POS}\). If \(N\) is negative, the control chain from \(\text{POS}\) is followed. If \(N\) is positive the access chain is followed. If \(N\) equals 0, \(\text{STKNTH}\) returns a stack pointer to \(\text{POS}\) (this provides a way to copy a stack pointer). Returns \(\text{NIL}\) if there are fewer than \(N\) frames in the appropriate chain. If \(\text{OLDPOS}\) is supplied and is a stack pointer, it is reused. If \(\text{OLDPOS}\) is not a stack pointer it is ignored.

Note: \((\text{STKNTH 0})\) causes an error, \text{Illegal stack arg}; it is not possible to create a stack pointer to the active frame.

\[(\text{STKNAME POS})\]  
[Function]  
Returns the frame name of the frame specified by the stack descriptor \(\text{POS}\).

\[(\text{SETSTKNAME POS NAME})\]  
[Function]  
Changes the frame name of the frame specified by \(\text{POS}\) to be \(\text{NAME}\). Returns \(\text{NAME}\).

\[(\text{STKNTHNAME N POS})\]  
[Function]  
Returns the frame name of the \(N\)th frame back from \(\text{POS}\). Equivalent to \((\text{STKNAME (STKNTH N POS)})\) but avoids creation of a stack pointer.

In summary, \(\text{STKPOS}\) converts function names to stack pointers, \(\text{STKNTH}\) converts numbers to stack pointers, \(\text{STKNAME}\) converts stack pointers to function names, and \(\text{STKNTHNAME}\) converts numbers to function names.

Variable Bindings in Stack Frames

The following functions are used for accessing and changing bindings. Some of functions take an argument, \(N\), which specifies a particular binding in the basic frame. If \(N\) is a literal atom, it is assumed to be the name of a variable bound in the basic frame. If \(N\) is a number, it is assumed to reference the \(N\)th binding in the basic frame. The first binding is 1. If the basic frame contains no binding with the given name or if the number is too large or too small, the error \text{Illegal arg} occurs.
VARIABLE BINDINGS AND THE STACK

(STKSCAN VAR IPOS OPOS) [Function]
Searches beginning at IPOS for a frame in which a variable named VAR is bound. The search follows the access chain. Returns a stack pointer to the frame if found, otherwise returns NIL. If OPOS is a stack pointer it is reused, otherwise it is ignored.

(FRAMESCAN ATOM POS) [Function]
Returns the relative position of the binding of ATOM in the basic frame of POS. Returns NIL if ATOM is not found.

(STKARG N POS —) [Function]
Returns the value of the binding specified by N in the basic frame of the frame specified by the stack descriptor POS. N can be a literal atom or number.

(STKARGNAME N POS) [Function]
Returns the name of the binding specified by N, in the basic frame of the frame specified by the stack descriptor POS. N can be a literal atom or number.

(SETSTKARG N POS VAL) [Function]
Sets the value of the binding specified by N in the basic frame of the frame specified by the stack descriptor POS. N can be a literal atom or a number. Returns VAL.

(SETSTKARGNAME N POS NAME) [Function]
Sets the variable name to NAME of the binding specified by N in the basic frame of the frame specified by the stack descriptor POS. N can be a literal atom or a number. Returns NAME. This function does not work for interpreted frames.

(STKNARGS POS —) [Function]
Returns the number of arguments bound in the basic frame of the frame specified by the stack descriptor POS.

(VARIABLES POS) [Function]
Returns a list of the variables bound at POS.

(STKARGS POS —) [Function]
Returns a list of the values of the variables bound at POS.

Evaluating Expressions in Stack Frames

The following functions are used to evaluate an expression in a different environment:

(ENVEVAL FORM APOS CPOS AFLG CFLG) [Function]
Evaluates FORM in the environment specified by APOS and CPOS. That is, a new active frame is created with the frame specified by the stack descriptor APOS as its ALINK, and the frame specified by the stack descriptor CPOS as its CLINK. Then FORM is evaluated. If
AFLG is not NIL, and APOS is a stack pointer, then APOS will be released. Similarly, if CFLG is not NIL, and CPOS is a stack pointer, then CPOS will be released.

(envapply fn args apos aflg cpos aflg cflg)  [Function]

APPLYs FN to ARGS in the environment specified by APOS and CPOS. AFLG and CFLG have the same interpretation as with ENVEVAL.

(evalv var pos relflg)  [Function]

Evaluates VAR, where VAR is assumed to be a symbol, in the access environment specified by the stack descriptor POS. If VAR is unbound, EVALV returns NOBIND and does not generate an error. If RELFLG is non-NIL and POS is a stack pointer, it will be released after the variable is looked up. While EVALV could be defined as (ENVEVAL VAR POS NIL RELFLG) it is in fact somewhat faster.

(stkeval pos form flg --)  [Function]

Evaluates FORM in the access environment of the frame specified by the stack descriptor POS. If FLG is not NIL and POS is a stack pointer, releases POS. The definition of STKEVAL is (ENVEVAL FORM POS NIL FLG).

(stkapply pos fn args flg)  [Function]

Like STKEVAL but applies FN to ARGS.

Altering Flow of Control

The following functions are used to alter the normal flow of control, possibly jumping to a different frame on the stack. RETEVAL and RETAPPLY allow evaluating an expression in the specified environment first.

(retfrom pos val flg)  [Function]

Return from the frame specified by the stack descriptor POS, with the value VAL. If FLG is not NIL, and POS is a stack pointer, then POS is released. An attempt to RETFROM the top level (e.g., (RETFROM T)) causes an error, Illegal stack arg. RETFROM can be written in terms of ENVEVAL as follows:

(RETFROM
 (lambda (pos val flg)
  (enveval (list 'quote val) nil
   (if (stknth -1 pos
         (if flg then pos))
       (else (errorx (list 19 pos)))
     nil
     t)))

(retto pos val flg)  [Function]

Like RETFROM, but returns to the frame specified by POS.
VARIABLE BINDINGS AND THE STACK

**RETEVAL** \[POS\ FORM\ FLG\] \[Function\]

Evaluates \textit{FORM} in the access environment of the frame specified by the stack descriptor \textit{POS}, and then returns from \textit{POS} with that value. If \textit{FLG} is not \texttt{NIL} and \textit{POS} is a stack pointer, then \textit{POS} is released. The definition of \textit{RETEVAL} is equivalent to \((\textit{ENVEVAL FORM POS (STKNTH -1 POS) FLG T})\), but \textit{RETEVAL} does not create a stack pointer.

**RETAPELY** \[POS FN ARGS FLG\] \[Function\]

Like \textit{RETEVAL} but applies \textit{FN} to \textit{ARGS}.

---

### Releasing and Reusing Stack Pointers

The following functions and variables are used for manipulating stack pointers:

**STACKP** \[X\] \[Function\]

Returns \texttt{X} if \texttt{X} is a stack pointer, otherwise returns \texttt{NIL}.

**RELSTK** \[POS\] \[Function\]

Release the stack pointer \textit{POS} (see below). If \textit{POS} is not a stack pointer, does nothing. Returns \textit{POS}.

**RELSTKP** \[X\] \[Function\]

Returns \texttt{T} is \texttt{X} is a released stack pointer, \texttt{NIL} otherwise.

**CLEARSTK** \[FLG\] \[Function\]

If \textit{FLG} is \texttt{T}, returns a list of all the active (unreleased) stack pointers. If \textit{FLG} is \texttt{NIL}, this call is a no-op. The ability to clear all stack pointers is inconsistent with the modularity implicit in a multi processing environment.

**CLEARSTKLST** \[Variable\]

A variable used by the top-level executive. Every time the top-level executive is re-entered (e.g., following errors, or Control-D), \texttt{CLEARSTKLST} is checked. If its value is \texttt{T}, all active stack pointers are released using \texttt{CLEARSTK}. If its value is a list, then all stack pointers on that list are released. If its value is \texttt{NIL}, nothing is released. \texttt{CLEARSTKLST} is initially \texttt{T}.

**NOCLEARSTKLST** \[Variable\]

A variable used by the top-level executive. If \texttt{CLEARSTKLST} is \texttt{T} (see above) all active stack pointers except those on \texttt{NOCLEARSTKLST} are released. \texttt{NOCLEARSTKLST} is initially \texttt{NIL}.

Creating a single stack pointer can cause the retention of a large amount of stack space. Furthermore, this space will not be freed until the next garbage collection, even if the stack pointer is no longer being used, unless the stack pointer is explicitly released or reused. If there is sufficient amount of stack space tied up in this fashion, a \texttt{STACK OVERFLOW} condition can occur, even in the simplest of computations. For this reason, you should consider releasing a stack pointer when the environment referenced by the stack pointer is no longer needed.
The effects of releasing a stack pointer are:

1. The link between the stack pointer and the stack is broken by setting the contents of the stack pointer to the “released mark”. A released stack pointer prints as #ADR/#0.

2. If this stack pointer was the last remaining reference to a frame extension; that is, if no other stack pointer references the frame extension and the extension is not contained in the active control or access chain, then the extension may be reclaimed, and is reclaimed immediately. The process repeats for the access and control chains of the reclaimed extension so that all stack space that was reachable only from the released stack pointer is reclaimed.

A stack pointer may be released using the function RELSTK, but there are some cases for which RELSTK is not sufficient. For example, if a function contains a call to RETFROM in which a stack pointer was used to specify where to return to, it would not be possible to simultaneously release the stack pointer. (A RELSTK appearing in the function following the call to RETFROM would not be executed!) To permit release of a stack pointer in this situation, the stack functions that relinquish control have optional flag arguments to denote whether or not a stack pointer is to be released (AFLG and CFLG). Note that in this case releasing the stack pointer will not cause the stack space to be reclaimed immediately because the frame referenced by the stack pointer will have become part of the active environment.

Another way to avoid creating new stack pointers is to reuse stack pointers that are no longer needed. The stack functions that create stack pointers (STKPOS, STKNTH, and STKSCAN) have an optional argument that is a stack pointer to reuse. When a stack pointer is reused, two things happen. First the stack pointer is released (see above). Then the pointer to the new frame extension is deposited in the stack pointer. The old stack pointer (with its new contents) is returned as the value of the function. Note that the reused stack pointer will be released even if the function does not find the specified frame.

Even if stack pointers are explicitly being released, creating many stack pointers can cause a garbage collection of stack pointer space. Thus, if your application requires creating many stack pointers, you definitely should take advantage of reusing stack pointers.

**Backtrace Functions**

The following functions perform a “backtrace,” printing information about every frame on the stack. Arguments allow only backtracing a selected range of the stack, skipping selected frames, and printing different amounts of information about each frame.

```
(BACKTRACE IPOS EPOS FLAGS FILE PRINTFN) [Function]
```

Performs a backtrace beginning at the frame specified by the stack descriptor IPOS, and ending with the frame specified by the stack descriptor EPOS. FLAGS is a number in which the options of the BACKTRACE are encoded. If a bit is set, the corresponding information is included in the backtrace.

- 1Q - print arguments of non-SUBRs
- 2Q - print temporaries of the interpreter
- 4Q - print SUBR arguments and local variables
- 10Q - omit printing of UNTRACE and function names
- 20Q - follow access chain instead of control chain
VARIABLE BINDINGS AND THE STACK

40Q - print temporaries, i.e. the blips (see the stack and interpreter section below)

For example: If $FLAGS = 47Q$, everything is printed. If $FLAGS = 21Q$, follows the
access chain, prints arguments.

$FILE$ is the file that the backtrace is printed to. $FILE$ must be open. $PRINTFN$ is used
when printing the values of variables, temporaries, blips, etc. $PRINTFN = NIL$ defaults to
$PRINT$.

(BAKTRACE IPOS EPOS SKIPFNS FLAGS FILE) [Function]

Prints a backtrace from $IPOS$ to $EPOS$ onto $FILE$. $FLAGS$ specifies the options of the
backtrace, e.g., do/don’t print arguments, do/don’t print temporaries of the interpreter,
etc., and is the same as for BAKTRACE.

$SKIPFNS$ is a list of functions. As BAKTRACE scans down the stack, the stack name of
each frame is passed to each function in $SKIPFNS$, and if any of them returnS non-NIL,
$POS$ is skipped (including all variables).

BAKTRACE collapses the sequence of several function calls corresponding to a call to a
system package into a single “function” using BAKTRACELST as described below. For
example, any call to the editor is printed as **EDITOR**, a break is printed as
**BREAK**, etc.

BAKTRACE is used by the BT, BTV, BTV+, BTV*, and BTV! break commands, with $FLAGS$
= 0, 1, 5, 7, and 47Q respectively.

If SYSPRETTYFLG = T, the values arguments and local variables will be prettyprinted.

BAKTRACELST [Variable]

Used to tell BAKTRACE (therefore, the BT, BTV, etc. commands) to abbreviate various
sequences of function calls on the stack by a single key, e.g. **BREAK**, **EDITOR**, etc.

Each entry on BAKTRACELST is a list of the form (FRAMENAME KEY . PATTERN) or
(FRAMENAME (KEY1 . PATTERN1) ... (KEYn . PATTERNn)), where a pattern is a
list of elements that are either atoms, which match a single frame, or lists, which are
interpreted as a list of alternative patterns, e.g. (PROGN **BREAK** EVAL ((ERRORSET
BREAK1A BREAK1) (BREAK1)))

BAKTRACE operates by scanning up the stack and, at each point, comparing the current frame name,
with the frame names on BAKTRACELST, i.e. it does an ASSOC. If the frame name does appear,
BAKTRACE attempts to match the stack as of that point with (one of) the patterns. If the match is
successful, BAKTRACE prints the corresponding key, and continues with where the match left off. If
the frame name does not appear, or the match fails, BAKTRACE simply prints the frame name and
continues with the next higher frame (unless the SKIPFNS applied to the frame name are non-NIL as
described above).

Matching is performed by comparing symbols in the pattern with the current frame name, and
matching lists as patterns, i.e. sequences of function calls, always working up the stack. For example,
either of the sequence of function calls “... BREAK1 BREAK1A ERRORSET EVAL PROGN ...”
INTERLISP-D REFERENCE MANUAL

or "... BREAK1 EVAL PROGN ..." would match with the sample entry given above, causing **BREAK** to be printed.

Special features:

- The symbol & can be used to match any frame.
- The pattern "-" can be used to match nothing. - is useful for specifying an optional match, e.g. the example above could also have been written as (PROGN **BREAK** EVAL ((ERRORSET BREAK1A) -) BREAK1).
- It is not necessary to provide in the pattern for matching dummy frames, i.e. frames for which DUMMYFRAMEP (see below) is true. When working on a match, the matcher automatically skips over these frames when they do not match.
- If a match succeeds and the KEY is NIL, nothing is printed. For example, (*PROG*LAM NIL EVALA *ENV). This sequence will occur following an error which then causes a break if some of the function’s arguments are LOCALVARS.

Other Stack Functions

(DUMMYFRAMEP POS) [Function]
Returns T if you never wrote a call to the function at POS, e.g. in Interlisp-10, DUMMYFRAMEP is T for *PROG*LAM, *ENV*, and FOOBLOCK frames (see the Block Compiling section of Chapter 18).

REALFRAMEP and REALSTKNTH can be used to write functions which manipulate the stack and work on either interpreted or compiled code:

(REALFRAMEP POS INTERPFLG) [Function]
Returns POS if POS is a "real" frame, i.e. if POS is not a dummy frame and POS is a frame that does not disappear when compiled (such as COND); otherwise NIL. If INTERPFLG = T, returns T if POS is not a dummy frame. For example, if (STKNAME POS) = COND, (REALFRAMEP POS) is NIL, but (REALFRAMEP T) is T.

(REALSTKNTH N POS INTERPFLG QLDPOS) [Function]
Returns a stack pointer to the Nth (or -Nth) frames for which (REALFRAMEP POS INTERPFLG) is POS.

(MAPDL MAPDLFN MAPDLPOS) [Function]
Starts at MAPDLPOS and applies the function MAPDLFN to two arguments (the frame name and a stack pointer to the frame), for each frame until the top of the stack is reached. Returns NIL. For example,

(MAPDL (FUNCTION (LAMBDA (X POS)
            (if (IGREATERP (STKNARGS POS) 2) then (PRINT X))]
will print all functions of more than two arguments.
VARIABLE BINDINGS AND THE STACK

**(SEARCHPDL SRCHFN SRCHPOS)**  
[Function]  
Like MAPDL, but searches the stack starting at position SRCHPOS until it finds a frame for which SRCHFN, a function of two arguments applied to the name of the frame and the frame itself, is not NIL. Returns (NAME . FRAME) if such a frame is found, otherwise NIL.

The Stack and the Interpreter  
In addition to the names and values of arguments for functions, information regarding partially-evaluated expressions is kept on the push-down list. For example, consider the following definition of the function FACT (intentionally faulty):

```
(FACT
  [LAMBDA (N)
    (COND
      ((ZEROP N) L)
      (T (ITIMES N (FACT (SUB1 N)))))
  ]
)
```

In evaluating the form (FACT 1), as soon as FACT is entered, the interpreter begins evaluating the implicit PROGN following the LAMBDA. The first function entered in this process is COND. COND begins to process its list of clauses. After calling ZEROP and getting a NIL value, COND proceeds to the next clause and evaluates T. Since T is true, the evaluation of the implicit PROGN that is the consequent of the T clause is begun. This requires calling the function ITIMES. However before ITIMES can be called, its arguments must be evaluated. The first argument is evaluated by retrieving the current binding of N from its value cell; the second involves a recursive call to FACT, and another implicit PROGN, etc.

At each stage of this process, some portion of an expression has been evaluated, and another is awaiting evaluation. The output below (from Interlisp-10) illustrates this by showing the state of the push-down list at the point in the computation of (FACT 1) when the unbound atom L is reached.
**TOP**

Internal calls to EVAL, e.g., from COND and the interpreter, are marked on the push-down list by a special mark or blip which the backtrace prints as *FORM*. The genealogy of *FORM*’s is thus a history of the computation. Other temporary information stored on the stack by the interpreter includes the tail of a partially evaluated implicit PROGN (e.g., a cond clause or lambda expression) and the tail of a partially evaluated form (i.e., those arguments not yet evaluated), both indicated on the backtrace by *TAIL*, the values of arguments that have already been evaluated, indicated by *ARGVAL*, and the names of functions waiting to be called, indicated by *FN*. *ARG1, . . ., ARGn* are used by the backtrace to indicate the (unnamed) arguments to SUBRs.

Note that a function is not actually entered and does not appear on the stack, until its arguments have been evaluated (except for nlambda functions, of course). Also note that the *ARG1, *FORM*, *TAIL*, etc. “bindings” comprise the actual working storage. In other words, in the above example, if a (lower) function changed the value of the *ARG1 binding, the COND would continue interpreting the new binding as a list of COND clauses. Similarly, if the *ARGVAL* binding were changed, the new value would be given to ITIMES as its first argument after its second argument had been evaluated, and ITIMES was actually called.

*FORM*, *TAIL*, *ARGVAL*, etc., do not actually appear as variables on the stack, i.e., evaluating *FORM* or calling STKSCAN to search for it will not work. However, the functions BLIPVAL, SETBLIPVAL, and BLIPSCAN described below are available for accessing these internal blips. These functions currently know about four different types of blips:

*FN* The name of a function about to be called

*ARGVAL* An argument for a function about to be called

*FORM* A form in the process of evaluation

*TAIL* The tail of a COND clause, implicit PROGN, PROG, etc.

(BLIPVAL BLIPTYP IPOS FLG) [Function]

Returns the value of the specified blip of type BLIPTYP. If FLG is a number N, finds the Nth blip of the desired type, searching the control chain beginning at the frame specified by the stack descriptor IPOS. If FLG is NIL, 1 is used. If FLG is T, returns the number of blips of the specified type at IPOS.

(SETBLIPVAL BLIPTYP IPOS N VAL) [Function]

Sets the value of the specified blip of type BLIPTYP. Searches for the Nth blip of the desired type, beginning with the frame specified by the stack descriptor IPOS, and following the control chain.

(BLIPSCAN BLIPTYP IPOS) [Function]

Returns a stack pointer to the frame in which a blip of type BLIPTYP is located. Search begins at the frame specified by the stack descriptor IPOS and follows the control chain.
Generators

A generator is like a subroutine except that it retains information about previous times it has been called. Some of this state may be data (for example, the seed in a random number generator), and some may be in program state (as in a recursive generator which finds all the atoms in a list structure).

For example, if LISTGEN is defined by:

```lisp
(DEFINEQ (LISTGEN (L)
    (if L then (PRODUCE (CAR L))
    (LISTGEN (CDR L)))))
```

we can use the function GENERATOR (described below) to create a generator that uses LISTGEN to produce the elements of a list one at a time, e.g.,

```lisp
(SETOQ GR (GENERATOR (LISTGEN '(A B C)))
```

creates a generator, which can be called by

```lisp
(GENERATE GR)
```

to produce as values on successive calls, A, B, C. When GENERATE (not GENERATOR) is called the first time, it simply starts evaluating (LISTGEN '(A B C)). PRODUCE gets called from LISTGEN, and pops back up to GENERATE with the indicated value after saving the state. When GENERATE gets called again, it continues from where the last PRODUCE left off. This process continues until finally LISTGEN completes and returns a value (it doesn't matter what it is). GENERATE then returns GR itself as its value, so that the program that called GENERATE can tell that it is finished, i.e., there are no more values to be generated.

```lisp
(GENERATOR FORM COMVAR) [NLambda Function]
```

An nlambda function that creates a generator which uses FORM to compute values. GENERATOR returns a generator handle which is represented by a dotted pair of stack pointers.

COMVAR is optional. If its value (EVAL of) is a generator handle, the list structure and stack pointers will be reused. Otherwise, a new generator handle will be constructed.

GENERATOR compiles open.

```lisp
(PRODUCE VAL) [Function]
```

Used from within a generator to return VAL as the value of the corresponding call to GENERATE.

```lisp
(GENERATE HANDLE VAL) [Function]
```

Restarts the generator represented by HANDLE. VAL is returned as the value of the PRODUCE which last suspended the operation of the generator. When the generator runs out of values, GENERATE returns HANDLE itself.

Examples:

The following function will go down recursively through a list structure and produce the atoms in the list structure one at a time.

```lisp
(DEFINEQ (LEAVESG (L)
    (if (ATOM L)
```
The following function prints each of these atoms as it appears. It illustrates how a loop can be set up to use a generator.

\[
\text{(DEFINEQ (PLEAVESG1 (L))}
\begin{align*}
&\text{(PROG (X LHANDLE))} \\
&\quad \text{(SETQ LHANDLE (GENERATOR (LEAVESG L)))} \\
&\quad \text{LP (SETQ X (GENERATE LHANDLE))} \\
&\quad \text{(if (EQ X LHANDLE) then (RETURN NIL))} \\
&\quad \text{(PRINT X)} \\
&\quad \text{(GO LP))]
\end{align*}
\]

The loop terminates when the value of the generator is \texttt{EQ} to the dotted pair which is the value produced by the call to \texttt{GENERATOR}. A CLISP iterative operator, \texttt{OUTOF}, is provided which makes it much easier to write the loop in \texttt{PLEAVESG1}. \texttt{OUTOF} (or \texttt{outof}) can precede a form which is to be used as a generator. On each iteration, the iteration variable will be set to successive values returned by the generator; the loop will be terminated automatically when the generator runs out. Therefore, the following is equivalent to the above program \texttt{PLEAVESG1}:

\[
\text{(DEFINEQ (PLEAVESG2 (L)) (for X outof (LEAVESG L) do (PRINT X)))}
\]

Here is another example; the following form will print the first \(N\) atoms.

\[
\text{(for X outof (MAPATOMS (FUNCTION PRODUCE)) as I from 1 to N do (PRINT X))}
\]

**Coroutines**

This package provides facilities for the creation and use of fully general coroutine structures. It uses a stack pointer to preserve the state of a coroutine, and allows arbitrary switching between \(N\) different coroutines, rather than just a call to a generator and return. This package is slightly more efficient than the generator package described above, and allows more flexibility on specification of what to do when a coroutine terminates.

\[
\text{(COROUTINE CALLPTR COROUTPTR COROUTFORM ENDFORM) [NLambda Function]}
\]

This nlambda function is used to create a coroutine and initialize the linkage. \texttt{CALLPTR} and \texttt{COROUTPTR} are the names of two variables, which will be set to appropriate stack pointers. If the values of \texttt{CALLPTR} or \texttt{COROUTPTR} are already stack pointers, the stack pointers will be reused. \texttt{COROUTFORM} is the form which is evaluated to start the coroutine; \texttt{ENDFORM} is a form to be evaluated if \texttt{COROUTFORM} actually returns when it runs out of values.

\texttt{COROUTINE} compiles open.

\[
\text{(RESUME FROMPTR TOPTR VAL) [Function]}
\]

Used to transfer control from one coroutine to another. \texttt{FROMPTR} should be the stack pointer for the current coroutine, which will be smashed to preserve the current state. \texttt{TOPTR} should be the stack pointer which has preserved the state of the coroutine to be transferred to, and \texttt{VAL} is the value that is to be returned to the latter coroutine as the value of the \texttt{RESUME} which suspended the operation of that coroutine.
VARIABLE BINDINGS AND THE STACK

For example, the following is the way one might write the LEAVES program using the coroutine package:

```lisp
(defineq (leavesc (l coroutptr callptr))
  (if (atom l)
      (resume coroutptr callptr l)
    else (leavesc (car l) coroutptr callptr)
    (if (cdr l) then (leavesc (cdr l) coroutptr callptr))))
```

A function PLEAVESC which uses LEAVESC can be defined as follows:

```lisp
(defineq (pleavesc (l))
  (bind plhandle lhandle
    first (coroutine plhandle lhandle
           (leavesc l lhandle plhandle)
           (retfrom 'pleavesc))
    do (print (resume plhandle lhandle))))
```

By RESUMING LEAVESC repeatedly, this function will print all the leaves of list L and then return out of PLEAVESC via the RETFROM. The RETFROM is necessary to break out of the non-terminating do-loop. This was done to illustrate the additional flexibility allowed through the use of ENDFORM.

We use two coroutines working on two trees in the example EQLEAVES, defined below. EQLEAVES tests to see whether two trees have the same leaf set in the same order, e.g., (eqleaves '(a b c) '(a b (c))) is true.

```lisp
(defineq (eqleaves (l1 l2))
  (bind elhandle1 elhandle2 pe el1 el2
    first (coroutine pe elhandle1 (leavesc l1 elhandle1 pe) 'no-more)
    (coroutine pe elhandle2 (leavesc l2 elhandle2 pe) 'no-more)
    do (setq el1 (resume pe elhandle1))
    (setq el2 (resume pe elhandle2))
    (if (neq el1 el2)
      then (return nil))
    repeatuntil (eq el1 'no-more)
    finally (return t)))
```

Possibilities Lists

A possibilities list is the interface between a generator and a consumer. The possibilities list is initialized by a call to POSSIBILITIES, and elements are obtained from it by using TRYNEXT. By using the spaghetti stack to maintain separate environments, this package allows a regime in which a generator can put a few items in a possibilities list, suspend itself until they have been consumed, and be subsequently aroused and generate some more.

```lisp
(possibilities form)
```

This nlambda function is used for the initial creation of a possibilities list. FORM will be evaluated to create the list. It should use the functions NOTE and AU-REVOIR described below to generate possibilities. Normally, one would set some variable to the possibilities list which is returned, so it can be used later, e.g.:

```lisp
(setq plist (possibilities (generfn v1 v2))).
```

POSSIBILITIES compiles open.
(NOTE VAL LSTFLG)       [Function]
Used within a generator to put items on the possibilities list being generated. If LSTFLG is equal to NIL, VAL is treated as a single item. If LSTFLG is non-NIL, then the list VAL is NCONCed on the end of the possibilities list. Note that it is perfectly reasonable to create a possibilities list using a second generator, and NOTE that list as possibilities for the current generator with LSTFLG equal to T. The lower generator will be resumed at the appropriate point.

(AU-REVOIR VAL)       [NoSpread Function]
Puts VAL on the possibilities list if it is given, and then suspends the generator and returns to the consumer in such a fashion that control will return to the generator at the AU-REVOIR if the consumer exhausts the possibilities list.

NIL is not put on the possibilities list unless it is explicitly given as an argument to AU-REVOIR, i.e., (AU-REVOIR) and (AU-REVOIR NIL) are not the same. AU-REVOIR and ADIEU are lambda nospreads to enable them to distinguish these two cases.

(ADIEU VAL)       [NoSpread Function]
Like AU-REVOIR but releases the generator instead of suspending it.

(TRYNEXT PLST ENDFORM VAL)       [NLambda Function]
This nlambda function allows a consumer to use a possibilities list. It removes the first item from the possibilities list named by PLST (i.e. PLST must be an atom whose value is a possibilities list), and returns that item, provided it is not a generator handle. If a generator handle is encountered, the generator is reawakened. When it returns a possibilities list, this list is added to the front of the current list. When a call to TRYNEXT causes a generator to be awakened, VAL is returned as the value of the AU-REVOIR which put that generator to sleep. If PLST is empty, it evaluates ENDFORM in the caller’s environment.

TRYNEXT compiles open.

(CLEANPOSPLST PLST)       [Function]
This function is provided to release any stack pointers which may be left in the PLST which was not used to exhaustion.

For example, FIB is a generator for fibonacci numbers. It starts out by NOTEing its two arguments, then suspends itself. Thereafter, on being re-awakened, it will NOTE two more terms in the series and suspends again. PRINTFIB uses FIB to print the first N fibonacci numbers.

(DEFINEQ (FIB (F1 F2)
 (do (NOTE F1)
 (NOTE F2)
 (SETQ F1 (IPLUS F1 F2))
 (SETQ F2 (IPLUS F1 F2))
 (AU-REVOIR)])

Note that this AU-REVOIR just suspends the generator and adds nothing to the possibilities list except the generator.
(DEFINEQ (PRINTFIB (N))
  (PROG ((FL (POSSIBILITIES (FIB 0 1))))
    (RPTQ N (PRINT (TRYNEXT FL)))
    (CLEANPOSLS LT FL))}

Note that FIB itself will never terminate.
Greeting and Initialization Files

Many of the features of Medley are controlled by variables that you can adjust to your own taste. In addition, you can modify the action of system functions in ways not specifically provided for by using ADVISE (see the Advise Functions section of Chapter 15). To encourage customizing Medley's environment, it includes a facility for automatically loading initialization files (or "init files") when it is first started. Each user can have a separate "user init file" that customizes Medley's environment to his/her tastes. In addition, there can be a "site init file" that applies to all users at a given physical site, setting system variables that are the same for all users such as the name of the nearest printer, etc.

The process of loading init files, also known as "greeting", occurs when a Medley system created by MAKESYS (see the Saving Virtual Memory State section below) is started for the first time. The user can also explicitly invoke the greeting operation at any time via the function GREET (below). The process of greeting includes the following steps:

1. Any previous greeting operation is undone. The side effects of the greeting operation are stored on a global variable as well as on the history list, thus enabling the previous greeting to be undone even if it has dropped off of the bottom of the history list.

2. All of the items on the list PREGREETFORMS are evaluated.

3. The site init file is loaded. GREET looks for a file by the name {DSK}INIT.LISP. If this is found, it is loaded. If it is not found, the system prints Please enter name of system init file (e.g. {server}\directory\INIT.extension): and waits for you to type a file name, followed by a carriage return. If you just type a carriage return without typing a file name, no site init file is loaded. Note: The site init file is loaded with LDFLG set to SYSLOAD, so that no file package information is saved, and nothing is printed out.

4. The user init file is loaded. The user init file is found by using the variable USERRGREETFILES (described below), which is normally set in the site init file. The user init file is loaded with normal file package settings, but under errorset protection and with PRETTYHEADER set to NIL to suppress the File created message.

5. All of the items on the list POSTGREETFORMS are evaluated.

6. The greeting "Hello, XXX." is printed, where XXX is the value of the variable FIRSTNAME (if non-NIL). The variable GREETDATES (below) can be set to modify this greeting for particular dates.

(GREET NAME —) [Function]

Performs the greeting for person whose username is NAME (if NAME = NIL, uses the login name). When Medley first starts up, it performs (GREET) .
(GREETFILENAME USER) [Function]

If USER is T, GREETFILENAME returns the file name of the site init file. If the file name
doesn’t exist, you are prompted for it. Otherwise, USER is interpreted to be a user’s
system name, and GREETFILENAME returns the file name for the user init file (if it exists).

USARGREETFILES [Variable]

USARGREETFILES specifies a series of file names to try as the user init file. The value of
USARGREETFILES is a list, where each element is a list of symbols. For each item in
USARGREETFILES, the user name is substituted for the symbol USER and the value of
COMPILE.EXT (see the Compiler Functions section of Chapter 18) is substituted for the
symbol COM, and the symbols are packed into a single file name. The first such file that is
found is the user init file.

For example, suppose that the value of USARGREETFILES was

\[
\begin{align*}
&\{(\text{ERIS}<\text{USER}>\text{LISP}>\text{INIT}.\text{COM}) \\
&\{(\text{ERIS}<\text{USER}>\text{LISP}>\text{INIT}) \\
&\{(\text{ERIS}<\text{USER}>\text{INIT}.\text{COM}) \\
&\{(\text{ERIS}<\text{USER}>\text{INIT})
\end{align*}
\]

If the user name was JONES, and the value of COMPILE.EXT was DCOM, then this would
search for the files \{ERIS\}<JONES>LISP>INIT.DCOM, \{ERIS\}<JONES>LISP>INIT,
\{ERIS\}<JONES>INIT.DCOM, and \{ERIS\}<JONES>INIT.

Note: The file name “specifications” in USARGREETFILES should be fully qualified,
including all host and directory information. The directory search path (the value of
DIRECTORIES, see the Searching File Directories section of Chapter 24) is not used to find
the user greet files.

GREETDATES [Variable]

The value of GREETDATES can be used to specify special greeting messages for various
dates. GREETDATES is a list of elements of the form (DATESTRING . STRING), e.g.
("25-DEC" . "Merry Christmas"). The user can add entries to this list in his/her
INIT.LISP file by using a ADDVARS file package command like (ADDVARS
(GREETDATES (*8-FEB* . "Happy Birthday"))). On the specified date, the
GREET will use the indicated salutation.

It is impossible to give a complete list of all of the variables and functions you may want
to set in your init files. The default values for system variables are chosen in the hope that
they will be correct for the majority of users, so many users get along with very small init
files. The following describes some of the variables that users may want to reset in their
init files:

Directories The variables DIRECTORIES and LISPUSERSDIRECTORIES (see the
Searching File Directories section of Chapter 24) contain lists of directories
used when searching for files. LOGINHOST/DIR (see the Incomplete File
Names section of Chapter 24) determines the default directory used when
you call CONN with no argument.
Fonts and Printing  The variables DISPLAYFONTDIRECTORIES, DISPLAYFONTEXTENSIONS, INTERPRESSFONTDIRECTORIES, and PRESSFON_TXTWIDTHSFILES (see the Font Files and Font Directories section of Chapter 27) must be set before fonts can be automatically loaded from files. DEFAULTPRINTINGHOST (see Chapter 29) should be set before attempting to generate hardcopy to a printer.

Network Systems  CH.DEFAULT.ORGANIZATION and CH.DEFAULT.DOMAIN (see the Name and Address Conventions section of Chapter 31) should be set to the default NS organization and domain, when using NS network communications. If CH.NET.HINT (see the Clearinghouse Functions section of Chapter 31) is set, it can reduce the amount of time spent searching for a clearinghouse.

Medley Executive  The variable PROMPT#FLG (see the Changing the Programmer’s Assistant section of Chapter 13) determines whether an “event number” is printed at the beginning of every input line. The function CHANGESLICE (see the Changing the Programmer’s Assistant section of Chapter 13) can be used to change the number of events that are remembered on the history list.

Copyright Notices  COPYRIGHTFLG, COPYRIGHTOWNERS, and DEFAULTCOPYRIGHTOWNER (see the Copyright Notices section of Chapter 17) control the inclusion of copyright notices on source files.

Printing Functions  **COMMENT**FLG (see the Comment Feature section of Chapter 26) determines how program comments are printed. FIRSTCOL, PRETTYFLG, and CLISPIFYPRETTYFLG (see the Special Prettyprint Controls section of Chapter 26) are among the many variables controlling how functions are pretty printed.

List Structure Editor  The variable INITIALSLST (see the Time Stamps section of Chapter 16) is used when “time-stamps” are inserted in a function when it is edited. EDITCHARACTERS (see the Time Stamps section of Chapter 16) is used to set the read macros used in the teletype editor.

**Idle Mode**

The Medley environment runs on small single-user computers, usually located in users’ offices. Often, users leave their computers up and running for days, which can cause several problems. First, the phosphor in the video display screen can be permanently marked if the same pattern is displayed for a long time (weeks). Second, if you go away, leaving a Medley system running, another person could possibly walk up and use the environment, taking advantage of any passwords that have been entered. To solve these problems, Medley implements the concept of “idle mode.”

If no keyboard or mouse action has occurred for a specified time, Medley automatically enters idle mode. While idle mode is on, the display screen is blanked out, to protect the phosphor. Idle mode also runs a program to display some moving pattern on the black screen, so the screen does not appear to be broken. Usually, idle mode can be exited by pressing any key on the keyboard or mouse. However, you can optionally specify that idle mode should erase the current password cache when it is entered, and require the next user to supply a password to exit idle mode.
If either shift key is pressed while Medley is in idle mode, the current user name and the amount of
time spent idling are displayed in the prompt window while the key is depressed.

Idle mode can also be entered by calling the function `IDLE`, or by selecting the Idle menu command
from the background menu (see Chapter 28). The Idle menu command has subitems that allow you to
interactively set the idle options (display program, erasing password, etc.) specified by the variable
`IDLE.PROFILE`.

**IDLE.PROFILE**

The value of this variable is a property list (see Chapter 3) which controls most aspects of
idle mode. The following properties are recognized:

- **TIMEOUT**  Value is a number that determines how long (in minutes) Medley
  will wait before automatically entering idle mode. If NIL, idle
  mode will never be entered automatically. Default is 10 minutes.

- **FORGET**  If this is the symbol FIRST, your password will be erased when
  idle mode is entered. If non-NIL, your password will be erased
  when idle mode is exited. Initial value is T (erase password on
  exit).

  If the password is erased on entry to idle mode (value FIRST),
  any programs left running when idle mode is entered will fail if
  they try doing anything requiring passwords (such as accessing
  file servers).

- **ALLOWED.LOGINS**  The value of this property can either be a list or a non-list. If the
  value is NIL or any other non-list, idle mode is exited without
  requesting login.

  If the value is a list the members of the list should be interpreted
  as follows:

  * If the value is a list containing * as it’s element, login is
    required but anyone can exit idle mode. This will overwrite
    the previous user’s user name and password each time idle
    mode is exited.

  T  Let the previous user (as determined by `USERNAME`) exit idle
      mode. If the username has not been set, this is equivalent to *

  user name  Let this specific user exit idle mode.

  group name  Let any member of this group (an NS clearinghouse group) exit
              idle mode.

- **AUTHENTICATE**  The value of this property determines the method used for
  logging in. The value can be one of the following:

  T or NS  Use the NS authentication protocol. This requires that you have
           an NS authentication server accessible on your net.
GV Authenticate the login via the GrapeVine protocol.

UNIX Use the unix login mechanism.

**Note:** Unix is case sensitive. If you try to login but fail, you may have typed the password with the caps-lock on.

LOGIN.TIMEOUT This is the number of seconds idle will wait for a login before resuming idle mode again.

DISPLAYFN The value of this property, which should be a function name or lambda expression, is called to display a moving pattern on the screen while in idle mode. This function is called with one argument, a window covering the whole screen. The default is IDLE.BOUNCING.BOX (below).

Any function used as a DISPLAYFN should call BLOCK (see Chapter 23) frequently, so other programs can run during idle mode.

SAVEVM Value is a number that determines how long (in minutes) after idle mode is entered that SAVEVM will be called to save the virtual memory. If NIL, SAVEVM is never called automatically from idle mode. Default is 10 minutes.

SUSPEND.PROCESS.NAMES Value is a list of names. For each name on this list, if a process by that name is found, it will be suspended upon entering idle mode and woken upon exiting idle mode.

IDLE.RESETVARS [Variable]

The value of this variable is a list of two-element lists: \((VAR_1 EXP_1) (VAR_2 EXP_2) \ldots\). On entering idle mode, each variable \(VAR_i\) is bound to the value of the corresponding expression \(EXP_i\). When idle mode is exited, each variable \(VAR_i\) is reset to its original value.

IDLE.SUSPEND.PROCESS.NAMES [Variable]

Value is a list of names. For each name on this list, if a process by that name is found, it will be suspended upon entering idle mode and woken upon exiting idle mode.

IDLE.PROFILE [Variable]

The value of this variable determines the menu raised by selecting the Display subitem of the Idle background menu command. It should be in the format used for the ITEMS field of a menu (see Chapter 28), with the selection of an item returning the appropriate display function.

(IDCLE.BOUNCING.BOX WINDOW BOX WAIT) [Variable]

This is the default display function used for idle mode. BOX is bounded about WINDOW, with bounces taking place every WAIT milliseconds. BOX can be a string, a bitmap, a window (whose image will be bounced about), or a list containing any number of these
MEDLEY REFERENCE MANUAL

(which will be cycled through). BOX defaults to the value of the variable IDLE.BOUNCING.BOX, which is initially a bitmap of the Venue logo. WAIT defaults to 1000 (one second).

Saving Virtual Memory State

Medley storage allocation occurs within a virtual memory space that is usually much larger than the physical memory on the computer. The virtual memory is stored as a large file on the computer’s hard disk, called the virtual memory file. Medley controls the swapping of pages between this file and the real memory, swapping in virtual memory pages as they are accessed, and swapping out pages that have been modified. At any moment, the total state of the Medley virtual memory is stored partially in the virtual memory file, and partially in the real physical memory.

Medley provides facilities for saving the total state of the virtual memory, either on the virtual memory file, or in a file on an arbitrary file device. The function LOGOUT is used to write all altered (dirty) pages from the real memory to the virtual memory file and stop Medley, so that Medley can be restarted from the state of the LOGOUT. SAVEVM updates the virtual memory file without stopping Medley, which puts the virtual memory file into a consistent state (temporarily), so it could be restarted if the system crashes. SYSOUT and MAKESYS are used to save a copy of the total virtual memory state on a file, which can be loaded into another machine to restore Medley’s state. VMEM.PURE.STATE can be used to “freeze” the current state of the virtual memory, so that Medley will come up in that state if it is restarted.

(LOGOUT FAST) [Function]

Stops Medley, and returns control to the operating system. If Medley is restarted, it should come up in the same state as when the LOGOUT was called. LOGOUT will not affect the state of open files.

LOGOUT writes out all altered pages from real memory to the virtual memory file. If FAST is T, Medley is stopped without updating the virtual memory file. Note that after doing (LOGOUT T) it will not be possible to restart Medley from the point of the LOGOUT, and it may not be possible to restart it at all. Typing (LOGOUT T) is preferable to just booting the machine, because it also does other cleanup operations (closing network connections, etc.).

If FAST is the symbol ?, LOGOUT acts like FLG = T if the virtual memory file is consistent, otherwise it acts like FLG = NIL. This insures that the virtual memory image can be restarted as of some previous state, not necessarily as of the LOGOUT.

(SAVEVM –) [Function]

This function is similar to logging out and continuing, but faster. It takes about as long as a logout, which can be as brief as 10 seconds or so if you have already written out most of your dirty pages by virtue of being idle a while. After the SAVEVM, and until the pagefault handler is next forced to write out a dirty page, your virtual memory image will be continuable (as of the SAVEVM) should there be a system crash or other disaster.

If the system has been idle long enough (no keyboard or mouse activity), there are dirty pages to be written, and there are few enough dirty pages left to write that a SAVEVM would be quick, SAVEVM is automatically called. When SAVEVM is called automatically,
the cursor is changed to a special cursor: ☦, stored in the variable SAVINGCURSOR. You can control how often SAVEVM is automatically called by setting the following two global variables:

SAVEVMWAIT [Variable]
SAVEVMMAX [Variable]

The system will call SAVEVM after being idle for SAVEVMWAIT seconds (initially 300) if there are fewer than SAVEVMMAX pages dirty (initially 600). These values are fairly conservative. If you want to be extremely wary, you can set SAVEVMWAIT = 0 and SAVEVMMAX = 10000, in which case SAVEVM will be called the first chance available after the first dirty page has been written.

The function SYSOUT saves the current state of Medley’s virtual memory on a file, known as a “sysout file”, or simply a “sysout”. The file package can be used to save particular function definitions and other arbitrary objects on files, but SYSOUT saves the total state of the system. This capability can be useful in many situations: for creating customized systems for other people to use, or to save a particular system state for debugging purposes. Note that a sysout file can be very large (thousands of pages), and can take a long time to create, so it is not to be done lightly. The file produced by SYSOUT can be loaded into Medley’s virtual memory and restarted to restore the virtual memory to the exact state that it had when the sysout file was made. The exact method of loading a sysout depend on the implementation. For more information on loading sysout files, see the users guide for your computer.

(SYSOUT FILE)

Saves the current state of Medley’s virtual memory on the file FILE, in a form that can be subsequently restarted. The current state of program execution is saved in the sysout file, so (PROGN (SYSOUT ‘FOO) (PRINT ‘HELLO)) will cause HELLO to be printed after the sysout file is restarted.

SYSOUT can take a very long time (ten or fifteen minutes), particularly when storing a file on a remote file server. To display some indication that something is happening, the cursor is changed to: ☦. Also, as the sysout file is being written, the cursor is inverted line by line, to show that activity is taking place, and how much of the sysout has completed. For example, after the SYSOUT is about two-thirds done, the cursor would look like: ☦. The SYSOUT cursor is stored in the variable SYSOUTCURSOR.

If FILE is non-NIL, the variable SYSOUTFILE is set to the body of FILE. If FILE is NIL, then the value of SYSOUTFILE instead. Therefore, (SYSOUT) will save the current state on the next higher version of a file with the same name as the previous SYSOUT. Also, if the extension for FILE is not specified, the value of SYSOUT.EXT is used. SYSOUT sets SYSOUTDATE (see the System Version Information section below) to (DATE), the time and date that the SYSOUT was performed.

If SYSOUT was not able to create the sysout file, because of disk or computer error, or because there was not enough space on the directory, SYSOUT returns NIL. Otherwise it returns the full file name of FILE.
Actually, SYSOUT “returns” twice; when the sysout file is first created, and when it is subsequently restarted. In the latter case, SYSOUT returns a list whose CAR is the full file name of FILE. For example, (if (LISTP (SYSOUT 'FOO)) then (PRINT 'HELLO)) will cause HELLO to be printed when the sysout file is restarted, but not when SYSOUT is initially performed.

Note: SYSOUT does not save the state of any open files. Use WHENCLOSE (see the Closing and Reopening Files section in Chapter 24) to associate certain operations with open files so that when a SYSOUT is started up, these files will be reopened, and file pointers repositioned.

SYSOUT evaluates the expressions on BEFORESYSOUTFORMS (see also AROUNDEXITFNS) before creating the sysout file. This variable initially includes expressions to:

1. Set the variables SYSOUTDATE and SYSOUTFILE as described above
2. Default the sysout file name FILE according to the values of the variables SYSOUTFILE and SYSOUT. EXT, as described above
3. Perform any necessary operations on open files as specified by calls to WHENCLOSE.

After a sysout file is restarted (but not when it is initially created), SYSOUT evaluates the expressions on AFTERSYSOUTFORMS (see also AROUNDEXITFNS). This initially includes expressions to:

1. Perform any necessary operations on previously-opened files as specified by calls to WHENCLOSE
2. Possibly print a message, as determined by the value of SYSOUTGAG (see below)
3. Call SETINITIALS to reset the initials used for time-stamping (see the Time Stamps section of Chapter 16).

AROUNDEXITFNS

[Variable]

This variable provides a way to “advise” the system on cleanup and restoration activities to perform around LOGOUT, SYSOUT, MAKESYS and SAVEVM; It subsumes the functionality of BEFORESYSOUTFORMS, AFTERLOGOUTFORMS, etc. It’s value is a list of functions (names) to call around every “exit” of the system. Each function is called with one argument, a symbol indicating which particular event is occuring. The symbols are:

BEFORELOGOUT The system is about to perform a LOGOUT.

BEFORESYSOUT
BEFOREMAKESYS
BEFORESAVEVM The system is about to perform a SYSOUT, MAKESYS or a SAVEVM.

AFTERLOGOUT
AFTERSYSOUT
AFTERMAKESYS
AFTERSAVEVM The system is starting up an image that was saved by performing a LOGOUT, SYSOUT, etc.

AFTERDOSYSOUT
The system just made a copy of the virtual memory and saved it to disk. The image continues to run. These events only exist to allow you to negate the effects of saving a copy of the virtual memory.

The value of SYSOUTGAG determines what is printed when a sysout file is restarted. If the value of SYSOUTGAG is a list, the list is evaluated, and no additional message is printed. This allows you to print a message. If SYSOUTGAG is non-NIL and not a list, no message is printed. Finally, if SYSOUTGAG is NIL (its initial value), and the sysout file is being restarted by the same user that made the sysout originally, you are greeted by printing the value of HERALDSTRING (see below) followed by a greeting message. If the sysout file was made by a different user, a message is printed, warning that the currently-loaded user init file may be incorrect for the current user (see the Greeting and Initialization Files section above).

(MAKESYS FILE NAME)

Used to store a new Medley system on the “makesys file” FILE. Like SYSOUT, but before the file is made, the system is “initialized” by undoing the greet history, and clearing the display.

When the system is first started up, a “herald” is printed identifying the system, typically “Medley-XX DATE ...”. If NAME is non-NIL, MAKESYS will use it instead of Medley-XX in the herald. MAKESYS sets HERALDSTRING to the herald string printed out.

MAKESYS also sets the variable MAKESYSDATE (see the next section below) to (DATE), i.e. the time and date the system was made.

Medley contains a routine that writes out dirty pages of the virtual memory during I/O wait, assuming that swapping has caused at least one dirty page to be written back into the virtual memory file (making it non-continuable). The frequency with which this routine runs is determined by:

This variable determines how often the routine that writes out dirty pages is run. The higher BACKGROUNDPAGEFREQ is set, the greater the time between running the dirty page writing routine. Initially it is set to 4. The lower BACKGROUNDPAGEFREQ is set, the less responsiveness you get at typein, so it may not be desirable to set it all the way down to 1.

(VMEM.PURE.STATE X)

VMEM.PURE.STATE modifies the swapper’s page replacement algorithm so that dirty pages are only written at the end of the virtual memory backing file. This “freezes” a given virtual memory state, so that Medley will come up in that state whenever it is restarted. This can be used to set up a “clean” environment on a pool machine, allowing each user to initialize the system simply by rebooting the computer.

The way to use VMEM.PURE.STATE is to set up the environment as you wish it to be “frozen,” evaluate (VMEM.PURE.STATE T), and then call any function that saves the virtual memory state (LOGOUT, SAVEVM, SYSOUT, or MAKESYS). From that point on,
whenever the system is restarted, it will return to the state as of the saving operation. Future LOGOUT, SAVEVM, etc. operations will not reset this state.

Note: When the system is running in “pure state” mode, it uses a significant amount of the virtual memory backing file to save the “frozen” memory image, so this will reduce the amount of virtual memory space available for use.

(VMEM.PURE.STATE) returns T if the system is running in “pure state” mode, NIL otherwise.

(REALMEMORYSIZE) [Function]
Returns the number of real memory pages in the computer.

(VMEMSIZE) [Function]
Returns the number of pages in use in the virtual memory. This is the roughly the same as the number of pages required to make a sysout file on the local disk (see SYSOUT, above).

\LASTVMEMFILEPAGE [Variable]
Value is the total size of the virtual memory backing file. This variable is set when the system is started. You should not set it.

Note: When the virtual memory expands to the point where the virtual memory backing file is almost full, a break will occur with the warning message “Your virtual memory backing file is almost full. Save your work & reload asap.” When this happens, it is strongly suggested that you save any important work and reload the system. If you continue working past this point, the system will start slowing down considerably, and it will eventually stop working.

System Version Information
Medley runs on a number of different machines, with many possible hardware configurations. There have been a number of different releases of the Medley software. These facts make it difficult to answer the important question “what software/hardware environment are you running?” when reporting bugs. The following functions allow the novice to collect this information.

(PRINT-LISP-INFORMATION STREAM FILESTRING) [NoSpread Function]
Prints out a summary of the software and hardware environment that Medley is running in, and a list of all loaded patch files:

Venue Medley version
Medley 2.0 sysout of 7-Oct-92 15:18:52 on mips,
Emulator created: 20-Nov-92, memory size: 0,
machine d022899 mo
based on Envos Medley version Medley 2.0 sysout of 7-Oct-92 15:18:52,
Patch files: NIL

STREAM is the stream used to print the summary. If not given, it defaults to T.
FILESTRING is a string used to determine what loaded files should be listed as “patch files.” All file names on LOADEDFILELIST (see the Noticing Files section of Chapter 17) that have FILESTRING as a substring as listed. If FILESTRING is not given, it defaults to the string “PATCH”.

(\texttt{CL:LISP-IMPLEMENTATION-TYPE}) [Function]

Returns a string identifying the type of implementation that is running, e.g., “Medley”.

(\texttt{CL:LISP-IMPLEMENTATION-VERSION}) [Function]

Returns a string identifying the version that is running. Currently gives the system name and date, e.g., “KOTO of 10-Sep-85 08:25:46”.

This uses the variables \texttt{MAKESYSNAME} and \texttt{MAKESYSDATE} (below), so it will change if you use \texttt{MAKESYS} (see the Saving Virtual Memory State section above) to create a custom sysout file, or explicitly changes these variables.

(\texttt{CL:SOFTWARE-TYPE}) [Function]

Returns a string identifying the operating system that Interlisp is running under. Currently returns the string “Envos Medley”.

(\texttt{CL:SOFTWARE-VERSION}) [Function]

Returns a string identifying the version of the operating system that Interlisp is running under. Currently, this returns the date that the Medley release was originally created, so it doesn’t change over \texttt{MAKESYS} or \texttt{SYSOUT}.

(\texttt{CL:MACHINE-TYPE}) [Function]

Returns a string identifying the type of computer hardware that Medley is running on, i.e., “1108”, “1132”, “1186”, “mips”, etc.

(\texttt{CL:MACHINE-VERSION}) [Function]

Returns a string identifying the version of the computer hardware that Medley is running on. Currently returns the microcode version and real memory size.

(\texttt{CL:MACHINE-INSTANCE}) [Function]

Returns a string identifying the particular machine that Medley is running on. Currently returns the machine’s NS address.

(\texttt{CL:SHORT-SITE-NAME}) [Function]

Returns a short string identifying the site where the machine is located. Currently returns (\texttt{ETHERHOSTNAME}) (if non-\texttt{NIL}) or the string “\texttt{unknown}”.

(\texttt{CL:LONG-SITE-NAME}) [Function]

Returns a long string identifying the site where the machine is located. Currently returns the same as \texttt{SHORT-SITE-NAME}.
SYSOUTDATE [Variable]

Value is set by SYSOUT (see the Saving Virtual Memory State section above) to the date before generating a virtual memory image file.

MAKESYSDATE [Variable]

Value is set by MAKESYS (see the Saving Virtual Memory State section above) to the date before generating a virtual memory image file.

MAKESYSNAME [Variable]

Value is a symbol identifying the release name of the current Medley system, e.g., :MEDLEY.

(SYSTEMTYPE) [Function]

Allows programmers to write system-dependent code. SYSTEMTYPE returns a symbol corresponding to the implementation of Interlisp: D (for Medley), TOPS-20, TENEX, JERIC0, or VAX.

In Medley, (SELECTQ (SYSTEMTYPE) ...) expressions are expanded at compile time so that this is an effective way to perform conditional compilation.

(MACHINETYPE) [Function]

Returns the type of machine that Medley is running on: either DORADO (for the Xerox 1132), DOLPHIN (for the Xerox 1100), DANDELION (for the Xerox 1108), DOVE (for the Xerox 1186), or MAIKO (for Unix, DOS, etc).

Date And Time Functions

(DATE FORMAT) [Function]

Returns the current date and time as a string with format "DD-MM-YY HH:MMM:SS", where DD is day, MM is month, YY year, HH hours, MMM minutes, SS seconds, e.g., "7-Jun-85 15:49:34".

If FORMAT is a date format as returned by DATEFORMAT (below), it is used to modify the format of the date string returned by DATE.

(IDATE STR) [Function]

STR is a date and time string. IDATE returns STR converted to a number such that if DATE1 is before (earlier than) DATE2, then (IDATE DATE1) < (IDATE DATE2). If STR is NIL, the current date and time is used.

Different Interlisp implementations can have different internal date formats. However, IDATE always has the essential property that (IDATE X) is less than (IDATE Y) if X is before Y, and (IDATE (GDATE N)) equals N. Programs which do arithmetic other than numerical comparisons between IDATE numbers may not work when moved from one implementation to another.
Generally, it is possible to increment an \texttt{IDATE} number by an integral number of days by computing a "1 day" constant, the difference between two convenient \texttt{IDATES}, e.g. 
\texttt{(IDIFFERENCE (IDATE "2-JAN-80 12:00") (IDATE "1-JAN-80 12:00"))}. This "1 day" constant can be evaluated at compile time.

\texttt{IDATE} is guaranteed to accept as input the dates that \texttt{DATE} will output. It will ignore the parenthesized day of the week (if any). \texttt{IDATE} also correctly handles time zone specifications for those time zones registered in the list \texttt{TIME.ZONES} (below).

\textbf{(GDATE DATE FORMAT –)} \hspace{1cm} \textbf{[Function]}

Like \texttt{DATE}, except that \texttt{DATE} can be a number in internal date and time format as returned by \texttt{IDATE}. If \texttt{DATE} is \texttt{NIL}, the current time and date is used.

\textbf{(DATEFORMAT KEY\textsubscript{1} \ldots KEY\textsubscript{n})} \hspace{1cm} \textbf{[NLambda NoSpread Function]}

\texttt{DATEFORMAT} returns a date format suitable as a parameter to \texttt{DATE} and \texttt{GDATE}. \texttt{KEY\textsubscript{1} \ldots KEY\textsubscript{n}} are a set of keywords (unevaluated). Each keyword affects the format of the date independently (except for \texttt{SLASHES} and \texttt{SPACES}). If the date returned by \texttt{(DATE)} with the default formatting was 7-Jun-85 15:49:34, the keywords would affect the formatting as follows:

- \texttt{NO.DATE} Doesn’t include the date information, e.g. "15:49:34".
- \texttt{NUMBER.OF.MONTH} Shows the month as a number instead of a name, e.g. "7-06-85 15:49:34".
- \texttt{YEAR.LONG} Prints the year using four digits, e.g. "7-Jun-1985 15:49:34".
- \texttt{SLASHES} Separates the day, month, and year fields with slashes, e.g. "7/6/85 15:49:34".
- \texttt{SPACES} Separates the day, month, and year fields with spaces, e.g. "7 Jun 85 15:49:34".
- \texttt{NO.LEADING.SPACES} By default, the day field will always be two characters long. If \texttt{NO.LEADING.SPACES} is specified, the day field will be one character for dates earlier than the 10th, e.g. "7-Jun-85 15:49:34" instead of "7-Jun-85 15:49:34".
- \texttt{NO.TIME} Doesn’t include the time information, e.g. "7-Jun-85".
- \texttt{TIME.ZONE} Includes the time zone in the time specification, e.g. "7-Jun-85 PST".
- \texttt{NO.SECONDS} Doesn’t include the seconds, e.g. "7-Jun-85 15:49".
- \texttt{DAY.OF.WEEK} Includes the day of the week in the time specification, e.g. "7-Jun-85 15:49:34 PDT (Friday)".
DAY.SHORT If DAY.OF.WEEK is specified to include the day of the week, the week day is shortened to the first three letters, e.g. "7-Jun-85 15:49:34 PDT (Fri)". Note that DAY.SHORT has no effect unless DAY.OF.WEEK is also specified.

(CLOCK N—) [Function]
If N = 0, CLOCK returns the current value of the time of day clock i.e., the number of milliseconds since last system start up.

If N = 1, returns the value of the time of day clock when you started up this Interlisp, i.e., difference between (CLOCK 0) and (CLOCK 1) is number of milliseconds (real time) since this Interlisp system was started.

If N = 2, returns the number of milliseconds of compute time since user started up this Interlisp (garbage collection time is subtracted off).

If N = 3, returns the number of milliseconds of compute time spent in garbage collections (all types).

(SETTIME DT) [Function]
Sets the internal time-of-day clock. If DT = NIL, SETTIME attempts to get the time from the communications net; if it fails, you are prompted for the time. If DT is a string in a form that IDATE recognizes, it is used to set the time.

The following variables are used to interpret times in different time zones. TimeZoneComp, BeginDST, and EndDST are normally set automatically if your machine is connected to a network with a time server. For standalone machines, it may be necessary to set them by hand (or in your init file, see the first section of this chapter) if you are not in the Pacific time zone.

TIME.ZONES [Variable]
Value is an association list that associates time zone specifications (PDT, EST, GMT, etc.) with the number of hours west of Greenwich (negative if east). If the time zone specification is a single letter, it is appended to "DT" or "ST" depending on whether daylight saving time is in effect. Initially set to:

\((8 . P) (7 . M) (6 . C) (5 . E) (0 . GMT))\)

This list is used by DATE and GDATE when generating a date with the TIME.ZONE format is specified, and by IDATE when parsing dates.

TimeZoneComp [Variable]
This variable should be initialized to the number of hours west of Greenwich (negative if east). For the U.S. west coast it is 8. For the east coast it is 5.

BeginDST [Variable]
EndDST [Variable]

\BeginDST is the day of the year on or before which Daylight Savings Time takes effect (i.e., the Sunday on or immediately preceding this day); \EndDST is the day on or before which Daylight Savings Time ends. Days are numbered with 1 being January 1, and
counting the days as for a leap year. In the USA where Daylight Savings Time is observed, \begin{DST} = 121 and \end{DST} = 305. In a region where Daylight Savings Time is not observed at all, set \begin{DST} to 367.

**Timers and Duration Functions**

Often one needs to loop over some code, stopping when a certain interval of time has passed. Some systems provide an “alarm clock” facility, which provides an asynchronous interrupt when a time interval runs out. This is not particularly feasible in the current Medley environment, so the following facilities are supplied for efficiently testing for the expiration of a time interval in a loop context.

Three functions are provided: \texttt{SETUPTIMER}, \texttt{SETUPTIMER.DATE}, and \texttt{TIMEREXPIRED?}. There are also several new i.s.o.prs: \texttt{forDuration}, \texttt{during}, \texttt{untilDate}, \texttt{timerUnits}, \texttt{usingTimer}, and \texttt{resourceName} (reasonable variations on upper/lower case are permissible).

These functions use an object called a timer, which encodes a future clock time at which a signal is desired. A timer is constructed by the functions \texttt{SETUPTIMER} and \texttt{SETUPTIMER.DATE}, and is created with a basic clock “unit” selected from among \texttt{SECONDS}, \texttt{MILLISECONDS}, or \texttt{TICKS}. The first two timer units provide a machine/system independent interface, and the latter provides access to the “real”, basic strobe unit of the machine’s clock on which the program is running. The default unit is \texttt{MILLISECONDS}.

Currently, the \texttt{TICKS} unit depends on what machine Medley is running on. The Xerox 1132 has about 1680 ticks per millisecond; the Xerox 1108 has about 34.746 ticks per millisecond; the Xerox 1185 and 1186 have about 62.5 ticks per millisecond. The advantage of using \texttt{TICKS} rather than one of the uniform interfaces is primarily speed; e.g., it may take over 400 microseconds to read the milliseconds clock (a software facility that uses the real clock), whereas reading the real clock itself may take less than ten microseconds. The disadvantage of the \texttt{TICKS} unit is its short roll-over interval (about 20 minutes) compared to the \texttt{MILLISECONDS} roll-over interval (about two weeks), and also the dependency on particular machine parameters.

\begin{verbatim}
(SETUPTIMER INTERVAL OldTimer? timerUnits intervalUnits)  [Function]

SETUPTIMER returns a timer that will “go off” (as tested by TIMEREXPIRED?) after a specified time-interval measured from the current clock time. SETUPTIMER has one required and three optional arguments:

INTERVAL must be a integer specifying how long an interval is desired. timerUnits specifies the units of measure for the interval (defaults to MILLISECONDS).

If OldTimer? is a timer, it will be reused and returned, rather than allocating a new timer. intervalUnits specifies the units in which the OldTimer? is expressed (defaults to the value of timerUnits).

(SETUPTIMER.DATE DTS OldTimer?)  [Function]

SETUPTIMER.DATE returns a timer (using the SECONDS time unit) that will “go off” at a specified date and time. DTS is a Date/Time string such as IDATE accepts (see the above section). If OldTimer? is a timer, it will be reused and returned, rather than allocating a new timer.
\end{verbatim}
SETUPTIMER.DATE operates by first subtracting (IDATE) from (IDATE DTS), so there may be some large integer creation involved, even if OLDTIMER? is given.

(TIMEREPLIED? TIMER ClockValue.or.timerUnits) [Function]

If TIMER is a timer, and ClockValue.or.timerUnits is the time-unit of TIMER, TIMEREPLIED? returns true if TIMER has “gone off”.

ClockValue.or.timerUnits can also be a timer, in which case TIMEREPLIED? compares the two timers (which must be in the same timer units). If X and Y are timers, then (TIMEREPLIED? X Y) is true if X is set for an earlier time than Y.

There are a number of i.s.oprs that make it easier to use timers in iterative statements (see the Interative Statement section of Chapter 9). These i.s.oprs are given below in the “canonical” form, with the second “word” capitalized, but the all-caps and all-lower-case versions are also acceptable.

forDuration INTERVAL [I.S. Operator]

during INTERVAL [I.S. Operator]

INTERVAL is an integer specifying an interval of time during which the iterative statement will loop.

timerUnits UNITS [I.S. Operator]

UNITS specifies the time units of the INTERVAL specified in forDuration.

untilDate DTS [I.S. Operator]

DTS is a Date/Time string (such as IDATE accepts) specifying when the iterative statement should stop looping.

usingTimer TIMER [I.S. Operator]

If usingTimer is given, TIMER is reused as the timer for forDuration or untilDate, rather than creating a new timer. This can reduce allocation if one of these i.s.oprs is used within another loop.

resourceName RESOURCE [I.S. Operator]

RESOURCE specifies a resource name to be used as the timer storage (see the File Package Types section of Chapter 17). If RESOURCE = T, it will be converted to an internal name.

Some examples:

(during 6MONTHS timerUnits 'SECONDS
until (TENANT-VACATED? HouseHolder)
do (DISMISS <for-about-a-day>)
(HARRASS HouseHolder)
finally (if (NOT (TENANT-VACATED? HouseHolder))
then (EVICT-TENANT HouseHolder)))

This example shows that how is is possible to have two termination condition: when the time interval of 6MONTHS has elapsed, or when the predicate (TENANT-VACATED? HouseHolder) becomes true. Note that the “finally” clause is executed regardless of which termination condition caused it.
Also note that since the millisecond clock will “roll over” about every two weeks, “6MONTHS”
wouldn’t be an appropriate interval if the timer units were the default case, namely MILLISECONDS.

(do (forDuration (CONSTANT (ITIMES 10 24 60 60 1000)))
  do (CARRY.ON.AS.USUAL)
  finally (PROMPTPRINT "Have you had your 10-day check-up?")
)

This infinite loop breaks out with a warning message every 10 days. One could question whether the
millisecond clock, which is used by default, is appropriate for this loop, since it rolls-over about every
two weeks.

(SBTQ \RandomTimer (SETUPTIMER 0))
(untilDate "31-DEC-83 23:59:59" usingTimer \RandomTimer
  when (WINNING?) do (RETURN)
  finally (ERROR "You’ve been losing this whole year!")
)

Here is a usage of an explicit date for the time interval; also, some storage has been squirreled away
(as the value of \RandomTimer) for use by the call to SETUPTIMER in this loop.

(forDuration SOMEINTERVAL
  resourceName \INNERLOOPBOX
  timerunits 'TICKS
  do (CRITICAL.INNER.LOOP))

For this loop, you don’t want any CONSing to take place, so \INNERLOOPBOX is defined as a resource
which “caches” a timer cell (if it isn’t already so defined), and wraps the entire statement in a WITH-
RESOURCES call. Furthermore, a time unit of TICKS is specified, for lower overhead in this critical
inner loop. In fact specifying a resourceName of T is the same as specifying it to be \ForDurationOfBox; this is just a simpler way to specify that a resource is wanted, without having
to think up a name.

Resources

Medley is based on the use of a storage-management system which allocates memory space for new
data objects, and automatically reclaim the space when no longer in use. More generally, Medley
manages shared “resources”, such as files, semaphors for processes, etc. The protocols for allocating
and freeing such resources resemble those of ordinary storage management.

Sometimes you need to explicitly manage the allocation of resources. You may want the efficiency of
explicit reclamation of certain temporary data; or it may be expensive to initialize a complex data
object; or there may be an application that must not allocate new cells during some critical section of
code.

The file manager type RESOURCES is available to help with the definition and usage of such classes of
data; the definition of a RESOURCE specifies prototype code to do the basic management operations.
The file manager command RESOURCES is used to save such definitions on files, and
INITRESOURCES (see the Miscellaneous File Manager Commands section of Chapter 17) causes the
initialization code to be output.

The basic needs of resource management are:
1. Obtaining a data item from the Lisp memory management system and configuring it to be a totally
   new instance of the resource in question
2. Freeing up an instance which is no longer needed
3. Getting an instance of the resource for temporary usage (whether “fresh” or a formerly freed-up instance)

4. Setting up any prerequisite global data structures and variables

A resources definition consists of four “methods”: INIT, NEW, GET, and FREE; each “method” is a form that will specialize the definition for four corresponding user-level macros INITRESOURCE, NEWRESOURCE, GETRESOURCE, and FREERESOURCE. PUTDEF is used to make a resources definition, and the four components are specified in a proplist:

```lisp
(PUTDEF 'RESOURCENAME 'RESOURCES
  '(NEW NEW-INSTANCE-GENERATION-CODE
  FREE FREEING-UP-CODE
  GET GET-INSTANCE-CODE
  INIT INITIALIZATION-CODE))
```

Each of the `xxx-CODE` forms is a form that will appear as if it were the body of a substitution macro definition for the corresponding macro (see the discussion on the macros below).

**A Simple Example**

Suppose one has several pieces of code which use a 256-character string as a scratch string. One could simply generate a new string each time, but that would be inefficient if done repeatedly. If you can guarantee that there are no re-entrant uses of the scratch string, then it could simply be stored in a global variable. However, if the code might be re-entrant on occasion, the program has to take precautions that two programs do not use the same scratch string at the same time. (This consideration becomes very important in a multi-process environment. It is hard to guarantee that two processes won’t be running the same code at the same time, without using elaborate locks.) A typical tactic would be to store the scratch string in a global variable, and set the variable to NIL whenever the string is in use (so that re-entrant usages would know to get a “new” instance). For example, assuming the global variable TEMPSTRINGBUFFER is initialized to NIL:

```lisp
[DEFINEQ (WITHSTRING NIL
  (PROG ((BUF (OR (PROG1 TEMPSTRINGBUFFER
       (SETQ TEMPSTRINGBUFFER NIL))
     (ALLOCSTRING 256)))
    ... use the scratch string in the variable BUF ...
    (SETQ TEMPSTRINGBUFFER BUF)
    (RETURN)]
```

Here, the basic elements of a “resource” usage may be seen:

1. A call `(ALLOCSTRING 256)` allocates fresh instances of “buffer”

2. After usage is completed the instance is returned to the “free” state, by putting it back in the global variable TEMPSTRINGBUFFER where a subsequent call will find it

3. The prog-binding of `BUF` will get an existing instance of a string buffer if there is one -- otherwise it will get a new instance which will later be available for reuse

4. Some initialization is performed before usage of the resource (in this case, it is the setting of the global variable TEMPSTRINGBUFFER).
Given the following resources definition:

```
(PUTDEF
 'STRINGBUFFER
 'RESOURCES
 ' (NEW (ALLOCSTRING 256)
   FREE (SETQ TEMPPSTRINGBUFFER (PROG1 . ARGS))
   GET (OR (PROG1 TEMPPSTRINGBUFFER
               (SETQ TEMPPSTRINGBUFFER NIL))
           (NEWRESOURCE TEMPPSTRINGBUFFER NIL))
   INIT (SETQ TEMPPSTRINGBUFFER NIL)))
```

we could then redo the example above as

```
(DEFINEQ (WITHSTRING NIL
  (PROG ((BUF (GETRESOURCE STRINGBUFFER)))
    ... use the string in the variable BUF ...
    (FREERESOURCE STRINGBUFFER BUF)
    (RETURN])
```

The advantage of doing the coding this way is that the resource management part of WITHSTRING is fully contained in the expansions of GETRESOURCE and FREERESOURCE, and thus there is no confusion between what is WITHSTRING code and what is resource management code. This particular advantage will be multiplied if there are other functions which need a “temporary” string buffer; and of course, the resultant modularity makes it much easier to contemplate minor variations on, as well as multiple clients of, the STRINGBUFFER resource.

In fact, the scenario just shown above in the WITHSTRING example is so commonly useful that an abbreviation has been added; if a resources definition is made with *only* a NEW method, then appropriate FREE, GET, and INIT methods will be inferred, along with a coordinated globalvar, to be parallel to the above definition. So the above definition could be more simply written

```
(DEFINEQ (WITHSTRING NIL
  (PROG ((BUF (GETRESOURCE STRINGBUFFER)))
    ... use the string in the variable STRINGBUFFER ...
    (FREERESOURCE STRINGBUFFER BUF)
    (RETURN])
```

and everything would work the same.

The macro WITH-RESOURCES simplifies the common scoping case, where at the beginning of some piece of code, there are one or more GETRESOURCE calls the results of which are each bound to a lambda variable; and at the ending of that code a FREERESOURCE call is done on each instance. Since the resources are locally bound to variables with the same name as the resource itself, the definition for WITHSTRING then simplifies to

```
(DEFINEQ (WITHSTRING NIL
  (WITH-RESOURCES (STRINGBUFFER))
    ... use the string in the variable STRINGBUFFER ...]
```

**Trade-offs in More Complicated Cases**

This simple example presumes that the various functions which use the resource are generally not re-entrant. While an occasional re-entrant use will be handled correctly (another example of the resource will simply be created), if this were to happen too often, then many of the resource requests will create and throw away new objects, which defeats one of the major purposes of using resources. A slightly more complex GET and FREE method can be of much benefit in maintaining a pool of available
resources; if the resource were defined to maintain a list of “free” instances, then the GET method could simply take one off the list and the FREE method could just push it back onto the list. In this simple example, the SETQ in the FREE method defined above would just become a “push”, and the first clause of the GET method would just be (pop TEMPSTRINGBUFFER)

A word of caution: if the datatype of the resource is something very small that Medley is “good” at allocating and reclaiming, then explicit user storage management will probably not do much better than the combination of cons/createcell and the garbage collector. This would especially be so if more complicated GET and FREE methods were to be used, since their overhead would be closer to that of the built-in system facilities. Finally, it must be considered whether retaining multiple instances of the resource is a net gain; if the re-entrant case is truly rare, it may be more worthwhile to retain at most one instance, and simply let the instances created by the rarely-used case be reclaimed in the normal course of garbage collection.

Macros for Accessing Resources

Four user-level macros are defined for accessing resources:

```
(NEWRESOURCE RESOURCENAME . ARGS)  [Macro]
(FREERESOURCE RESOURCENAME . ARGS)  [Macro]
(GETRESOURCE RESOURCENAME . ARGS)   [Macro]
(INITRESOURCE RESOURCENAME . ARGS)   [Macro]
```

Each of these macros behave as if they were defined as a substitution macro of the form

```
((RESOURCENAME . ARGS) MACROBODY)
```

where the expression MACROBODY is selected by using the “code” supplied by the corresponding method from the RESOURCENAME definition.

Note that it is possible to pass “arguments” to your resource allocation macros. For example, if the GET method for the resource FOO is (GETFOO . ARGS), then (GETRESOURCE FOO X Y) is transformed into (GETFOO X Y). This form was used in the FREE method of the STRINGBUFFER resource described above, to pass the old STRINGBUFFER object to be freed.

```
(WITH-RESOURCES (RESOURCE1 RESOURCE2 ...) FORM1 FORM2 ...)  [Macro]
```

The WITH-RESOURCES macro binds lambda variables of the same name as the resources (for each of the resources RESOURCE1, RESOURCE2, etc.) to the result of the GETRESOURCE macro; then executes the forms FORM1, FORM2, etc., does a FREERESOURCE on each instance, and returns the value of the last form (evaluated and saved before the FREERESOURCES).

**Note:** (WITH-RESOURCES RESOURCE ...) is interpreted the same as (WITH-RESOURCES (RESOURCE) ...). Also, the singular name WITH-RESOURCE is accepted as a synonym for WITH-RESOURCES.

### Saving Resources in a File

Resources definitions may be saved on files using the RESOURCES file package command (see the Miscellaneous File Package Commands section of Chapter 17). Typically, one only needs the full definition available when compiling or interpreting the code, so it is appropriate to put the file package command in a (DECLARE: EVAL@COMPILE DONTCOPY ...) declaration, just as one might
do for a RECORDS declaration. But just as certain record declarations need *some* initialization in the run-time environment, so do most resources. This initialization is specified by the resource’s INIT method, which is executed automatically when the resource is defined by the PUTDEF output by the RESOURCES command. However, if the RESOURCES command is in a DONTCOPY expression and thus is not included in the compiled file, then it is necessary to include a separate INITRESOURCES command (see the Miscellaneous File Manager Commands section of Chapter 17) in the filecoms to insure that the resource is properly initialized.
In most Common Lisp implementations, there is a “top-level read-eval-print loop,” which reads an expression, evaluates it, and prints the results. In Medley, the Exec acts as the top-level loop, but does much more.

The Exec traps all THROWS, and recovers gracefully. It prints all values resulting from evaluation, on separate lines. (When zero values are returned, nothing is printed).

The Exec keeps track of your previous inputs, in the history list. Each entry you type creates a history event, which stores the input and its values.

It’s easy to use the results of earlier events, redo and event, or recall an earlier input, edit it, and run it. This makes it much easier to get your work done.

**Multiple Execs and the Exec’s Type**

Sometimes you need more than one Exec open at a time. It’s easy to open as many as you need by using the right button background menu and selecting the kind of Exec you need. The Execs are differentiated from one another by their “names” in their title bars and by their prompts. For example, the second Exec you open may have a prompt like 2/50 > if it’s the second Common Lisp Exec you’ve opened. Events in each Exec are placed on the global history list with their Exec number so the system can tell them apart.

Several variables are very important to an Exec since they control the format of reading and printing. Together these variables describe a type of exec, or its mode. Some standard bindings for the variables have been named to make mode setting easy. The names provide you with an Exec of the Common Lisp (LISP), Interlisp or Old Interlisp (IL), or Medley (XCL) type. An Exec’s type is displayed in the title bar of its window:

```
Exec 2 (XCL)
```

A Brief Example of Exec Interactions

The following dialogue contains examples and gives the flavor of the use of an Exec. The commands are described in greater detail in the following sections. For now, be sure to type these examples to an Exec whose *PACKAGE* is set to the XCL-USER package. The Exec that Medley starts up with is set to the XCL-USER package. Each prompt consists of an Exec number, an event number and a prompt character (”>“ for Common Lisp and “←” for Interlisp).
You have instructed the Exec to UNDO the previous event.

The Exec accepts input both in APPLY format (the SET) and EVAL format (the SETQ). In event 1196, you added a property MYPROP to the symbols A, B, and C.

You told the Exec to go back to event 1196, substitute LST2 for LST1, and then re-execute the expression.

If STRING were computationally expensive (it isn’t), you might be caching its value for later use.

You now decide you would like to redo the SETF with a different value. You can specify the event using any symbol in the expression.
Here you ask the Exec (using the ?? command) what it has on its history list for the last input. Since the event corresponds to a command, the Exec displays both the original command and the generated input.

You’ll usually deal with the Exec at top level or in the debugger, where you type in expressions for evaluation, and see the values printed out. An Exec acts much like a standard Lisp top-level loop, but before it evaluates an input, it first adds it to the history list. If the operation is aborted or causes an error, the input is still available for you to modify or re-execute.

After updating the history list, the Exec executes the computation (i.e., evaluates the form or applies the function to its arguments), saves the value in the history-list entry for that input, and prints the result. Finally the Exec displays a prompt to show it’s again ready for input.

**Input Formats**

The Exec accepts three forms of input: an expression to be evaluated (EVAL-format), a function-name and arguments to apply it to (APPLY-format), and Exec commands, as follows:

- **EVAL-format input** If you type a single expression, either followed by a carriage-return, or, in the case of a list, terminated with balanced parenthesis, the expression is evaluated and the value is returned. For example, if the value of FOO is the list (A B C):

```
> (FOO)
(A B C)
```

Similarly, if you type a Lisp expression, beginning with a left parenthesis and terminated by a matching right parenthesis, the form is simply passed to EVAL for evaluation. Notice that it is not necessary to type a carriage return at the end of such a form; the reader will supply one automatically. If a carriage-return is typed before the final matching right parenthesis or bracket, it is treated the same as a space, and input continues. The following examples are interpreted identically:

```
> (1 (+ 2 3))
3
```

- **APPLY-format input** Often, you call functions with constant argument values, which would have to be quoted if you typed them in EVAL-format. For convenience, if you type a symbol immediately followed by a list, the symbol is APPLYed to the elements within the list, unevaluated. The input is terminated by the matching right parenthesis. For example, typing LOAD(FOO) is equivalent to typing (LOAD ’FOO), and GET(X

```
> (LOAD FOO)
(A B C)
```

---

13-3
COLOR) is equivalent to (GET 'X 'COLOR). As a simple special case, a single
right parenthesis is treated as a balanced set of parentheses, e.g. UNBREAK) is
equivalent to UNBREAK()

The reader will only supply the “carriage return” automatically if no space
appears between the initial symbol and the list that follows; if there is a space after
the initial symbol on the line and the list that follows, the input is not terminated
until you type a carriage return.

The Exec will not consider unparenthesized input with more than one argument to
be in apply format, e.g.:
LIST (1) is apply format (executes after closing parenthesis is typed)
LIST (1) is apply format (second argument is a list, no trailing arguments
given)
LIST '(1) 2 3 is NOT apply format, arguments are evaluated
LIST 1 2 3 is NOT apply format, arguments are evaluated
LIST 1 not legal input: second argument is not a list

Note that APPLY-format input cannot be used for macros or special forms.

Exec commands
The Exec recognizes a number of commands, which usually refer to past events on
the history list. These commands are treated specially; for example, they may not
be put on the history list. The format of a command is always a line beginning
with the command name. (The Exec looks up the command name independent of
package.) The remainder of the line, if any, is treated as “arguments” to the
command. For example,
128> UNDO
mapc undone
129> UNDO (FOO --)
foo undone

are both valid command inputs.

Event Specification
Exec commands, like UNDO, frequently refer to previous events in the session’s history. All Exec
commands use the same conventions and syntax for indicating which event(s) the command refers to.
This section shows you the syntax used to specify previous events.

An event address identifies one event on the history list. For example, the event address 42 refers to
the event with event number 42, and -2 refers to two events back in the current Exec. Usually, an
event address will contain only one or two commands.

Event addresses can be concatenated. For example, if FOO refers to event N, FOO FIE will refer to the
first event before event N which contains FIE.

The symbols used in event addresses (such as AND, F, etc.) are compared with STRING-EQUAL, so
that it does not matter what the current package is when you type an event address address symbol to an
Exec.
Specifications used below of the form EventAddress refer to event addresses, as described above. Since an event address may contain multiple words, the event address is parsed by searching for the words which delimit it. For example, in EventAddress$_1$ AND EventAddress$_2$, the notation EventAddress$_1$ corresponds to all words up to the AND in the event specification, and EventAddress$_2$ to all words after the AND in the event specification.

Event addresses are interpreted as follows:

- **N** (an integer) If N is positive, it refers to the event with event number N (no matter which Exec the event occurred in.) If N is negative, it always refers to the event -N events backwards, counting only events belonging to the current Exec.
- **F** Specifies that the next object in the event address is to be searched for, regardless of what it is. For example, $F -2$ looks for an event containing 2.
- **FROM** EventAddress All events since EventAddress, inclusive. For example, if there is a single Exec and the current event is number 53, then FROM 49 specifies events 49, 50, 51, and 52. FROM includes events from all Execs.
- **ALL** EventAddress Specifies all events satisfying EventAddress. For example, ALL LOAD, ALL SUCHTHAT FOO-P.
- **empty** If nothing is specified, it is the same as specifying -1, i.e., the last event in the current Exec.

EventSpec$_1$ AND EventSpec$_2$ AND \ldots AND EventSpec$_N$

Each of the is an event specification. The lists of events are concatenated. For example, REDO ALL MAPC AND ALL STRING AND 32 redoes all events containing MAPC, all containing STRING, and also event 32. Duplicate events are removed.

**Exec Commands**

You enter an Exec commands by typing the name of the command at the prompt. The name of an Exec command is not a symbol and therefore is not sensitive to the setting of the current package (the value of *PACKAGE*).

EventSpec is used to denote an event specification which in most cases will be either a specific event address (e.g., 42) or a relative one (e.g., -3). Unless specified otherwise, omitting EventSpec is the same as specifying EventSpec = -1. For example, REDO and REDO -1 are the same.

**REDO** EventSpec

Redoes the event or events specified by EventSpec. For example, REDO 123 redoes the event numbered 123.
MEDLEY REFERENCE MANUAL

RETRY EventSpec

Like REDO but sets the debugger parameters so that any errors that occur while executing EventSpec will cause breaks.

USE NEW [FOR OLD ] [IN EventSpec ]

Substitutes NEW for OLD in the events specified by EventSpec, and redoes the result. NEW and OLD can include lists or symbols, etc.

For example, USE SIN (- X) FOR COS X IN -2 AND -1 will substitute SIN for every occurrence of COS in the previous two events, and substitute (- X) for every occurrence of X, and reexecute them. (The substitutions do not change the previous information saved about these events on the history list.)

If IN EventSpec is omitted, the first member of OLD is used to search for the appropriate event. For example, USE DEFAULTFONT FOR DEFLATFONT is equivalent to USE DEFAULTFONT FOR DEFLATFONT IN F DEFLATFONT. The F is inserted to handle the case where the first member of OLD could be interpreted as an event address command.

If OLD is omitted, substitution is for the “operator” in that command. For example FBOUNDP (FF) followed by USE CALLS is equivalent to USE CALLS FOR FBOUNDP IN -1.

If OLD is not found, USE will print a question mark, several spaces and the pattern that was not found. For example, if you specified USE Y FOR X IN 104 and X was not found, “X ?” is printed to the Exec.

You can also specify more than one substitution simultaneously as follows:

USE NEW1 FOR OLD1 AND ... AND NEWn FOR OLDn [IN EventSpec ]

[The USE command is parsed by a small finite state parser to distinguish the expressions and arguments. For example, USE FOR FOR AND AND FOR FOR will be parsed correctly.]

Every USE command involves three pieces of information: the expressions to be substituted, the arguments to be substituted for, and an event specification that defines the input expression in which the substitution takes place. If the USE command has the same number of expressions as arguments, the substitution procedure is straightforward. For example, USE X Y FOR U V means substitute X for U and Y for V, and is equivalent to USE X FOR U AND Y FOR V.

However, the USE command also permits distributive substitutions for substituting several expressions for the same argument. For example, USE A B C FOR X means first substitute A for X then substitute B for X (in a new copy of the expression), then substitute C for X. The effect is the same as three separate USE commands.

Similarly, USE A B C FOR D AND X Y Z FOR W is equivalent to USE A FOR D AND X FOR W, followed by USE B FOR D AND Y FOR W, followed by USE C FOR D AND Z FOR W. USE A B C FOR D AND X FOR Y also corresponds to three substitutions, the first with A for D and X for Y, the second with B for D, and X for Y, and the third with C
for D, and again X for Y. However, USE A B C FOR D AND X Y FOR Z is ambiguous and will cause an error.

Essentially, the USE command operates by proceeding from left to right handling each AND separately. Whenever the number of expressions exceeds the available expressions, multiple USE expressions are generated. Thus USE A B C D FOR E F means substitute A for E at the same time substituting B for F, then in another copy of the indicated expression, substitute C for E and D for F. This is also equivalent to USE A C FOR E AND B D FOR F.

The USE command correctly handles the situation where one of the old expressions is the same as one of the new ones, USE X Y FOR Y X, or USE X FOR Y AND Y FOR X.

? NAME

If NAME is not provided describes all available Exec commands by printing the name, argument list, and description of each. With NAME, only that command is described.

?? EventSpec

Prints the most recent event matching the given EventSpec. Without EventSpec, lists all entries on the history list from all execs, not necessarily in the order in which they occurred (since the list is in allocation order). If you haven’t completed typing a command it will be listed as "<in progress>".

Note: Event nubmers are allocated at the time the prompt is printed, except in the Old Interlisp exec where they are assigned at the end of type-in. This means that if activity occurs in another exec, the number printed next to the command is not necessarily the number associated with the event.

CONN DIRECTORY

Changes default pathname to DIRECTORY.

DA

Returns current date and time.

DIR PATHNAME KEYWORDS

Shows a directory listing for PATHNAME or the connected directory. If provided, KEYWORDS indicate information to be displayed for each file. Some keywords are: AUTHOR, AU, CREATIONDATE, DA, etc.

DO-EVENTS INPUTS ENV

DO-EVENTS is intended as a way of putting together several different events, which can include commands. It executes the multiple INPUTS as a single event. The values returned by the DO-EVENTS event are the concatenation of the values of the inputs. An input is not an EventSpec, but a call to a function or command. If ENV is provided it is a lexical environment in which all evaluations (functions and commands) will take place. Event specification in the INPUTS should be explicit, not relative, since referring to the last event will reinvoke the executing DO-EVENTS command.
MEDLEY REFERENCE MANUAL

**FIX** EventSpec  
[Exec command]
Edits the specified event prior to re-executing it. If the number of characters in the fixed line is less than the variable TTYINFIXLIMIT then it will be edited using TTYIN, otherwise the Lisp editor is called via EDITE.

**FORGET** EventSpec  
[Exec command]
Erases UNDO information for the specified events.

**NAME** COMMAND-NAMESPACE ARGUMENTS EVENT-SPEC  
[Exec command]
Defines a new command, COMMAND-NAMESPACE, and its ARGUMENTS, containing the events in EVENT-SPEC.

**NDIR** PATHNAME KEYWORDS  
[Exec command]
Shows a directory listing for PATHNAME or the connected directory in abbreviated format. If provided, KEYWORDS indicate information to be displayed for each file. Some keywords are: AUTHOR, AU, CREATIONDATE, DA, etc.

**PL** SYMBOL  
[Exec command]
Prints the property list of SYMBOL in an easy to read format.

**REMEMBER** &REST EVENT-SPEC  
[Exec command]
Tells File Manager to remember type-in from specified event(s), EVENT-SPEC, as expressions to save.

**SHH** LINE  
[Exec command]
Executes LINE without history list processing.

**UNDO** EventSpec  
[Exec command]
Undoes the side effects of the specified event (see below under “Undoing”).

**PP** NAME TYPES  
[Exec command]
Shows (prettyprinted) the definitions for NAME specified by TYPES.

**SEE** FILES  
[Exec command]
Prints the contents of FILES in the Exec window, hiding comments.

**SEE** FILES  
[Exec command]
Prints the contents of FILES in the Exec window, showing comments.

**TIME** FORM &KEY REPEAT &ENVIRONMENT ENV  
[Exec command]
Times the evaluation of FORM in the lexical environment ENV, repeating REPEAT number of times. Information is displayed in the Exec window.

**TY** FILES  
[Exec command]
Exactly like the TYPE Exec command.
TYPE FILE$ [Exec command]

Prints the contents of FILE$ in the Exec window, hiding comments.

Variables

A number of variables are provided for convenience in the Exec.

IL:IT [Variable]

Whenever an event is completed, the global value of the variable IT is reset to the event’s value. For example,

```
(s ort 2)
1.4142135
1.8192871
```

Following a ?? command, IL:IT is set to the value of the last event printed. The inspector has an option for setting the variable IL:IT to the current selection or inspected object, as well. The variable IL:IT is global, and is shared among all Execs. IL:IT is a convenient mechanism for passing values from one process to another.

Note: IT is in the Interlisp package and these examples are intended for an Exec whose *PACKAGE* is set to XCL-USER. Thus, IT must be package qualified (the IL:).

The following variables are maintained independently by each Exec. (When a new Exec is started, the initial values are NIL, or, for a nested Exec, the value for the “parent” Exec. However, events executed under a nested Exec will not affect the parent values.)

CL:- [Variable]
CL:+ [Variable]
CL:++ [Variable]
CL:+++ [Variable]

While a form is being evaluated by the Exec, the variable CL:- is bound to the form, CL:+ is bound to the previous form, CL:++ the one before, etc. If the input is in apply-format rather than eval-format, the value of the respective variable is just the function name.

CL:* [Variable]
CL:** [Variable]
CL:*** [Variable]

While a form is being evaluated by the Exec, the variable CL:* is bound to the (first) value returned by the last event, CL:** to the event before that, etc. The variable CL:* differs from IT in that IT is global while each separate Exec maintains its own copy of CL:*, CL:** and CL:***. In addition, the history commands change IT, but only inputs that are retained on the history list can change CL:*.
While a form is being evaluated by an Exec, the variable CL:/ is bound to a list of the
results of the last event in that Exec, CL:// to the values of the event before that, etc.

Fonts in the Exec

The Exec can use different fonts for displaying the prompt, user’s input, intermediate printout, and
the values returned by evaluation. The following variables control the Exec’s font use:

- **PROMPTFONT**
  - Font used for printing the event prompt.
- **INPUTFONT**
  - Font used for echoing your type-in.
- **PRINTOUTFONT**
  - Font used for any intermediate printing caused by execution of a command or evaluation
    of a form. Initially the same as DEFAULTFONT.
- **VALUEFONT**
  - Font used to print the values returned by evaluation of a form. Initially the same as
    DEFAULTFONT.

Modifying an Exec

**(CHANGESLICE N HISTORY —)**

Changes the maximum number of events saved on the history list HISTORY to N. If NIL,
HISTORY defaults to the top level history LISPXHISTORY.

The effect of increasing the time-slice is gradual: the history list is simply allowed to grow
to the corresponding length before any events are forgotten. Decreasing the time-slice will
immediately remove a sufficient number of the older events to bring the history list down
to the proper size. However, CHANGESLICE is undoable, so that these events are
(temporarily) recoverable. Therefore, if you want to recover the storage associated with
these events without waiting N more events until the CHANGESLICE event drops off the
history list, you must perform a FORGET command.

Defining New Commands

You can define new Exec commands using the XCL:DEFCOMMAND macro.

**(XCL:DEFCOMMAND NAME ARGUMENT-LIST &REST BODY)**

XCL:DEFCOMMAND is like XCL:DEFMACRO, but defines new Exec commands. The
ARGUMENT-LIST can have keywords, and use all of the features of macro argument lists.
When NAME is subsequently typed to the Exec, the rest of the line is processed like the
arguments to a macro, and the BODY is executed. XCL:DEFCOMMAND is a definer; the
File Manager will remember typed-in definitions and allow them to be saved, edited with EDITDEF, etc.

There are three kinds of commands that can be defined, :EVAL, :QUIET, and :INPUT. Commands can also be marked as only for the debugger, in which case they are labelled as :DEBUGGER. The command type is noted by supplying a list for the NAME argument to XCL:DEFCOMMAND, where the first element of the list is the command name, and the other elements are keyword(s) for the command type and, optionally :DEBUGGER.

The documentation string in user defined Exec commands is automatically added to the documentation descriptions by the CL:DOCUMENTATION function under the COMMANDS type and can be shown using the ? Exec command.

:EVAL This is the default. The body of the command just gets executed, and its value is the value of the event. For example (in an XCL Exec),

```
XCL Exec (XCL)

(lambda (LS EVAL)
  (VALUES)
  (NAMESTRING)
  (FORMAT "*" "-A" "-A" (NAMESTRING PATHNAME))
  (APPLY "DIRECTORY NAMESTRING"
    (DIRECTORY-KEYWORDS))
  (VALUES))

LS
```

would define the LS command to print out all file names that match the input NAMESTRING. The (VALUES) means that no value will be printed by the event, only the intermediate output from the FORMAT.

:QUIET These commands are evaluated, but neither your input nor the results of the command are stored on the history list. For example, the ?? and SHH commands are quiet.

:INPUT These commands work more like macros, in that the result of evaluating the command is treated as a new line of input. The FIX command is an input command. The result is treated as a line; a single expression in EVAL-format should be returned as a list of the expression to EVAL.

**Undoing**

**Note:** This discussion only applies to undoing under the Exec or Debugger, and within the UNDOABLY macro; text and structure editors handle undoing differently.

The UNDO facility allows recording of destructive changes such that they can be played back to restore a previous state. There are two kinds of undoing: one is done by the Exec, the other is available for use in your code. Both methods share information about what kind of operations can be undone and where the changes are recorded.
Undoing in the Exec

**UNDO EventSpec**

The Exec’s `UNDO` command is implemented by watching the evaluation of forms and requiring undoable operations in that evaluation to save enough information on the history list to reverse their side effects. The Exec simply executes operations, and any undoable changes that occur are automatically saved on the history list by the responsible functions. The `UNDO` command works on itself the same way: it recovers the saved information and performs the corresponding inverses. Thus, `UNDO` is effective on itself, so that you can `UNDO` an `UNDO`, and `UNDO` that, etc.

Only when you attempt to undo an operation does the Exec check to see whether any information has been saved. If none has been saved, and you have specifically named the event you want undone, the Exec types `nothing saved`. (When you just type `UNDO`, the Exec only tries to undo the last operation.)

`UNDO` watches evaluation using `CL:EVALHOOK` (thus, calling `CL:EVALHOOK` cannot be undone). Each form given to `EVAL` is examined against the list `LISPXFNS` to see if it has a corresponding undoable version. If an undoable version of a call is found, it is called with the same arguments instead of the original. Therefore, before evaluating all subforms of your input, the Exec substitutes the corresponding undoable call for any destructive operation. For example, if you type `(DEFUN FOO ...)`, undoable versions of the forms that set the definition into the symbol function cell are evaluated. FOO’s function definition itself is not made undoable.

Undoing in Programs

There are two ways to make a program undoable. The simplest method is to wrap the program’s form in the `UNDOABLY` macro. The other is to call undoable versions of destructive operations directly.

**(XCL:UNDOABLY &REST FORMS)**

Executes the forms in `FORMS` using undoable versions of all destructive operations. This is done by “walking” (see `WALKFORM`) all of the `FORMS` and rewriting them to use the undoable versions of destructive operations (`LISPXFNS` makes the association).

**(STOP-UNDOABLY &REST FORMS)**

 Normally executes as `PROGN`; however, within an `UNDOABLY` form, explicitly causes `FORMS` not to be done undoably. Turns off rewriting of the `FORMS` to be undoable inside an `UNDOABLY` macro.

Undoable Versions of Common Functions

When efficiency is a serious concern, you may need more control over the saving of undo information than that provided by the `UNDOABLY` macro.

To make a function undoable, you can simply substitute the corresponding undoable function in your program. When the undoable function is called, it will save the undo information in the current event on the history list.
Various operations, most notably `SETF`, have undoable versions. The following undoable macros are initially available:

- `UNDOABLY-POP`  
- `UNDOABLY-PUSH`  
- `UNDOABLY-PUSHNEW`  
- `UNDOABLY-REMF`  
- `UNDOABLY-ROTATEF`  
- `UNDOABLY-SHIFTF`  
- `UNDOABLY-DECF`  
- `UNDOABLY-INCF`  
- `UNDOABLY-SETQ`  
- `UNDOABLY-SET-SYMBOL`  
- `UNDOABLY-MAKUNBOUND`  
- `UNDOABLY-PSETF`  
- `UNDOABLY-SETF-SYMBOL-FUNCTION`  
- `UNDOABLY-SETF-MACRO-FUNCTION`  
- `XCL:UNDOABLY-SETF`

**Note:** Many destructive Common Lisp functions do not have undoable versions, e.g., `CL:NREVERSE`, `CL:SORT`, etc. You can see the current list of undoable functions on the association list `LISPXFNS`.

**Modifying the UNDO Facility**

You may want to extend the UNDO facility after creating a form whose side effects might be undoable, for instance a file renaming function.

You need to write an undoable version of the function. You can do this by explicitly saving previous state information, or by renaming calls in the function to their undoable equivalent. Undo information should be saved on the history list using `IL:UNDOSAVE`.

You must then hook the undoable version of the function into the undo facility. You do this by either using the `IL:LISPXFNS` association list, or in the case of a `SETF` modifier, on the `IL:UNDOABLE-SETF-INVERSE` property of the `SETF` function.

**LISPXFNS**

[Variable]

Contains an association list that maps from destructive operations to their undoable form. Initially this list contains:

```lisp
((CL:POP . UNDOABLY-POP)  
 (CL:PSETF . UNDOABLY-PSETF)  
 (CL:PUSH . UNDOABLY-PUSH)  
 (CL:PUSHNEW . UNDOABLY-PUSHNEW)  
 ((CL:REMF) . UNDOABLY-REMF)  
 ((CL:ROTATEF . UNDOABLY-ROTATEF)  
 (CL:SHIFTF . UNDOABLY-SHIFTF)  
 (CL:DECF . UNDOABLY-DECF)  
 (CL:INCF . UNDOABLY-INCF)  
 (CL:SET . UNDOABLY-SET-SYMBOL)  
 (CL:MAKUNBOUND . UNDOABLY-MAKUNBOUND)  
 ... plus the original Interlisp undo associations)
```

**(XCL:UNDOABLY-SETF** Pl**ACE VALUE ...)**

[Macro]

Like `CL:SETF` but saves information so it may be undone. `UNDOABLY-SETF` uses undoable versions of the `SETF` function located on the `UNDOABLE-SETF-INVERSE` property of the function being `SETF`ed. Initially these `SETF` names have such a property:

- `CL:SYMBOL-FUNCTION - UNDOABLY-SETF-SYMBOL-FUNCTION`  
- `CL:MACRO-FUNCTION - UNDOABLY-SETF-MACRO-FUNCTION`
Typed-in SETQs (and SETFs on symbols) are made undoable by substituting a call to UNDOABLY-SETQ. UNDOABLY-SETQ operates like SETQ on lexical variables or those with dynamic bindings; it only saves information on the history list for changes to global, “top-level” values.

Adds the undo information UNDOFORM to the SIDE property of the history event HISTENTRY. If there is no SIDE property, one is created. If the value of the SIDE property is NOSAVE, the information is not saved. HISTENTRY specifies an event. If HISTENTRY=NIL, the value of LISPXHIST is used. If both HISTENTRY and LISPXHIST are NIL, UNDOSAVE is a no-op.

The form of UNDOFORM is (FN . ARGS). Undoing is done by performing (APPLY (CAR UNDOFORM) (CDR UNDOFORM)).

The maximum number of UNDOFORMs to be saved for a single event. When the count of UNDOFORMs reaches this number, UNDOSAVE prints the message CONTINUE SAVING?, asking if you want to continue saving. If you answer NO or default, UNDOSAVE discards the previously saved information for this event, and makes NOSAVE be the value of the property SIDE, which disables any further saving for this event. If you answer YES, UNDOSAVE changes the count to -1, which is then never incremented, and continues saving. The purpose of this feature is to avoid tying up large quantities of storage for operations that will never need to be undone.

If \#UNDOSAVES is negative, then when the count reaches (ABS \#UNDOSAVES), UNDOSAVE simply stops saving without printing any messages or other interactions. \#UNDOSAVES = NIL is equivalent to \#UNDOSAVES = infinity. \#UNDOSAVES is initially NIL.

The configuration described here is very satisfactory. You pay a very small price for the ability to undo what you type in, since the interpreted evaluation is simply watched for destructive operations, or if you wish to protect yourself from malfunctioning in your own programs, you can explicitly call, or rewrite your program to explicitly call, undoable functions.

Undoing Out of Order

UNDOABLY-SETF operates undoably by saving (on the history list) the cell that is to be changed and its original contents. Undoing an UNDOABLY-SETF restores the saved contents.

This implementation can produce unexpected results when multiple modifications are made to the same piece of storage and then undone out of order. For example, if you type (SETF (CAR FOO) 1), followed by (SETF (CAR FOO) 2), then undo both events by undoing the most recent event first, then undoing the older event, FOO will be restored to its state before either event operated. However if you undo the first event, then the second event, (CAR FOO) will be 1, since this is what was in CAR of FOO before (UNDOABLY-SETF (CAR FOO) 2) was executed. Similarly, if you type...
(NCONC FOO '(1)), followed by (NCONC FOO '(2)), undoing just (NCONC FOO '(1)) will remove both 1 and 2 from FOO. The problem in both cases is that the two operations are not independent.

In general, operations are always independent if they affect different lists or different sublists of the same list. Undoing in reverse order of execution, or undoing independent operations, is always guaranteed to do the right thing. However, undoing dependent operations out of order may not always have the predicted effect.

### Format and Use of the History List

**LISPXHISTORY**

The Exec currently uses one primary history list, LISPXHISTORY for the storing events.

The history list is in the form \((EVENTS \ EVENT\# \ SIZE \ MOD)\), where \(EVENTS\) is a list of events with the most recent event first, \(EVENT\#\) is the event number for the most recent event on \(EVENTS\), \(SIZE\) is the maximum length \(EVENTS\) is allowed to grow, \(MOD\) is the maximum event number to use, after which event numbers roll over. \(LISPXHISTORY\) is initialized to \((\text{NIL} \ 0 \ 100 \ 1000)\).

The history list has a maximum length, called its time-slice. As new events occur, existing events are aged, and the oldest events are forgotten. The time-slice can be changed with the function \(\text{CHANGESLICE}\). Larger time-slices enable longer memory spans, but tie up correspondingly greater amounts of storage. Since you seldom need really ancient history, a relatively small time-slice such as 30 events is usually adequate, although some users prefer to set the time-slice as large as 200 events.

Each individual event on \(EVENTS\) is a list of the form \((INPUT \ ID \ VALUE \ . \ PROPS)\). For Exec events, \(ID\) is a list \((\text{EVENT-NUMBER} \ EXEC-ID)\). The \(\text{EVENT-NUMBER}\) is the number of the event, while the \(\text{EXEC-ID}\) is a string that uniquely identifies the Exec. (The \(\text{EXEC-ID}\) is used to identify which events belong to the “same” Exec.) \(VALUE\) is the (first) value of the event. \(PROPS\) is a property list used to associate other information with the event (described below).

\(INPUT\) is the input sequence for the event. Normally, this is just the input that you type in. For an \(APPLY\)-format input this is a list consisting of two expressions; for an \(EVAL\)-format input, this is a list of just one expression; for an input entered as list of atoms, \(INPUT\) is simply that list. For example,

**User Input**

\[
\begin{align*}
\text{LIST}(1 \ 2) & \quad \Rightarrow (\text{LIST} \ (1 \ 2)) \\
(\text{LIST} \ 1 \ 1)  & \quad \Rightarrow ((\text{LIST} \ 1 \ 1)) \\
\text{DIR} \ "\{\text{DSK}\}\text{<LISPFILES}>"cr & \quad \Rightarrow (\text{DIR} \ "\{\text{DSK}\}\text{<LISPFILES}>")
\end{align*}
\]

If you type in an Exec command that executes other events (REDO, USE, etc.), several events might result. When there is more than one input, they are wrapped together into one invocation of the \text{DEVENTS} command.

The same convention is used for representing multiple inputs when a \text{USE} command involves sequential substitutions. For example, if you type \(\text{FBOUNDP} \ (\text{FOO})\) and then \text{USE}
FIE FUM FOR FOO, the input sequence that will be constructed is DO-EVENTS (EVENT FBOUNDP (FIE)) (EVENT FBOUNDP (FUM)), which is the result of substituting FIE for FOO in (FBOUNDP (FOO)) concatenated with the result of substituting FUM for FOO in (FBOUNDP (FOO)).

PROPS is a property list of the form \((PROPERTY_1 \ VALUE_1 \ PROPERTY_2 \ VALUE_2 \ ...\)\), that can be used to associate arbitrary information with a particular event. Currently, the following properties are used by the Exec:

**SIDE**

A list of the side effects of the event. See UNDOSAVE.

**LISPXRPRINT**

Used to record calls to EXEC-FORMAT, and printed by the ?? command.

### Making or Changing an Exec

(XCL:ADD-EXEC &KEY PROFILE REGION TTY ID)  [Function]

Creates a new process and window with an Exec running in it. PROFILE is the type of the Exec to be created (see below under XCL:SET-EXEC-TYPE). REGION optionally gives the shape and location of the window to be used. If not provided you will be prompted. TTY is a flag, which, if true, causes the tty to be given to the new Exec process. ID is a string identifier to use for events generated in this exec. ID defaults to the number given to the Exec process created.

(XCL:EXEC &KEY WINDOW PROMPT COMMAND-TABLES ENVIRONMENT PROFILE TOP-LEVEL-P TITLE FUNCTION ID)  [Function]

This is the main entry to the Exec. The arguments are:

WINDOW defaults to the current TTY display stream, or can be provided a window in which the Exec will run.

PROMPT is the prompt to print.

COMMAND-TABLES is a list of hash-tables for looking up commands (e.g., *EXEC-COMMAND-TABLE* or *DEBUGGER-COMMAND-TABLE*).

ENVIRONMENT is a lexical environment used to evaluate things in.

READTABLE is the default readable to use (defaults to the “Common Lisp” readable).

PROFILE is a way to set the Exec’s type (see above, “Multiple Execs and the Exec’s Type”).

TOP-LEVEL-P is a boolean, which should be true if this Exec is at the top level (it’s NIL for debugger windows, etc).

TITLE is an identifying title for the window title of the Exec.

FUNCTION is a function used to actually evaluate events, default is EVAL-INPUT.
**MEDLEY EXECUTIVES**

*ID* is a string identifier to use for events generated in this Exec.  *ID* defaults to the number given to the Exec process.

**XCL:*PER-EXEC-VARIABLES* [Variable]

A list of pairs of the form (VAR INIT). Each time an Exec is entered, the variables in *PER-EXEC-VARIABLES* are rebound to the value returned by evaluating INIT. The initial value of *PER-EXEC-VARIABLES* is:

```
((*PACKAGE* *PACKAGE*)
 (* *)
 (** **)  
 (** **)
 (+ +)
 (++ ++)
 (+++ +++)
 (- -)
 (/ /)
 (/ /)
 (/ /)
 (/ /)

(HELPFLAG T)
(*EVALHOOK* NIL)
(*APPLYHOOK* nil)
(*ERROR-OUTPUT* *TERMINAL-IO*)
(*READTABLE* *READTABLE*)
(*package* *package*)
(*eval-function* *eval-function*)
(*exec-prompt* *exec-prompt*)
(*debugger-prompt* *debugger-prompt*)```

Most of these cause the values to be (re)bound to their current value in any inferior Exec, or to NIL, their value at the “top level”.

**XCL:*EVAL-FUNCTION* [Variable]

Bound to the function used by the Exec to evaluate input. Typically in an Interlisp Exec this is IL:EVAL, and in a Common Lisp Exec, CL:EVAL.

**XCL:*EXEC-PROMPT* [Variable]

Bound to the string printed by the Exec as a prompt for input. Typically in an Interlisp Exec this is “←”, and in a Common Lisp Exec, “>”.

**XCL:*DEBUGGER-PROMPT* [Variable]

Bound to the string printed by the debugger Exec as a prompt for input. Typically in an Interlisp Exec this is “←:”, and in a Common Lisp Exec, “:".

**XCL:EXEC-EVAL FORM &OPTIONAL ENVIRONMENT** [Function]

Evaluates FORM (using EVAL) in the lexical environment ENVIRONMENT the same as though it were typed in to EXEC, i.e., the event is recorded, and the evaluation is made undoable by substituting the UNDOABLE-functions for the corresponding destructive functions. **XCL:EXEC-EVAL** returns the value(s) of the form, but does not print it, and does not reset the variables *, **, ***, etc.
In addition to saving inputs and values, the Exec saves many system messages on the history list. For example, `FILE CREATED ...`, `FN redefined`, `VAR reset`, output of `TIME`, `BREAKDOWN`, `ROOM`, save their output on the history list, so that when `??` prints the event, the output is also printed. The function `XCL:EXEC-FORMAT` can be used in your code similarly. `XCL:EXEC-FORMAT` performs `(APPLY #'CL:FORMAT *TERMINAL-IO* CONTROL-STRING &REST ARGUMENTS)` and also saves the format string and arguments on the history list associated with the current event.

Sets the type of the current Exec to that indicated by `NAME`. This can be used to set up the Exec to your liking. `NAME` may be an atom or string. Possible names are:

- INTERLISP, IL: `*READTABLE* INTERLISP`
- COMMON-LISP, CL: `*READTABLE* LISP`
- OLD-INTERLISP-T: `*READTABLE* OLD-INTERLISP-T`
- XEROX-COMMON-LISP, XCL: `*READTABLE* XCL`
- XCL: `*READTABLE* XCL-USER`

Like `XCL:SET-EXEC-TYPE`, but sets the type of Execs created by default, as from the background menu. Initially XCL. This can be used in your greet file to set default Execs to your liking.

### Editing Exec Input

The Exec features an input editor which provides completion, spelling correction, help facility, and character-level editing. The implementation is borrowed from the Interlisp module `TTYIN`. This section describes the use of the `TTYIN` editor from the perspective of the Exec.

### Editing Your Input

Some editing operations can be performed using any of several characters; characters that are interrupts will, of course, not be read, so several alternatives are given. The following characters may be used to edit your input:

- `CONTROL-A`
**BACKSPACE** Deletes a character. At the start of the second or subsequent lines of your input, deletes the last character of the previous line.

**CONTROL-W** Deletes a “word”. Generally this means back to the last space or parenthesis.

**CONTROL-Q** Deletes the current line, or if the current line is blank, deletes the previous line.

**CONTROL-R** Refreshes the current line. Two in a row refreshes the whole buffer (when doing multiline input).

**ESCAPE** Tries to complete the current word from the spelling list USERWORDS. In the case of ambiguity, completes as far as is uniquely determined, or beeps.

**UNDO** Retries characters from the previous non-empty buffer when it is able to; e.g., when typed at the beginning of the line this command restores the previous line you typed; when typed in the middle of a line fills in the remaining text from the old line; when typed following **CONTROL-Q** or **CONTROL-W** restores what those commands erased.

**CONTROL-X** Goes to the end of your input (or end of expression if there is an excess right parenthesis) and returns if parentheses are balanced.

If you are already at the end of the input and the expression is balanced except for lacking one or more right parentheses, **CONTROL-X** adds the required right parentheses to balance and returns.

During most kinds of input, lines are broken, if possible, so that no word straddles the end of the line. The pseudo-carriage return ending the line is still read as a space, however; i.e., the program keeps track of whether a line ends in a carriage return or is merely broken at some convenient point. You will not get carriage returns in your strings unless you explicitly type them.

**Using the Mouse**

Editing with the mouse during TTYIN input is slightly different than with other modules. The mouse buttons are interpreted as follows during TTYIN input:

**LEFT** Moves the caret to where the cursor is pointing. As you hold down **LEFT**, the caret moves around with the cursor; after you let up, any type-in will be inserted at the new position.

**MIDDLE**

**LEFT+RIGHT** Like **LEFT**, but moves only to word boundaries.

**RIGHT** Deletes text from the caret to the cursor, either forward or backward. While you hold down **RIGHT**, the text to be deleted is inverted; when you let up, the text goes away. If you let up outside the scope of the text, nothing is deleted (this is how to cancel this operation).

If you hold down **MOVE**, **COPY**, **SHIFT** or **CTRL** while pressing the mouse buttons, you instead get secondary selection, move selection or delete selection. The selection is made by holding the appropriate key down while pressing the mouse buttons **LEFT** (to select a character) or **MIDDLE** (to select a word), and optionally extend the selection either left or right using **RIGHT**. While you are doing this, the caret does not move, but the selected text is highlighted in a manner indicating what is about to happen. When the selection is complete, release the mouse buttons and then lift up on **MOVE/COPY/CTRL/SWIFT** and the appropriate action will occur:
COPY
SHIFT The selected text is inserted as if it were typed. The text is highlighted with a broken underline during selection.

CTRL The selected text is deleted. The text is complemented during selection.

MOVE
CTRL+SHIFT Combines copy and delete. The selected text is moved to the caret.

You can cancel a selection in progress by pressing LEFT or MIDDLE as if to select, and moving outside the range of the text.

The most recent text deleted by mouse command can be inserted at the caret by typing the UNDO key. This is the same key that retrieves the previous buffer when issued at the end of a line.

Editing Commands

A number of characters have special effects while typing to the Exec. Some of them merely move the caret inside the input stream. While caret positioning can often be done more conveniently with the mouse, some of the commands, such as the case changing commands, can be useful for modifying the input.

In the descriptions below, current word means the word the cursor is under, or if under a space, the previous word. Currently, parentheses are treated as spaces, which is usually what you want, but can occasionally cause confusion in the word deletion commands.

Most commands can be preceded by a numeric argument. A numeric argument can be a number or an escape. You enter the numeric argument by holding down the meta key and entering a number. You only need to hold down the meta key for the first digit of the argument. Entering escape as a numeric argument means infinity.

Some commands also accept negative arguments, but some only look at the magnitude of the argument. Most of these commands are confined to work within one line of text unless otherwise noted.

Cursor Movement Commands

Meta-BACKSPACE Backs up one (or n) characters.
Meta-SPACE Moves forward one (or n) characters.
Meta-^ Moves up one (or n) lines.
Meta-LINEFEED Moves down one (or n) lines.
Meta-( Moves back one (or n) words.
Meta-) Moves ahead one (or n) words.
Meta-tab Moves to end of line; with an argument moves to nth end of line; Meta-Control-tab goes to end of buffer.
Meta-Control-L Moves to start of line (or nth previous, or start of buffer).
Meta-{ Goes to start of buffer.
Meta-} Goes to end of buffer.
**Buffer Modification Commands**

- **Meta-Zx** Zaps characters from cursor to next (or nth) occurrence of x. There is no unzap command.
- **Meta-A** Repeats the last S, B, or Z command, regardless of any intervening input.
- **Meta-R** Kills the character under the cursor, or n chars starting at the cursor.
- **Meta-CR** When the buffer is empty is the same as undo i.e. restores buffer’s previous contents. Otherwise is just like a <cr> (except that it also terminates an insert). Thus, **Meta-CR Meta-CR** will repeat the previous input (as will undo<cr> without the meta key).
- **Meta-O** Does “Open line”, inserting a crlf after the cursor, i.e., it breaks the line but leaves the cursor where it is.
- **Meta-T** Transposes the characters before and after the cursor. When typed at the end of a line, transposes the previous two characters. Refuses to handle odd cases, such as tabs.
- **Meta-G** Grabs the contents of the previous line from the cursor position onward. **Meta-n Meta-G** grabs the nth previous line.
- **Meta-L** Puts the current word, or n words on line, in lower case. **Meta-<escape> Meta-L** puts the rest of the line in lower case; or if given at the end of line puts the entire line in lower case.
- **Meta-U** Analogous to **Meta-L**, for putting word, line, or portion of line in upper case.
- **Meta-C** Capitalizes. If you give it an argument, only the first word is capitalized; the rest are just lowercased.
- **Meta-Control-Q** Deletes the current line. **Meta-<escape> Meta-Control-Q** deletes from the current cursor position to the end of the buffer. No other arguments are handled.
- **Meta-Control-W** Deletes the current word, or the previous word if sitting on a space.

**Miscellaneous Commands**

- **Meta-P** Prettyprints buffer. Clears the buffer and reprints it using prettyprint. If there are not enough right parentheses, it will supply more; if there are too many, any excess remains unprettyprinted at the end of the buffer. May refuse to do anything if there is an unclosed string or other error trying to read the buffer.
**Meta-N** Refreshes line. Same as Control-R. Meta-<escape>Meta-N refreshes the whole buffer; Meta-n Meta-N refreshes n lines. Cursor movement in TTYIN depends on TTYIN being the only source of output to the window; in some circumstances, you may need to refresh the line for best results.

**Meta-Control-Y** Gets an Interlisp Exec. Meta-<escape>Meta-Control-Y Gets an Interlisp Exec, but first unreads the contents of the buffer from the cursor onward. Thus if you typed at TTYIN something destined for Interlisp, you can do Meta-Control-L Meta-<escape>Meta-Control-Y and give it to Lisp.

**Meta-_** Adds the current word to the spelling list USERWORDS. With zero argument, removes word. See TTYINCOMPLETEFLG.

### Useful Macros

If the event is considered short enough, the Exec command FIX will load the buffer with the event’s input, rather than calling the structure editor. If you really wanted the Lisp editor for your fix, you can say FIX EVENT - |TTY:|.

### ?= Handler

Typing the characters ?=<cr> displays the arguments to the function currently in progress. Since TTYIN wants you to be able to continue editing the buffer after a ?=, it prints the arguments below your type-in and then puts the cursor back where it was when ?= was typed.

### Assorted Flags

These flags control aspects of TTYIN’s behavior. Some have already been mentioned. All are initially set to T.

**?ACTIVATEFLG** [Variable]

If true, enables the feature whereby ? lists alternative completions from the current spelling list.

**SHOWPARENFLG** [Variable]

If true, then whenever you are typing Lisp input and type a right parenthesis, TTYIN will briefly move the cursor to the matching parenthesis, assuming it is still on the screen. The cursor stays there for about 1 second, or until you type another character (i.e., if you type fast you will never notice it).

**USERWORDS** [Variable]

USERWORDS contains words you mentioned recently: functions you have defined or edited, variables you have set or evaluated at the executive level, etc. This happens to be a very convenient list for context-free escape completion; if you have recently edited a function, chances are good you may want to edit it again (typing "ED(xx$)" or type a call to it. If there is no completion for the current word from USERWORDS, or there is more than one possible completion, TTYIN beeps. If typed when not inside a word, Escape completes to the value of LASTWORD, i.e., the last thing you typed that the Exec noticed,
except that Escape at the beginning of the line is left alone (it is an Old Interlisp Exec command).

If you really wanted to enter an escape, you can, of course, just quote it with a CONTROL- V, like you can other control characters.

You may explicitly add words to USERWORDS yourself that would not get there otherwise. To make this convenient online the edit command [←] means “add the current atom to USERWORDS” (you might think of the command as pointing out this atom). For example, you might be entering a function definition and want to point to one or more of its arguments or prog variables. Giving an argument of zero to this command will instead remove the indicated atom from USERWORDS.

Note that this feature loses some of its value if the spelling list is too long, if there are too many alternative completions for you to get by with typing a few characters followed by escape. Lisp’s maintenance of the spelling list USERWORDS keeps the temporary section (which is where everything goes initially unless you say otherwise) limited to \#USERWORDS atoms, initially 100. Words fall off the end if they haven’t been used (they are used if FIXSPELL corrects to one, or you use <escape> to complete one).

**Old Interlisp T compatibility**

The Old Interlisp exec contains a few extra Exec commands not listed above. They are explained here.

In addition to the normal Event addresses you can also specify the following Event addresses:

- \(=\) Specifies that the next object is to be searched for in the values of events, instead of the inputs

- SUCHTHAT \(\text{PRED}\) Specifies an event for which the function \(\text{PRED}\) returns true. \(\text{PRED}\) should be a function of two arguments, the input portion of the event, and the event itself.

- \(\text{PAT}\) Any other event address command specifies an event whose input contains an expression that matches \(\text{PAT}\). When multiple Execs are active, all events are searched, no matter which Exec they belong to. The pattern can be a simple symbol, or a more complex search pattern.

**Significant Changes in MEDLEY Release**

There are two major differences between the Medley release and older versions of the system:

- \(\text{SETQ}\) does not interact with the File Manager. In older releases (Koto, etc.), when you typed in \((\text{SETQ FOO some-new-value})\) the executive responded with \((\text{FOO reset})\) and the file manager was told that FOO’s value had changed. Files containing FOO were marked for cleanup, if none existed you were prompted for one when you typed \((\text{FILES})\).

This is still the case in the Old Interlisp executive but not in any of the others. If you are setting a variable that is significant to a program and you want to save it on a file, you should use the Common Lisp macro \(\text{CL:DEFPARAMETER}\) instead of \(\text{SETQ}\). This will give the symbol a definition of type \(\text{VARIABLES}\) (instead of \(\text{VARS}\)), and it will be noticed by the File Manager. Subsequent
changes to the variable must be done by another call to CL:DEFPARAMETER or by editing it using ED (not DV).

- The following functions and variables are only available in the Old Interlisp Exec: LISPX, USEREXEC, LISPXEVAL, READBUF, (READLINE), (LISPXREAD), (LISPXREADP), (LISPXUNREAD), (PROMPTCHAR), (HISTORYSAVE), (LISPXSTOREVALUE), (LISPXFIND), (HISTORYFIND), (HISROTYMATCH), (ENTRY), (UNDOSAVE), #UNDOSAVES, (NEW/FN), (LISPX/), (UNDOLISPX), (UNDOLISPX1), and (PRINTHISTORY).

The function USEREXEC invokes an old-style executive, but uses the package and readtable of its caller. Callers of LISPXEVAL should use EXEC-EVAL instead.
Occasionally, while a program is running, an error occurs which stops the computation. Errors can be caused in different ways. A coding mistake may have caused the wrong arguments to be passed to a function, or caused the function to attempt something illegal. For example, PLUS will cause an error if its arguments are not numbers. It is also possible to interrupt a computation by typing one of the “interrupt characters,” such as Control-D or Control-E (Medley interrupt characters are listed in Chapter 30). Finally, you can specify that certain functions automatically cause an error whenever they are entered (see Chapter 15). This facilitates debugging by allowing you to examine the context within the computation.

When an error occurs, the system can either reset and unwind the stack, or go into a “break”, and attempt to debug the program. You can modify the mechanism that decides whether to unwind the stack or break, and is described in the Controlling When to Break section in this chapter. Within a break, Medley offers an extensive set of “break commands”.

This chapter explains what happens when errors occur. It also tells you how to handle program errors using breaks and break commands. The debugging capabilities of the break window facility are described, as well as the variables that control its operation. Finally, advanced facilities for modifying and extending the error mechanism are presented.

Breaks

One of the most useful debugging facilities in Medley is the ability to put the system into a “break”, stopping a computation at any point, allowing you to interrogate the state of the world and affect the course of the computation. When a break occurs, a “break window” (see the Break Windows section below) is brought up near the TTY window of the broken process. The break window looks like a top-level executive window, except that the prompt character is “:” instead of “←” as in the top-level executive. A break saves the environment where the break occurred, so that you may evaluate variables and expressions in the broken environment. In addition, the break program recognizes a number of useful “break commands”, providing an easy way to interrogate the state of the broken computation.

Breaks may be entered in several ways. Some interrupt characters (Chapter 30) automatically cause a break whenever you type them. Function errors may also cause a break, depending on the depth of the computation (see Controlling When to Break below). Finally, Medley provides facilities which make it easy to “break” suspect functions so that they always cause a break whenever they are entered.

Within a break you have access to all of the power of Medley; you can do anything you can do at the top-level executive. For example, you can evaluate an expression, call the editor, change the function, and evaluate the expression again, all without leaving the break. You can also type in commands like REDO, and UNDO (Chapter 13), to redo or undo previously executed events, including break commands.

Similarly, you can prettyprint functions, define new functions or redefine old ones, load a file, compile functions, time a computation, etc. In addition, you can examine the stack (see Chapter 11), and even force a return back to some higher function via the functions RETFROM or RETEVAL.

Once a break occurs, you are in complete control of the flow of the computation, and the computation will not proceed without specific instruction from you. If you type in an expression whose evaluation
causes an error, the break is maintained. Similarly if you abort a computation initiated from within the break (by typing Control-E), the break is maintained. Only if you give one of the commands that exits from the break, or evaluates a form which does a RETFROM or RETEVAL out of BREAK1, will the computation continue. Also, BREAK1 does not “turn off” Control-D, so a Control-D will force an immediate return to the top level.

**Break Windows**

When a break occurs, a break window is brought up near the TTY window of the broken process and the terminal stream switched to it. The title of the break window is changed to the name of the broken function and the reason for the break. If a break occurs under a previous break, a new break window is created.

If a break is caused by a storage full error, the display break package will not try to open a new break window, since this would cause an infinite loop.

While in a break window, clicking the middle button brings up a menu of break commands: EVAL, EDIT, revert, ↑, OK, BT, BT!, and ?. Clicking on these commands is equivalent to typing the corresponding break command, except BT and BT! which behave differently from the typed-in commands (see Break Commands below).

The BT and BT! menu commands bring up a backtrace menu beside the break window showing the frames on the stack. BT shows frames for which REALFRAMEP is T; BT! shows all frames. When one of the frames is selected from the backtrace menu, it is grayed and the function name and the variables bound in that frame (including local variables and PROG variables) are printed in the “backtrace frame window.” If the left button is used for the selection, only named variables are printed. If the middle button is used, all variables are printed (variables without names appear as *var* N). The “backtrace frame” window is an inspect window (see Chapter 26). In this window, the left button is used to select the name of the function, the names of the variables or the values of the variables. For example, below is a picture of a break window with a backtrace menu created by BT. The OPENSTREAM stack frame has been selected, so its variables are shown in an inspect window on top of the break window:

```
After selecting an item, the middle button brings up a menu of commands that apply to the selected item. If the function name is selected, you are given a choice of editing the function or seeing the compiled code with INSPECTCODE (Chapter 26). If you edit the function in this way, the editor is called in the broken process, so variables evaluated in the editor are in the broken process.
If a variable name is selected, the command SET is offered. Selecting SET will READ a value and set the selected to the value read.

**Note:** The inspector will only allow the setting of named variables. Even with this restriction it is still possible to crash the system by setting variables inside system frames. Exercise caution in setting variables in other than your own code.

If a value is selected, the inspector is called on the selected value.

The internal break variable LASTPOS (see the section below) is set to the selected backtrace menu frame so that the normal break commands EDIT, revert, and ?= work on the currently selected frame. The commands EVAL, revert, ↑, OK, and ?= in the break menu cause the corresponding commands to be “typed in.” This means that these break commands will not have the intended effect if characters have already been typed in. The typed-in break commands BT, BTV, etc. use the value of LASTPOS to determine where to start listing the stack, so selecting a stack frame name in the backtrace menu affects these commands.

### Break Commands

The basic function of the break package is BREAK1. BREAK1 is just another Interlisp function, not a special system feature like the interpreter or the garbage collector. It has arguments, and returns a value, the same as any other function. For more information on the function BREAK1, see Creating Breaks with BREAK1 below.

The value returned by BREAK1 is called “the value of the break.” You can specify this value explicitly by using the RETURN break command (see below). But in most cases, the value of a break is given implicitly, via a GO or OK command, and is the result of evaluating “the break expression.” The break expression, stored in the variable BRKEXP, is an expression equivalent to the computation that would have taken place had no break occurred. For example, if you break on the function FOO, the break expression is the body of the definition of FOO. When you type OK or GO, the body of FOO is evaluated, and its value returned as the value of the break, i.e., to whatever function called FOO. BRKEXP is set up by the function that created the call to BREAK1. For functions broken with BREAK or TRACE, BRKEXP is equivalent to the body of the definition of the broken function (see Chapter 15). For functions broken with BREAKIN, using BEFORE or AFTER, BRKEXP is NIL. For BREAKIN AROUND, BRKEXP is the indicated expression (see Chapter 15).

BREAK1 recognizes a large set of break commands. These are typed in without parentheses. In order to facilitate debugging of programs that perform input operations, the carriage return that is typed to complete the GO, OK, EVAL, etc. commands is discarded by BREAK1, so that it will not be part of the input stream after the break.

**GO**

[Break Command]

Evaluates BRKEXP, prints its value, and returns it as the value of the break. Releases the break and allows the computation to proceed.

**OK**

[Break Command]

Same as GO except that the value of BRKEXP is not printed.
**EVAL**  
[Break Command] 
Same as OK except that the break is maintained after the evaluation. The value of EVAL is bound to the local variable !VALUE, which you can interrogate. Typing GO or OK following EVAL will not cause BRKEXP to be reevaluated, but simply returns the value of !VALUE as the value of the break. Typing another EVAL will cause reevaluation. EVAL is useful when you are not sure whether the break will produce the correct value and want to examine it before continuing with the computation.

**RETURN FORM**  
[Break Command] 
FORM is evaluated, and returned as the value of the break. For example, one could use the EVAL command and follow this with RETURN (REVERSE !VALUE).

↑  
[Break Command] 
Calls ERROR! and aborts the break, making it “go away” without returning a value. This is a useful way to unwind to a higher level break. All other errors, including those encountered while executing the GO, OK, EVAL, and RETURN commands, maintain the break.

The following four commands refer to “the broken function”, whose name is stored in the BREAK1 argument BRKFN.

**!GO**  
[Break Command] 
The broken function is unbroken, the break expression is evaluated, the function is rebroken, and then the break is exited with the value printed.

**!OK**  
[Break Command] 
The broken function is unbroken, the break expression is evaluated, the function is rebroken, and then the break is exited without the value printed.

**UB**  
[Break Command] 
Unbreaks the broken function.

**@**  
[Break Command] 
Resets the variable LASTPOS, which establishes a context for the commands ?-, ARGS, BT, BTV, BTV*, EDIT, and IN? described below. LASTPOS is the position of a function call on the stack. It is initialized to the function just before the call to BREAK1, i.e., (STKNTH -1 ‘BREAK1).

When control passes from BREAK1, e.g. as a result of an EVAL, OK, GO, REVERT, ↑ command, or via a RETFROM or RETEVAL you type in, (RELSTK LASTPOS) is executed to release this stack pointer.

@ treats the rest of the teletype line as its argument(s). It first resets LASTPOS to (STKNTH -1 ‘BREAK1) and then for each atom on the line, @ searches down the stack for a call to that atom. The following atoms are treated specially:
Do not reset LASTPOS to (STKNTH -1 "BREAK1") but leave it as it was, and continue searching from that point.

If negative, move LASTPOS down the stack N frames. If positive, move LASTPOS up the stack N frames.

The next atom on the line (which should be a number) specifies that the previous atom should be searched for that many times. For example, "@ FOO / 3" is equivalent to "@ FOO FOO FOO".

Resets LASTPOS to the value of the next expression, e.g., if the value of FOO is a stack pointer, "@ = FOO FIE" will search for FIE in the environment specified by (the value of) FOO.

For example, if the push-down stack looks like:

```
[9] BREAK1
[8] FOO
[7] COND
[6] FIE
[5] COND
[4] FIE
[3] COND
[2] FIE
[1] FUM
```

then "@ FIE COND" will set LASTPOS to the position corresponding to [5]; "@ @ COND" will then set LASTPOS to [3]; and "@ FIE / 3 - 1" to [1].

If @ cannot successfully complete a search for function FN, it searches the stack again from that point looking for a call to a function whose name is a possible misspelling of FN (see spelling correction in Chapter 20). If the search is still unsuccessful, @ types (FN NOT FOUND), and then aborts.

When @ finishes, it types the name of the function at LASTPOS, i.e., (STKNAME LASTPOS).

@ can be used on BRKCOMS (see Creating Breaks with BREAK1 below). In this case, the next command on BRKCOMS is treated the same as the rest of the teletype line.

This is a multi-purpose command. Its most common use is to interrogate the value(s) of the arguments of the broken function. For example, if FOO has three arguments (X Y Z), then typing ?= to a break on FOO will produce:

```
;?= X = value of X
   Y = value of Y
   Z = value of Z
;  
```
? = operates on the rest of the teletype line as its arguments. If the line is empty, as in the above case, it operates on all of the arguments of the broken function. If the you type ? = X (CAR Y), you will see the value of X, and the value of (CAR Y). The difference between using ? = and typing X and (CAR Y) directly to BREAK1 is that ? = evaluates its inputs as of the stack frame LASTPOS, i.e., it uses STKEVAL. This provides a way of examining variables or performing computations as of a particular point on the stack. For example, @ FOO / 2 followed by ? = X will allow you to examine the value of X in the previous call to FOO, etc.

? = also recognizes numbers as referring to the correspondingly numbered argument, i.e., it uses STKARG in this case. Thus

: @ FIE
FIE
?: = 2

will print the name and value of the second argument of FIE.

? = can also be used on BRKCOMS (see Creating Breaks with BREAK1 below), in which case the next command on BRKCOMS is treated as the rest of the teletype line. For example, if BRKCOMS is (EVAL ? = (X Y) GO), BRKEXP is evaluated, the values of X and Y printed, and then the function exited with its value being printed.

? = prints variable values using the function SHOWPRINT (see Chapter 25), so that if SYSPRETTYFLG = T, the value is prettyprinted.

? = is a universal mnemonic for displaying argument names and their corresponding values. In addition to being a break command, ? = is an edit macro that prints the argument names and values for the current expression (see Chapter 16), and a read macro (actually ? is the read macro character) which does the same for the current level list being read.

PB

[Break Command]
Prints the bindings of a given variable. Similar to ? =, except ascends the stack starting from LASTPOS, and, for each frame in which the given variable is bound, prints the frame name and value of the variable (with PRINTLEVEL reset to (2 . 3)), e.g.

: PB FOO
@ FN1:  3
@ FN2:  10
@ TOP: NOBIND

PB is also a programmer’s assistant command (see Chapter 13) that can be used when not in a break. PB is implemented via the function PRINTBINDINGS.

BT

[Break Command]
Prints a backtrace of function names starting at LASTPOS. The value of LASTPOS is changed by selecting an item from the backtrace menu (see the Break Window Variables section below) or by the @ command. The several nested calls in system packages such as break, edit, and the top level executive appear as the single entries **BREAK***, **EDITOR***, and **TOP** respectively.
ERRORS AND DEBUGGING

**BTV**  
[Break Command]  
Prints a backtrace of function names *with* variables beginning at LASTPOS.

The value of each variable is printed with the function SHOWPRINT (see Chapter 25), so that if SYSPRETTYFLG = T, the value is prettyprinted.

**BTV+**  
[Break Command]  
Same as BTV except also prints local variables and arguments to SUBRs.

**BTV**  
[Break Command]  
Same as BTV except prints arguments to local variables.

**BTV!**  
[Break Command]  
Same as BTV except prints *everything* on the stack.

BT, BTV, BTV+, BTV*, and BTV! all take optional functional arguments. Use these arguments to choose functions to be *skipped* on the backtrace. As the backtrace scans down the stack, the name of each stack frame is passed to each of the arguments of the backtrace command. If any of these functions returns a non-NIL value, then that frame is skipped, and not shown in the backtrace. For example, BT EXPRP will skip all functions defined by expr definitions, BTV (LAMBDA (X) (NOT (MEMB X FOOFNS))) will skip all but those functions on FOOFNS. If used on BRKCOMS (see Creating Breaks with BREAK1 below) the functional argument is no longer optional, i.e., the next element on BRKCOMS must either be a list of functional arguments, or NIL if no functional argument is to be applied.

For BT, BTV, BTV+, BTV*, and BTV!, if Control-P is used to change a printlevel during the backtrace, the printlevel is restored after the backtrace is completed.

The value of BREAKDELIMITER, initially the carriage return character, is printed to delimit the output of ?= and backtrace commands. You can reset it (e.g. to a comma) for more linear output.

**ARGS**  
[Break Command]  
Prints the names of the variables bound at LASTPOS, i.e., (VARIABLES LASTPOS) (see Chapter 11). For most cases, these are the arguments to the function entered at that position, i.e., (ARGLIST (STKNAME LASTPOS)).

**REVERT**  
[Break Command]  
Goes back to position LASTPOS on stack and reenters the function called at that point with the arguments found on the stack. If the function is not already broken, REVERT first breaks it, and then unbreaks it after it is reentered.

REVERT can be given the position using the conventions described for @, e.g., REVERT FOO -1 is equivalent to @ FOO -1 followed by REVERT.

REVERT is useful for restarting a computation in the situation where a bug is discovered at some point below where the problem actually occurred. REVERT essentially says “go back there and start over in a break.” REVERT will work correctly if the names or arguments to the function, or even its function type, have been changed.
ORIGINAL

[Break Command]

For use in conjunction with BREAKMACROS (see Creating Breaks with BREAK1 below).
Form is (ORIGINAL . COMS). COMS are executed without regard for BREAKMACROS. Useful for redefining a break command in terms of itself.

EDIT

[Break Command]

Designed for use in conjunction with breaks caused by errors. Facilitates editing the expression causing the break:

```
NON-NUMERIC ARG
NIL
(IPLUS BROKEN)
:EDIT
IN FOO...
(IPLUS X Z)
EDIT
*(3 Y)
*OK
FOO
:
```

and you can continue by typing OK, EVAL, etc.

This command is very simple conceptually, but its implementation is complicated by all of the exceptional cases involving interactions with compiled functions, breaks on user functions, error breaks, breaks within breaks, et al. Therefore, we shall give the following simplified explanation which will account for 90% of the situations arising in actual usage. For those others, EDIT will print an appropriate failure message and return to the break.

EDIT begins by searching up the stack beginning at LASTPOS (set by @ command, initially position of the break) looking for a form, i.e., an internal call to EVAL. Then EDIT continues from that point looking for a call to an interpreted function, or to EVAL. It then calls the editor on either the EXPR or the argument to EVAL in such a way as to look for an expression EQ to the form that it first found. It then prints the form, and permits interactive editing to begin. You can then type successive 0's to the editor to see the chain of superforms for this computation.

If you exit from the edit with an OK, the break expression is reset, if possible, so that you can continue with the computation by simply typing OK. (Evaluating the new BRKEXP will involve reevaluating the form that causes the break, so that if (PUTD (QUOTE (FOO)) BIG-COMPUTATION) were handled by EDIT, BIG-COMPUTATION would be reevaluated.) However, in some situations, the break expression cannot be reset. For example, if a compiled function FOO incorrectly called PUTD and caused the error Arg not atom followed by a break on PUTD, EDIT might be able to find the form headed by FOO, and also find that form in some higher interpreted function. But after you corrected the problem in the FOO-form, if any, you would still not have informed EDIT what to do about the immediate problem, i.e., the incorrect call to PUTD. However, if FOO were interpreted, EDIT would find the PUTD form itself, so that when you corrected that form, EDIT could use the new corrected form to reset the break expression.
ERRORS AND DEBUGGING

IN? [Break Command]

Similar to EDIT, but just prints parent form, and superform, but does not call the editor, e.g.,

\[
\text{ATTEMPT TO RPLAC NIL}
\]
\[
\text{T}
\]
\[
(RPLACD BROKEN)
\]
\[
;IN? (RPLACD X Z)
\]

Although EDIT and IN? were designed for error breaks, they can also be useful for user breaks. For example, if upon reaching a break on his function FOO, you determine that there is a problem in the call to FOO, you can edit the calling form and reset the break expression with one operation by using EDIT.

Controlling When to Break

When an error occurs, the system has to decide whether to reset and unwind the stack, or go into a break. In the middle of a complex computation, it is usually helpful to go into a break, so that you may examine the state of the computation. However, if the computation has only proceeded a little when the error occurs, such as when you mistype a function name, you would normally just terminate a break, and it would be more convenient for the system to simply cause an error and unwind the stack in this situation. The decision over whether or not to induce a break depends on the depth of the computation, and the amount of time invested in the computation. The actual algorithm is described in detail below; suffice it to say that the parameters affecting this decision have been adjusted empirically so that trivial type-in errors do not cause breaks, but deep errors do.

(BREAKCHECK ERRORPOS ERXN) [Function]

BREAKCHECK is called by the error routine to decide whether or not to induce a break when a error occurs. ERRORPOS is the stack position at which the error occurred; ERXN is the error number. Returns T if a break should occur; NIL otherwise.

BREAKCHECK returns T (and a break occurs) if the “computation depth” is greater than or equal to HELPDEPTH. HELPDEPTH is initially set to 7, arrived at empirically by taking into account the overhead due to LISPX or BREAK.

If the depth of the computation is less than HELPDEPTH, BREAKCHECK next calculates the length of time spent in the computation. If this time is greater than HELPTIME milliseconds, initially set to 1000, then BREAKCHECK returns T (and a break occurs), otherwise NIL.

BREAKCHECK determines the “computation depth” by searching back up the stack looking for an ERRORSET frame (ERRORSETs indicate how far back unwinding is to take place when an error occurs, see the Catching Errors section below). At the same time, it counts the number of internal calls to EVAL. As soon as the number of calls to EVAL exceeds HELPDEPTH, BREAKCHECK immediately stops searching for an ERRORSET and returns T. Otherwise, BREAKCHECK continues searching until either an ERRORSET is found or the top of the stack is reached. (If the second argument to ERRORSET is INTERNAL, the ERRORSET is ignored by BREAKCHECK during this search.) BREAKCHECK then counts the number of function calls between the error and the last ERRORSET, or the top of the stack.
The number of function calls plus the number of calls to \texttt{EVAL} (already counted) is used as the “computation depth”.

\texttt{BREAKCHECK} determines the computation time by subtracting the value of the variable \texttt{HELPCLOCK} from the value of \texttt{(CLOCK 2)}, the number of milliseconds of compute time (see Chapter 12). \texttt{HELPCLOCK} is rebound to the current value of \texttt{(CLOCK 2)} for each computation typed in to \texttt{LISPX} or to a break. The time criterion for breaking can be suppressed by setting \texttt{HELPTIME} to \texttt{NIL} (or a very big number), or by setting \texttt{HELPCLOCK} to \texttt{NIL}. Setting \texttt{HELPCLOCK} to \texttt{NIL} will not have any effect beyond the current computation, because \texttt{HELPCLOCK} is rebound for each computation typed in to \texttt{LISPX} and \texttt{BREAK}.

You can suppress all error breaks by setting the top level binding of the variable \texttt{HELPFLAG} to \texttt{NIL} using \texttt{SETTOPVAL} (\texttt{HELPFLAG} is bound as a local variable in \texttt{LISPX}, and reset to the global value of \texttt{HELPFLAG} on every \texttt{LISPX} line, so just \texttt{SETQ}ing it will not work.) If \texttt{HELPFLAG = T} (the initial value), the decision whether to cause an error or break is decided based on the computation time and the computation depth, as described above. Finally, if \texttt{HELPFLAG = BREAK!}, a break will always occur following an error.

\textbf{Break Window Variables}

The appearance and use of break windows is controlled by the following variables:

\begin{itemize}
  \item \textbf{\texttt{(WBREAK ONFLG)}} \hspace{1cm} \textbf{[Function]}
    \begin{itemize}
      \item If \texttt{ONFLG} is non-\texttt{NIL}, break windows and trace windows are enabled. If \texttt{ONFLG} is \texttt{NIL}, break windows are disabled (break windows do not appear, but the executive prompt is changed to “\texttt{:}” to indicate that the system is in a break). \texttt{WBREAK} returns \texttt{T} if break windows are currently enabled; \texttt{NIL} otherwise.
    \end{itemize}
  \item \textbf{MaxBkMenuWidth} \hspace{1cm} \textbf{[Variable]}
  \item \textbf{MaxBkMenuHeight} \hspace{1cm} \textbf{[Variable]}
    \begin{itemize}
      \item The variables \texttt{MaxBkMenuWidth} (default 125) and \texttt{MaxBkMenuHeight} (default 300) control the maximum size of the backtrace menu. If this menu is too small to contain all of the frames in the backtrace, it is made scrollable in both vertical and horizontal directions.
    \end{itemize}
  \item \textbf{AUTOBACKTRACEFLG} \hspace{1cm} \textbf{[Variable]}
    \begin{itemize}
      \item This variable controls when and what kind of backtrace menu is automatically brought up. The value of \texttt{AUTOBACKTRACEFLG} can be one of the following:
        \begin{itemize}
          \item \texttt{NIL} The backtrace menu is not automatically brought up (the default).
          \item \texttt{T} On error breaks the \texttt{BT} menu is brought up.
          \item \texttt{BT!} On error breaks the \texttt{BT!} menu is brought up.
          \item \texttt{ALWAYS} The \texttt{BT} menu is brought up on both error breaks and user breaks (calls to functions broken by \texttt{BREAK}).
          \item \texttt{ALWAYS!} On both error breaks and user breaks the \texttt{BT!} menu is brought up.
        \end{itemize}
    \end{itemize}
\end{itemize}
ERRORS AND DEBUGGING

BACKTRACEFONT [Variable]

The backtrace menu is printed in the font BACKTRACEFONT.

CLOSEBREAKWINDOWFLG [Variable]

The system normally closes break windows after the break is exited. If CLOSEBREAKWINDOWFLG is NIL, break windows will not be closed on exit. In this case, you must close all break windows.

BREAKREGIONSPEC [Variable]

Break windows are positioned near the TTY window of the broken process, as determined by the variable BREAKREGIONSPEC. The value of this variable is a region (see Chapter 27) whose LEFT and BOTTOM fields are an offset from the LEFT and BOTTOM of the TTY window. The WIDTH and HEIGHT fields of BREAKREGIONSPEC determine the size of the break window.

TRACEWINDOW [Variable]

The trace window, TRACEWINDOW, is used for tracing functions. It is brought up when the first tracing occurs and stays up until you close it. TRACEWINDOW can be set to a particular window to cause the tracing formation to print there.

TRACEREGION [Variable]

The trace window is first created in the region TRACEREGION.

Creating Breaks with BREAK1

The basic function of the break package is BREAK1, which creates a break. A break appears to be a regular executive, with the prompt “:”, but BREAK1 also detects and interpretes break commands (see the Break Commands section above).

(BREAK1 BRKEXP BRKWHEN BRKFN BRKCOMS BRKTYPE ERRORN) [NLambda Function]

If BRKWHEN (evaluated) is non-NIL, a break occurs and commands are then taken from BRKCOMS or the terminal and interpreted. All inputs not recognized by BREAK1 are simply passed on to the programmer’s assistant.

If BRKWHEN is NIL, BRKEXP is evaluated and returned as the value of BREAK1, without causing a break.

When a break occurs, if ERRORN is a list whose CAR is a number, ERRORMESS (see the Signalling Errors section below) is called to print an identifying message. If ERRORN is a list whose CAR is not a number, ERRORMESS1 (see the Signalling Errors section below) is called. Otherwise, no preliminary message is printed. Following this, the message (BRKFN broken) is printed.

Since BREAK1 itself calls functions, when one of these is broken, an infinite loop would occur. BREAK1 detects this situation, and prints Break within a break on FN, and then simply calls the function without going into a break.
The commands GO, !GO, OK, !OK, RETURN and ↑ are the only ways to leave BREAK1. The command EVAL causes BRKEXP to be evaluated, and saves the value on the variable !VALUE. Other commands can be defined for BREAK1 via BREAKMACROS (below).

BRKTYPE is NIL for user breaks, INTERRUPT for Control-H breaks, and ERRORX for error breaks. For breaks when BRKTYPE is not NIL, BREAK1 will clear and save the input buffer. If the break returns a value (i.e., is not aborted via ↑ or Control-D) the input buffer is restored.

The fourth argument to BREAK1 is BRKCOMS, a list of break commands that BREAK1 interprets and executes as though they were keyboard input. One can think of BRKCOMS as another input file which always has priority over the keyboard. Whenever BRKCOMS = NIL, BREAK1 reads its next command from the keyboard. Whenever BRKCOMS is non-NIL, BREAK1 takes (CAR BRKCOMS) as its next command and sets BRKCOMS to (CDR BRKCOMS). For example, suppose you wished to see the value of the variable X after a function was evaluated. You could set up a break with BRKCOMS = (EVAL (PRINT X) OK), which would have the desired effect. If BRKCOMS is non-NIL, the value of a break command is not printed. If you desire to see a value, you must print it yourself, as in the above example. The function TRACE (see Chapter 15) uses BRKCOMS: it sets up a break with two commands; the first one prints the arguments of the function, or whatever you specify, and the second is the command GO, which causes the function to be evaluated and its value printed.

Note: If an error occurs while interpreting the BRKCOMS commands, BRKCOMS is set to NIL, and a full interactive break occurs.

The break package has a facility for redirecting output to a file. All output resulting from BRKCOMS is output to the value of the variable BRKFILE, which should be the name of an open file. Output due to user type-in is not affected, and will always go to the terminal. BRKFILE is initially T.

BREAKMACROS

BREAKMACROS is a list of the form ((NAME1 COM11 ... COM1n) (NAME2 COM21 ... COM2n) ...). Whenever an atomic command is given to BREAK1, it first searches the list BREAKMACROS for the command. If the command is equal to NAMEi, BREAK1 simply appends the corresponding commands to the front of BRKCOMS, and goes on. If the command is not found on BREAKMACROS, BREAK1 then checks to see if it is one of the built in commands, and finally, treats it as a function or variable as before.

If the command is not the name of a defined function, bound variable, or LISPX command, BREAK1 will attempt spelling correction using BREAKCOMSLLST as a spelling list. If spelling correction is unsuccessful, BREAK1 will go ahead and call LISPX anyway, since the atom may also be a misspelled history command.

For example, the command ARGS could be defined by including on BREAKMACROS the form:

ARGS (PRINT (VARIABLES LASTPOS T))
(BREAKREAD TYPE)  

[Function]

Useful within BREAKMACROS for reading arguments. If BRKCOMS is non-NIL (the command in which the call to BREAKREAD appears was not typed in), returns the next break command from BRKCOMS, and sets BRKCOMS to (CDR BRKCOMS).

If BRKCOMS is NIL (the command was typed in), then BREAKREAD returns either the rest of the commands on the line as a list (if TYPE = LINE) or just the next command on the line (if TYPE is not LINE).

For example, the BT command is defined as (BAKTRACE LASTPOS NIL (BREAKREAD 'LINE) 0 T). Thus, if you type BT, the third argument to BAKTRACE is NIL. If you type BT SUBRP, the third argument is (SUBRP).

BREAKRESETFORMS  

[Variable]

If you are developing programs that change the way a user and Medley normally interact (e.g., change or disable the interrupt or line-editing characters, turn off echoing, etc.), debugging them by breaking or tracing may be difficult, because Medley might be in a “funny” state at the time of the break. BREAKRESETFORMS is designed to solve this problem. You put in BREAKRESETFORMS expressions suitable for use in conjunction with RESETFORM or RESETSAVE (see Changing and Restoring System State below). When a break occurs, BREAK1 evaluates each expression on BREAKRESETFORMS before any interaction with the terminal, and saves the values. When the break expression is evaluated via an EVAL, OK, or GO, BREAK1 first restores the state of the system with respect to the various expressions on BREAKRESETFORMS. When control returns to BREAK1, the expressions on BREAKRESETFORMS are again evaluated, and their values saved. When the break is exited with an OK, GO, RETURN, or ↑ command, by typing Control-D, or by a RETFROM or RETEVAL you type in, BREAK1 again restores state. Thus the net effect is to make the break invisible with respect to your programs, but nevertheless allow you to interact in the break in the normal fashion.

All user type-in is scanned to make the operations undoable, as described in Chapter 13. At this point, RETFROMs and RETEVALs are also noticed. However, if you type in an expression which calls a function that then does a RETFROM, this RETFROM will not be noticed, and the effects of BREAKRESETFORMS will not be reversed.

As mentioned earlier, BREAK1 detects “Break within a break” situations, and avoids infinite loops. If the loop occurs because of an error, BREAK1 simply rebinds BREAKRESETFORMS to NIL, and calls HELP. This situation most frequently occurs when there is a bug in a function called by BREAKRESETFORMS.

SETQ expressions can also be included on BREAKRESETFORMS for saving and restoring system parameters, e.g. (SETQ LISPXHISTORY NIL), (SETQ DWIMFLG NIL), etc. These are handled specially by BREAK1 in that the current value of the variable is saved before the SETQ is executed, and upon restoration, the variable is set back to this value.
MEDLEY REFERENCE MANUAL

Signalling Errors

With the Medley release, Interlisp errors use the Xerox Common Lisp (XCL) error system. Most of the functions still exist for compatibility with previous releases, but the underlying machinery has changed. There are some incompatible differences, especially with respect to error numbers. All errors are now handled by signalling an object of type XCL::CONDITION. This means the error numbers generated are different from the old Interlisp method of registered numbers for well-known errors and error messages for all other errors. The mapping from Interlisp errors to Lisp error conditions is listed in the Error List sections below. The obsolete error numbers still generate error messages, but they are useless.

(ERRORX ERXM)

Calls CL::ERROR after first converting ERXM into a condition. If ERXM is NIL the value of *LAST-CONDITION* is used. If ERXM is an Interlisp error descriptor, it is first converted to a condition. If ERXM is already a condition, it is passed along unchanged. ERRORX also sets a proceed case for XCL::PROCEED, which will attempt to re-evaluate the caller of ERRORX, much as OK did in older versions of the break package.

(ERROR MESS1 MESS2 NOBREAK)

Prints MESS1 (using PRIN1), followed by a space if MESS1 is an atom, otherwise a carriage return. Then MESS2 is printed (using PRIN1 if MESS2 is a string; otherwise PRINT). For example, (ERROR "NON-NUMERIC ARG" T) prints NON-NUMERIC ARG T and (ERROR 'FOO "NOT A FUNCTION") prints FOO NOT A FUNCTION. If both MESS1 and MESS2 are NIL, the message printed is simply ERROR.

If NOBREAK = T, ERROR prints its message and then calls ERROR! (below). Otherwise it calls (ERRORX '(17 (MESS1 . MESS2))), i.e., generates error number 17, in which case the decision as to whether to break, and whether to print a message, is handled as any other error.

If the value of HELPFLAG (see the Controlling When to Break section above) is BREAK!, a break will always occur, irregardless of the value of NOBREAK.

If ERROR causes a break, the “break expression” is (ERROR MESS1 MESS2 NOBREAK). Using the GO, OK, or EVAL break commands (see the Break Commands section above) will simply call ERROR again. It is sometimes helpful to design programs that call ERROR such that if the call to ERROR returns (as the result of using the RETURN break command), the operation is tried again. This lets you fix any problems within the break environment, and try to continue the operation.

HELP MESS1 MESS2 BRKTYPE)

Prints MESS1 and MESS2 similar to ERROR, and then calls BREAK1 passing BRKTYPE as the BRKTYPE argument. If both MESS1 and MESS2 are NIL, Help! is used for the message. HELP is a convenient way to program a default condition, or to terminate some portion of a program which the computation is theoretically never supposed to reach.
ERRORS AND DEBUGGING

(Shouldn't MESS) [Function]
Useful in situations when a program detects a condition that should never occur. Calls HELP with the message arguments MESS and “Shouldn’t happen!” and a BRKTYPE argument of ’ERRORX.

(ERROR!) [Function]
Equivalent to XCL:ABORT, except that if no ERRORSET or XCL:CATCH-ABORT isa found, it unwinds to the top of the process.

(RESET) [Function]
Programmable Control-D; immediately returns to the top level.

*LAST-CONDITION* [Variable]
Value is the condition object most recently signaled.

(SetERROR Num MESS) [Function]
Converts its arguments into a condition, then sets the value of *LAST-CONDITION* to the result.

(ERRORMESS U) [Function]
Prints message corresponding to its first argument. For example, (ERRORMESS ’(17 T)) would print: T is not a LIST

(ERRORMESS1 MESS1 MESS2 MESS3) [Function]
Prints the message corresponding to a HELP or ERROR break.

(ERRORSTRING X) [Function]
Returns as a new string the message corresponding to error number X, e.g., (ERRORSTRING 10) = “NON-NUMERIC ARG”.

Catching Errors
All error conditions are not caused by program bugs. For some programs, it is reasonable for some errors to occur (such as file not found errors) and it is possible for the program to handle the error itself. There are a number of functions that allow a program to “catch” errors, rather than abort the computation or cause a break.

(ERRORSET FORM FLAG) [Function]
Performs (EVAL FORM). If no error occurs in the evaluation of FORM, the value of ERRORSET is a list containing one element, the value of (EVAL FORM). If an error did occur, the value of ERRORSET is NIL.

ERRORSET is a lambda function, so its arguments are evaluated before it is entered, i.e., (ERRORSET X) means EVAL is called with the value of X. In most cases, ERSETQ and NLSETQ (below) are more useful.
Note: Beginning with the Medley release, there are no longer frames named ERRORSET on the stack and any programs that explicitly look for them must be changed.

Performance Note: When a call to ERSETQ or NLSETQ is compiled, the form to be evaluated is compiled as a separate function. However, compiling a call to ERRORSET does not compile FORM. Therefore, if FORM performs a lengthy computation, using ERSETQ or NLSETQ can be much more efficient than using ERRORSET.

The argument FLAG controls the printing of error messages if an error occurs. If a break occurs below an ERRORSET, the message is printed regardless of the value of FLAG.

If FLAG = T, the error message is printed; if FLAG = NIL, the error message is not printed (unless NLSETQGAG is NIL, see below).

If FLAG = INTERNAL, this ERRORSET is ignored for the purpose of deciding whether or not to break or print a message (see the Controlling When to Break section above). However, the ERRORSET is in effect for the purpose of flow of control, i.e., if an error occurs, this ERRORSET returns NIL.

If FLAG = NOBREAK, no break will occur, even if the time criterion for breaking is met (the Controlling When to Break section above). FLAG = NOBREAK will not prevent a break from occurring if the error occurs more than HELPDEPTH function calls below the errorset, since BREAKCHECK will stop searching before it reaches the ERRORSET. To guarantee that no break occurs, you would also either have to reset HELPDEPTH or HELPFLAG.

(ERSETQ FORM) [NLambda Function]
Evaluates FORM, letting a break happen if an error occurs, but 9 returns you back to the ERSETQ. Performs (ERRORSET 'FORM T), printing error messages.

(NLSETQ FORM) [NLambda Function]
Evaluates FORM, without breaking, returning NIL if an error occurs or a list containing FORM if no error occurs. Performs (ERRORSET 'FORM NIL), without printing error messages.

NLSETQGAG [Variable]
If NLSETQGAG is NIL, error messages will print, regardless of the FLAG argument of ERRORSET. NLSETQGAG effectively changes all NLSETQs to ERSETQs. NLSETQGAG is initially T.

Changing and Restoring System State

In Medley, a computation can be interrupted/aborted at any point due to an error, or more forcefully, because a Control-D was typed, causing return to the top level. This situation creates problems for programs that need to perform a computation with the system in a "different state", e.g., different radix, input file, readable, etc. but want to be able to restore the state when the computation has completed. While program errors and Control-E are "caught" by ERRORSETs, Control-D is not. The program could redefine Control-D as a user interrupt (see Chapter 30), check for it, reenable it, and
call **RESET** or something similar. Thus the system may be left in its changed state as a result of the computation being aborted. The following functions address this problem.

These functions cannot handle the situation where their environment is exited via anything other than a normal return, an error, or a reset. Therefore, a **RETEVAL**, **RETFROM**, **RESUME**, etc., will never be seen.

\[**RESETLST** \ FORM\_i \ldots \ FORM\_n\]  

**RESETLST** evaluates its arguments in order, after setting up an **ERRORSET** so that any reset operations performed by **RESETSAVE** (see below) are restored when the forms have been evaluated (or an error occurs, or a Control-D is typed). If no error occurs, the value of **RESETLST** is the value of **FORM\_n**, otherwise **RESETLST** generates an error (after performing the necessary restorations).

**RESETLST** compiles open.

\[**RESETSAVE** \ X \ Y\]  

**RESETSAVE** is used within a call to **RESETLST** to change the system state by calling a function or setting a variable, while specifying how to restore the original system state when the **RESETLST** is exited (normally, or with an error or Control-D).

If \(X\) is atomic, resets the top level value of \(X\) to the value of \(Y\). For example, \(\text{(RESETSAVE LISPXHISTORY EDITHISTORY)}\) resets the value of **LISPXHISTORY** to the value of **EDITHISTORY**, and provides for the original value of **LISPXHISTORY** to be restored when the **RESETLST** completes operation, (or an error occurs, or a Control-D is typed).

**Note**: If the variable is simply rebound, the **RESETSAVE** will not affect the most recent binding but will change only the top level value, and therefore probably not have the intended effect.

If \(X\) is not atomic, it is a form that is evaluated. If \(Y\) is **NIL**, \(X\) must return as its value its “former state”, so that the effect of evaluating the form can be reversed, and the system state can be restored, by applying **CAR** of \(X\) to the value of \(X\). For example, \(\text{(RESETSAVE (RADIX 8))}\) performs \(\text{(RADIX 8)}\), and provides for **RADIX** to be reset to its original value when the **RESETLST** completes by applying **RADIX** to the value returned by \(\text{(RADIX 8)}\).

In the special case that **CAR** of \(X\) is **SETQ**, the **SETQ** is transparent for the purposes of **RESETSAVE**, i.e. you could also have written \(\text{(RESETSAVE \ SETQ X \ (RADIX 8))}\), and restoration would be performed by applying **RADIX**, not **SETQ**, to the previous value of **RADIX**.

If \(Y\) is **NIL**, it is evaluated (before \(X\)), and its **value** is used as the restoring expression. This is useful for functions which do not return their “previous setting”. For example,

\[\text{[RESETSAVE \ (SETBRK \ldots) \ LIST \ SETBRK \ GETBRK]}\]

will restore the break characters by applying **SETBRK** to the value returned by **GETBRK**, which was computed before the **SETBRK \ldots** expression was evaluated. The restoration expression is “evaluated” by applying its **CAR** to its **CDR**. This insures that the “arguments” in the **CDR** are not evaluated again.
If X is NIL, Y is still treated as a restoration expression. Therefore,

\[(\text{RESETSAVE} \, \text{NIL} \, \text{LIST} \, \text{"CLOSEFILE"})\]

will cause FILE to be closed when the \text{RESETLST} that the \text{RESETSAVE} is under completes
(or an error occurs or a Control-D is typed).

\text{RESETSAVE} can be called when \textit{not} under a \text{RESETLST}. In this case, the restoration is
performed at the next \text{RESET}, i.e., Control-D or call to \text{RESET}. In other words, there is an
"implicit" \text{RESETLST} at the top-level executive.

\text{RESETSAVE} compiles open. Its value is not a "useful" quantity.

\[(\text{RESETVAR} \, \text{VAR} \, \text{NEWVALUE} \, \text{FORM})\]

\text{Simplified form of \text{RESETLST} and \text{RESETSAVE} for resetting and restoring global
variables. Equivalent to \text{(RESETLST} \, \text{(RESETSAVE} \, \text{VAR} \, \text{NEWVALUE}) \, \text{FORM}). For example, \text{(RESETVAR} \, \text{LISPXHISTORY} \, \text{EDITHISTORY} \, \text{(FOO)}) \text{resets LISPXHISTORY to
the value of EDITHISTORY while evaluating \text{(FOO)}. \text{RESETVAR} compiles open. If no
error occurs, its value is the value of \text{FORM}.}

\[(\text{RESETVARS} \, \text{VARSLST} \, \text{E1} \, \text{E2} \ldots \text{EN})\]

\text{Similar to \text{PROG}, except that the variables in \text{VARSLST} are global variables. In a deep
bound system (like Medley), each variable is "rebound" using \text{RESETSAVE}.}

In a shallow bound system (like Interlisp-10) \text{RESETVARS} and \text{PROG} are identical, except
that the compiler insures that variables bound in a \text{RESETVARS} are declared as \text{SPECVARS}
(see Chapter 18).

\text{RESETVARS, like GETATOMVAL and SETATOMVAL (see Chapter 2), is provided to permit
compatibility (i.e. transportability) between a shallow bound and deep bound system
with respect to conceptually global variables.}

\text{Note: Like PROG, \text{RESETVARS} returns \text{NIL} unless a RETURN statement is executed.}

\[(\text{RESETFORM} \, \text{RESETFORM} \, \text{FORM1} \, \text{FORM2} \ldots \text{FORMN})\]

\text{Simplified form of \text{RESETLST} and \text{RESETSAVE} for resetting a system state when
the corresponding function returns as its value the "previous setting." Equivalent to
\text{(RESETLST} \, \text{(RESETSAVE} \, \text{RESETFORM} \, \text{FORM1} \, \text{FORM2} \ldots \text{FORMN})\}. For example,
\text{(RESETFORM} \, \text{(RADIX 8)} \, \text{(FOO)}) \text{. \text{RESETFORM} compiles open. If no error occurs, it
returns the value returned by \text{FORMN}.}

For some applications, the restoration operation must be different depending on whether the
computation completed successfully or was aborted somehow (e.g., by an error or by typing Control-
D). To facilitate this, while the restoration operation is being performed, the value of \text{RESETSTATE} is
bound to \text{NIL, ERROR, RESET, or HARDRESET} depending on whether the exit was normal, due to an
error, due to a reset (i.e., Control-D), or due to call to \text{HARDRESET} (see Chapter 23). As an example of
the use of \text{RESETSTATE},

\[(\text{RESETLST} \, \text{(RESETSAVE} \, \text{INFILE} \, \text{X})\]
ERRORS AND DEBUGGING

(LIST ' [LAMBDA (FL)
        (COND ((EQ RESETSTATE 'RESET)
                (CLOSEF FL)
                DELFILE FL]
                X))]
FORMS)

will cause X to be closed and deleted only if a Control-D was typed during the execution of FORMS.

When specifying complicated restoring expressions, it is often necessary to use the old value of the saving expression. For example, the following expression will set the primary input file (to FL) and execute some forms, but reset the primary input file only if an error or Control-D occurs.

(RESETLST
  (SETQ TEM (INPUT FL))
  (RESETSAVE NIL
   (LIST ' (LAMBDA (X) (AND RESETSTATE (INPUT X)))
         TEM))
FORMS)

So that you will not have to explicitly save the old value, the variable OLDVALUE is bound at the time the restoring operation is performed to the value of the saving expression. Using this, the previous example could be recoded as:

(RESETLST
  (RESETSAVE (INPUT FL)
            ' (AND RESETSTATE (INPUT OLDVALUE)))
FORMS)

As mentioned earlier, restoring is performed by applying CAR of the restoring expression to the CDR, so RESETSTATE and (INPUT OLDVALUE) will not be evaluated by the APPLY. This particular example works because AND is an nlambda function that explicitly evaluates its arguments, so APPLYing AND to (RESETSTATE (INPUT OLDVALUE)) is the same as EVALing (AND RESETSTATE (INPUT OLDVALUE)). PROGN also has this property, so you can use a lambda function as a restoring form by enclosing it within a PROGN.

The function RESETUNDO (see Chapter 13) can be used in conjunction with RESETLST and RESETSAVE to provide a way of specifying that the system be restored to its prior state by undoing the side effects of the computations performed under the RESETLST.

Error List

There are currently fifty-plus types of errors in Medley. Some of these errors are implementation dependent, i.e., appear in Medley but may not appear in other Interlisp systems. The error number is set internally by the code that detects the error before it calls the error handling functions, and is used by ERRORMESS for printing error messages.

Most errors will print the offending expression as part of the error message. Error number 18 (Control-B) always causes a break (unless HELPFLAG is NIL). All other errors cause breaks if BREAKCHECK returns T (see Controlling When to Break above).

The following error messages are arranged numerically with the printed message next to the error number. X is the offending expression in each error message. The obsolete error numbers still generate error messages, but they aren’t particularly useful. For information on how to use the Common Lisp error conditions in your own programs, see Common Lisp: the Language by Steele.
MEDLEY REFERENCE MANUAL

0 Obsolete.

1 Obsolete.

2 Stack Overflow
Occurs when computation is too deep, either with respect to number of function calls, or number of variable bindings. Usually because of a non-terminating recursive computation, i.e., a bug. Condition type: STACK-OVERFLOW.

3 RETURN to nonexistent block: 
Call to RETURN when not inside of an interpreted PROG. Condition type: ILLEGAL-RETURN.

4 X is not a LIST
RPLACA called on a non-list. Condition type: XCL:SMPLE-TYPE-ERROR culprit :EXPECTED-TYPE 'LIST

5 Device error: X
An error with the local disk drive. Condition type: XCL:SMPLE-DEVICE-ERROR message

6 Serious condition XCL:ATTEMPT-TO-CHANGE-CONSTANT occurred.
Via SET or SETQ. Condition type: XCL:ATTEMPT-TO-CHANGE-CONSTANT

7 Attempt to rplac NIL with X
Attempt either to RPLACA or to RPLACD NIL with something other than NIL. Condition type: XCL:ATTEMPT-TO-RPLAC-NIL message

8 GO to a nonexistent tag: X
GO when not inside of a PROG, or GO to nonexistent label. Condition type: ILLEGAL-GO tag

9 File won't open: X
From OPENSTREAM (see Chapter 24). Condition type: XCL:FILE-WONT-OPEN pathname

10 X is not a NUMBER
A numeric function e.g., PLUS, TIMES, GREATERP, expected a number and didn’t get one. Condition type: XCL:SMPLE-TYPE-ERROR culprit :EXPECTED-TYPE 'CL:NUMBER

11 Symbol name too long
Attempted to create a symbol (via PACK, or typing one in, or reading from a file) with too many characters. In Medley, the maximum number of characters in a symbol is 255. Condition type: XCL:SMPLE-NAME-TOO-LONG

12 Symbol hash table full
No room for any more (new) atoms. Condition type: XCL:SMPLE-HT-FULL

13 Stream not open: X
From an I/O function, e.g., READ, PRINT, CLOSEF. Condition type: XCL:SMPLE-STREAM-NOT-OPEN stream

14 X is not a SYMBOL.
SETQ, PUTPROP, GETTOPVAL, etc., given a non-atomic argument. Condition type: XCL:SMPLE-TYPE-ERROR culprit :EXPECTED-TYPE 'CL:SMPLE-
15 Obsolete

16 **End of file X**
From an input function, e.g., READ, READC, RATOM. After the error occurs, the file will still be left open. Condition type: **END-OF-FILE** stream

17 **X varying messages.**
Call to ERROR (see Signalling Errors above). Condition type: **INTERLISP-ERROR MESSAGE**

18 Obsolete

19 **Illegal stack arg: X**
A stack function expected a stack position and was given something else. This might occur if the arguments to a stack function are reversed. Also occurs if you specified a stack position with a function name, and that function was not found on the stack (see Chapter 11). Condition type: **ILLEGAL-STACK-ARG** arg.

20 Obsolete

21 **Array space full**
System will first initiate a garbage collection of array space, and if no array space is reclaimed, will then generate this error. Condition type: **XCL:ARRAY-SPACE-FULL**

22 **File system resources exceeded: X**
Includes no more disk space, disk quota exceeded, directory full, etc. Condition type: **XCL:FS-RESOURCE-EXCEEDED**

23 **File not found**
File name does not correspond to a file in the corresponding directory. Can also occur if file name is ambiguous. Condition type: **XCL:FILE-NOT-FOUND** pathname

24 Obsolete

25 **Invalid argument: X**
A form ends in a non-list other than NIL, e.g., (CONS T 3). Condition type: **INVALID-ARGUMENT-LIST** argument

26 **Hash table full: X**
See hash array functions, Chapter 6. Condition type: **XCL:HASH-TABLE-FULL** table

27 **Invalid argument: X**
Catch-all error. Currently used by PUTD, EVALA, ARG, FUNARG, etc. Condition type: **INVALID-ARGUMENT-LIST** argument

28 **X is not a ARRAYP.**
ELT or SETA given an argument that is not a legal array (see Chapter 5). Condition type: **XCL:SIMPLE-TYPE-ERROR** culprit :EXPECTED-TYPE 'ARRAYP

29 Obsolete

30 **Stack ptr ahs been released NOBIND**
A released stack pointer was supplied as a stack descriptor for a purpose other than as a stack pointer to be re-used (see Chapter 11). Condition type: **STACK-POINTER-RELEASED** name
Serious condition XCL:STORAGE-EXHAUSTED occurred.
Following a garbage collection, if not enough words have been collected, and there is no unallocated space left in the system, this error is generated. Condition type: XCL:STORAGE-EXHAUSTED

Obsolete

No more data types available
All available user data types have been allocated (see Chapter 8). Condition type: XCL:DATA-TYPES-EXHAUSTED

Serious condition XCL:ATTEMPT-TO-CHANGE-CONSTANT occurred.
In a PROG or LAMBDA expression. Condition type: XCL:ATTEMPT-TO-CHANGE-CONSTANT

Obsolete

X is not a READTABLEP.
The argument was expected to be a valid read table (see Chapter 25). Condition type: XCL:SIMPLE-TYPE-ERROR culprit :EXPECTED-TYPE 'READTABLEP

X is not a TERMTABLEP.
The argument was expected to be a valid terminal table (see Chapter 30). Condition type: XCL:SIMPLE-TYPE-ERROR culprit :EXPECTED-TYPE 'TERMTABLEP

Protection violation: X
Attempt to open a file that you do not have access to. Also reference to unassigned device. Condition type: XCL:FS-PROTECTION-VIOLATION

Invalid pathname: X
Illegal character in file specification, illegal syntax, e.g. two ;'s etc. Condition type: XCL:INVALID-PATHNAME pathname

Obsolete

X is an unbound variable
This occurs when a variable (symbol) was used which had neither a stack binding (wasn’t an argument to a function nor a PROG variable) nor a top level value. The “culprit” ((CADR ERRORMESS)) is the symbol. If DWIM corrects the error, no error occurs and the error number is not set. However, if an error is going to occur, whether or not it will cause a break, the error number will be set. Condition type: UNBOUND-VARIABLE name

Serious condition UNDEFINED-CAR-OF-FORM occurred.
Undefined function error. This occurs when a form is evaluated whose function position (CAR) does not have a definition as a function. Condition type: UNDEFINE-CAR-OF-FORM function
46  X varying messages.
    This error is generated if APPLY is given an undefined function. Culprit is (LIST FN ARGS)
    Condition type: UNDEFINED-FUNCTION-IN-APPLY
47  CONTROL-E
    Control-E was typed. Condition type: XCL:CONTROL-E-INTERRUPT
48  Floating point underflow.
    Underflow during floating-point operation. Condition type: XCL:FLOATING-UNDERFLOW
49  Floating point overflow.
    Overflow during floating-point operation. Condition type: XCL:OVERFLOW
50  Obsolete
51  X is not a HASH-TABLE
    Hash array operations given an argument that is not a hash array. Condition type: XCL:SIMPLE-TYPE-ERROR culprit :EXPECTED-TYPE 'CL:HASH-TABLE
52  Too many arguments to X
    Too many arguments given to a lambda-spread, lambda-nospread, or nlambda-spread function.
    Medley does not cause an error if more arguments are passed to a function than it is defined with.
    This argument occurs when more individual arguments are passed to a function than Medley can
    store on the stack at once. The limit is currently 80 arguments.
    In addition, many system functions, e.g., DEFINE, ARGLIST, ADVISE, LOG, EXPT, etc, also
    generate errors with appropriate messages by calling ERROR (see Signalling Errors above) which
    causes error number 17. Condition type: TOO-MANY-ARGUMENTS callee :MAXIMUM
    CL:CALL-ARGUMENTS-LIMIT
[This page intentionally left blank]
15. BREAKING, TRACING, AND ADVISING

Medley provides several different facilities for modifying the behavior of a function without actually editing its definition. By “breaking” a function, you can cause breaks to occur at various times in the running of an incomplete program, so that the program state can be inspected. “Tracing” a function causes information to be printed every time the function is entered or exited.

“Advising” is a facility for specifying longer-term function modifications. Even system functions can be changed through advising.

Breaking Functions and Debugging

Debugging a collection of Lisp functions involves isolating problems within particular functions and/or determining when and where incorrect data are being generated and transmitted. In the Medley, there are three facilities which allow you to (temporarily) modify selected function definitions so that you can follow the flow of control in your programs, and obtain this debugging information. All three redefine functions in terms of a system function, BREAK1 (see Chapter 14).

BREAK modifies the definition of a function \( FN \), so that whenever \( FN \) is called and a break condition (user-defined) is satisfied, a function break occurs. You can then interrogate the state of the machine, perform any computation, and continue or return from the call.

TRACE modifies a definition of a function \( FN \) so that whenever \( FN \) is called, its arguments (or some other user-specified values) are printed. When the value of \( FN \) is computed it is printed also. TRACE is a special case of BREAK.

BREAKIN allows you to insert a breakpoint inside an expression defining a function. When the breakpoint is reached and if a break condition (defined by you) is satisfied, a temporary halt occurs and you can again investigate the state of the computation.

The following two examples illustrate these facilities. In the first example, the function \( FACTORIAL \) is traced. TRACE redefines \( FACTORIAL \) so that it print its arguments and value, and then goes on with the computation. When an error occurs on the fifth recursion, a full interactive break occurs. The situation is then the same as though \( (\text{BREAK FACTORIAL}) \) had been performed instead of \( (\text{TRACE FACTORIAL}) \), now you can evaluate various Interlisp forms and direct the course of the computation. In this case, the variable \( N \) is examined, and BREAK1 is instructed to return 1 as the value of this cell to \( FACTORIAL \). The rest of the tracing proceeds without incident. Presumably, \( FACTORIAL \) would be edited to change \( L \) to 1.

```lisp
\( \leftarrow \text{PP FACTORIAL}
(\text{FACTORIAL}
 [\text{LAMBDA} (N)
 (\text{COND} ((\text{ZEROP} N)
 (L)
 (T (\text{TIMES} N (\text{FACTORIAL} (SUB1 N)))))
 \text{FACTORIAL}
 \leftarrow (\text{TRACE FACTORIAL})
 (\text{FACTORIAL})
 \leftarrow (\text{FACTORIAL} 4)
 \text{FACTORIAL}:
 N = 4\)```

15 - 1
In the second example, a non-recursive definition of FACTORIAL has been constructed. BREAKIN is used to insert a call to BREAK1 just after the PROG label LOOP. This break is to occur only on the last two iterations, when N is less than 2. When the break occurs, in trying to look at the value of N, NN is mistakenly typed. The break is maintained, however, and no damage is done. After examining N and M the computation is allowed to continue by typing OK. A second break occurs after the next iteration, this time with N = 0. When this break is released, the function FACTORIAL returns its value of 120.

←PP FACTORIAL

((FACTORIAL) BROKEN)
:N
:OK
(FACTORIAL)
120 ←

Note: BREAK and TRACE can also be used on CLISP words which appear as CAR of form, e.g. FETCH, REPLACE, IF, FOR, DO, etc., even though these are not implemented as functions. For conditional breaking, you can refer to the entire expression via the variable EXP, e.g. (BREAK (FOR (MEMB 'UNTIL EXP))).

(BREAK0 FN WHEN COMS — —) [Function]

Sets up a break on the function FN; returns FN. If FN is not defined, returns (FN NOT DEFINED).

The value of WHEN, if non-NIL, should be an expression that is evaluated whenever FN is entered. If the value of the expression is non-NIL, a break is entered, otherwise the function simply called and returns without causing a break. This provides the means of conditionally breaking a function.

The value of COMS, if non-NIL, should be a list of break commands, that are interpreted and executed if a break occurs. (See the BRKCOMS argument to BREAK1, Chapter 14.)

BREAK0 sets up a break by doing the following:

Redefines FN as a call to BREAK1 (Chapter 14), passing an equivalent definition of FN, WHEN, FN, and COMS as the BRKEXP, BRKWHEN, BRKFN, and BRKCOMS arguments to BREAK1

Defines a GENSYM (Chapter 2) with the original definition of FN, and puts it on the property list of FN under the property BROKEN

Puts the form (BREAK0 WHEN COMS) on the property list of FN under the property BRKINFO (for use in conjunction with REBREAK)

Adds FN to the front of the list BROKENFNS.

If FN is non-atomic and of the form (FN1 IN FN2), BREAK0 breaks every call to FN1 from within FN2. This is useful for breaking on a function that is called from many places, but where one is only interested in the call from a specific function, e.g., (RPLACA IN FOO), (PRINT IN FIB), etc. It is similar to BREAKIN described below, but can be performed even when FN2 is compiled or blockcompiled, whereas BREAKIN only works on interpreted functions. If FN1 is not found in FN2, BREAK0 returns the value (FN1 NOT FOUND IN FN2).

BREAK0 breaks one function inside another by first calling a function which changes the name of FN, wherever it appears inside of FN2, to that of a new function, FN1-IN-FN2, which is initially given the same function definition as FN1. Then BREAK0 proceeds to
break on \textit{FN1-IN-FN2} exactly as described above. In addition to breaking \textit{FN1-IN-FN2} and adding \textit{FN1-IN-FN2} to the list \textsc{brokenfns}, \textsc{break0} adds \textit{FN1} to the property value for the property \textit{nameschanged} on the property list of \textit{FN2}, and puts \textit{(FN2 . \textit{FN1})} on the property list of \textit{FN1-IN-FN2} under the property \textit{alias}. This will enable \textsc{unbreak} to recognize what changes have been made and restore the function \textit{FN2} to its original state.

If \textit{FN} is nonatomic and not of the above form, \textsc{break0} is called for each member of \textit{FN} using the same values for \textit{when}, \textit{coms}, and \textit{file}. This distributivity permits you to specify complicated break conditions on several functions. For example,

\begin{verbatim}
  (break0 'foo1 ((print prin1) in (foo2 foo3)))
  '(neq x t)
  '(eval ?= (y z) ok)
\end{verbatim}

will break on \textit{foo1}, \textit{print-in-foo2}, \textit{print-in-foo3}, \textit{prin1-in-foo2} and \textit{prin1-in-foo3}.

If \textit{FN} is non-atomic, the value of \textsc{break0} is a list of the functions broken.

\textbf{(\textsc{break} \textit{x})} \hfill \textbf{[NLambda NoSpread Function]}

For each atomic argument, it performs \textsc{break0 \ atom \ t}. For each list, it performs \textsc{apply \ 'break0 \ list}. For example, \textsc{(break \ foo1 \ (foo2 \ (greaterp \ n \ 5) \ (eval)))} is equivalent to \textsc{(break0 \ 'foo1 \ t)} and \textsc{(break0 \ 'foo2 \ '(greaterp \ n \ 5) \ '(eval))}.

\textbf{(\textsc{trace} \textit{x})} \hfill \textbf{[NLambda NoSpread Function]}

For each atomic argument, it performs \textsc{break0 \ atom \ t \ '(trace \ ?= \ nil \ go)}. The flag \textit{trace} is checked for in \textsc{break1} and causes the message \textit{"function: "} to be printed instead of \textsc{\textit{function broken}}.

For each list argument, \textit{car} is the function to be traced, and \textit{cdr} the forms to be viewed, i.e., \textsc{trace} performs:

\begin{verbatim}
  (break0 \ (car \ list) \ t \ (list \ 'trace \ ?= \ (cdr \ list) \ 'go))
\end{verbatim}

For example, \textsc{(trace \ foo1 \ (foo2 \ y))} causes both \textit{foo1} and \textit{foo2} to be traced. All the arguments of \textit{foo1} are printed; only the value of \textit{y} is printed for \textit{foo2}. In the special case when you want to see only the value, you can perform \textsc{(trace \ \textit{function})}. This sets up a break with commands \textsc{(\textit{trace} \ ?= \ \textit{nil} \ go)}.

\textbf{Note:} You can always call \textsc{break0} to obtain combination of options of \textsc{break1} not directly available with \textsc{break} and \textsc{trace}. These two functions merely provide convenient ways of calling \textsc{break0}, and will serve for most uses.

\textbf{Note:} \textsc{break0}, \textsc{break}, and \textsc{trace} print a warning if you try to modify a function on the list \textsc{unsafe.to.modify.fns} (Chapter 10).

\textbf{(\textsc{breakin} \ \textit{fn} \ where \ when \ coms)} \hfill \textbf{[NLambda Function]}

\textsc{breakin} enables you to insert a break, i.e., a call to \textsc{break1} (Chapter 14), at a specified location in the interpreted function \textit{fn}. \textsc{breakin} can be used to insert breaks before or after \textsc{prog} labels, particular \textsc{setq} expressions, or even the evaluation of a variable. This
is because BREAKIN operates by calling the editor and actually inserting a call to BREAK1 at a specified point inside of the function. If FN is a compiled function, BREAKIN returns (FN UNBREAKABLE) as its value.

WHEN should be an expression that is evaluated whenever the break is entered. If the value of the expression is non-NIL, a break is entered, otherwise the function simply called and returns without causing a break. This provides the means of creating a conditional break. For BREAKIN, unlike BREAK0, if WHEN is NIL, it defaults to T.

COMS, if non-NIL, should be a list of break commands, that are interpreted and executed if a break occurs. (See the BRKCONMS argument to BREAK1, Chapter 14.)

WHERE specifies where in the definition of FN the call to BREAK1 is to be inserted. WHERE should be a list of the form (BEFORE ...), (AFTER ...), or (AROUND ...). You specify where the break is to be inserted by a sequence of editor commands, preceded by one of the symbols BEFORE, AFTER, or AROUND, which BREAKIN uses to determine what to do once the editor has found the specified point, i.e., put the call to BREAK1 BEFORE that point, AFTER that point, or AROUND that point. For example, (BEFORE COND) will insert a break before the first occurrence of COND, (AFTER COND 2 1) will insert a break after the predicate in the first COND clause, (AFTER BF (SETQ X &)) after the last place X is set. Note that (BEFORE TTY:) or (AFTER TTY:) permit you to type in commands to the editor, locate the correct point, and verify it, and exit from the editor with OK. BREAKIN then inserts the break BEFORE, AFTER, or AROUND that point.

Note: A STOP command typed to TTY: produces the same effect as an unsuccessful edit command in the original specification, e.g., (BEFORE CONDD). In both cases, the editor aborts, and BREAKIN types (NOT FOUND).

If WHERE is (BEFORE ...) or (AFTER ...), the break expression is NIL, since the value of the break is irrelevant. For (AROUND ...), the break expression will be the indicated form. In this case, you can use the EVAL command to evaluate that form, and examine its value, before allowing the computation to proceed. For example, if you inserted a break after a COND predicate, e.g., (AFTER (EQUAL X Y)), you would be powerless to alter the flow of computation if the predicate were not true, since the break would not be reached. However, by breaking (AROUND (EQUAL X Y)), you can evaluate the break expression, i.e., (EQUAL X Y), look at its value, and return something else if desired.

If FN is interpreted, BREAKIN types SEARCHING... while it calls the editor. If the location specified by WHERE is not found, BREAKIN types (NOT FOUND) and exits. If it is found, BREAKIN puts T under the property BROKEN-IN and (WHERE WHEN COMS) under the the property BRKINFO on the property list of FN, and adds FN to the front of the list BROKENFNs.

Multiple break points, can be inserted with a single call to BREAKIN by using a list of the form ((BEFORE ...) ... (AROUND ...)) for WHERE. It is also possible to call BREAK or TRACE on a function which has been modified by BREAKIN, and conversely to BREAKIN a function which has been redefined by a call to BREAK or TRACE.
The message typed for a \texttt{BREAKIN} break is \((\texttt{FN} \text{ BROKEN})\), where \texttt{FN} is the name of the function inside of which the break was inserted. Any error, or typing control-E, will cause the full identifying message to be printed, e.g., \((\texttt{FOO BROKEN AFTER COND 2 1})\).

A special check is made to avoid inserting a break inside of an expression headed by any member of the list \texttt{NOBREAKS}, initialized to \((\texttt{GO QUOTE *})\), since this break would never be activated. For example, if \((\texttt{GO L})\) appears before the label \(L\), \texttt{BREAKIN} \((\texttt{AFTER L})\) will not insert the break inside of the \texttt{GO} expression, but skip this occurrence of \(L\) and go on to the next \(L\), in this case the label \(L\). Similarly, for \texttt{BEFORE} or \texttt{AFTER} breaks, \texttt{BREAKIN} checks to make sure that the break is being inserted at a “safe” place. For example, if you request a break \((\texttt{AFTER X})\) in \((\texttt{PROG \ldots (SETQ X &) \ldots})\), the break will actually be inserted after \((\texttt{SETQ X &})\), and a message printed to this effect, e.g., \texttt{BREAK INSERTED AFTER (SETQ X &)}.

\begin{verbatim}
(UNBREAK X) [NLambda NoSpread Function]
UNBREAK takes an indefinite number of functions modified by \texttt{BREAK}, \texttt{TRACE}, or \texttt{BREAKIN} and restores them to their original state by calling \texttt{UNBREAK0}. Returns list of values of \texttt{UNBREAK0}.

(UNBREAK) will unbreak all functions on \texttt{BROKENFNS}, in reverse order. It first sets \texttt{BRKINFOLST} to \texttt{NIL}.

(UNBREAK T) unbreaks just the first function on \texttt{BROKENFNS}, i.e., the most recently broken function.

(UNBREAK0 FN \(\rightarrow\)) [Function]
Restores \texttt{FN} to its original state. If \texttt{FN} was not broken, value is \((\texttt{NOT BROKEN})\) and no changes are made. If \texttt{FN} was modified by \texttt{BREAKIN}, \texttt{UNBREAKIN} is called to edit it back to its original state. If \texttt{FN} was created from \((\texttt{FN1 IN FN2})\), (i.e., if it has a property \texttt{ALIAS}), the function in which \texttt{FN} appears is restored to its original state. All dummy functions that were created by the break are eliminated. Adds property value of \texttt{BRKINFO} to the front of \texttt{BRKINFOLST}.

\textbf{Note:} \((\texttt{UNBREAK0 ' (FN1 IN FN2)})\) is allowed: \texttt{UNBREAK0} will operate on \((\texttt{FN1-IN-FN2})\) instead.

(UNBREAKIN FN) [Function]
Performs the appropriate editing operations to eliminate all changes made by \texttt{BREAKIN}. \texttt{FN} may be either the name or definition of a function. Value is \texttt{FN}.

\texttt{UNBREAKIN} is automatically called by \texttt{UNBREAK} if \texttt{FN} has property \texttt{BROKEN-IN} with value \texttt{T} on its property list.

(REBREAK X) [NLambda NoSpread Function]
Nlambda nospread function for rebreaking functions that were previously broken without having to respecify the break information. For each function on \(X\), \texttt{REBREAK} searches \texttt{BRKINFOLST} for break(s) and performs the corresponding operation. Value is a
BREAKING, TRACING, AND ADVISING

list of values corresponding to calls to BREAK0 or BREAKIN. If no information is found for a particular function, returns (FN - NO BREAK INFORMATION SAVED).

(REBREAK) rebreaks everything on BRKINFOLST, so (REBREAK) is the inverse of (UNBREAK).

(REBREAK T) rebreaks just the first break on BRKINFOLST, i.e., the function most recently unbroken.

(CHANGENAME FN FROM TO) [Function]

Replaces all occurrences of FROM by TO in the definition of FN. If FN is defined by an expr definition, CHANGENAME performs (ESUBST TO FROM (GETD FN)) (see Chapter 16). If FN is compiled, CHANGENAME searches the literals of FN (and all of its compiler generated subfunctions), replacing each occurrence of FROM with TO.

Note that FROM and TO do not have to be functions, e.g., they can be names of variables, or any other literals.

CHANGENAME returns FN if at least one instance of FROM was found, otherwise NIL.

(VIRGINFN FN FLG) [Function]

The function that knows how to restore functions to their original state regardless of any amount of breaks, breakins, advising, compiling and saving exprs, etc. It is used by PRETTYPRINT, DEFINE, and the compiler.

If FLG = NIL, as for PRETTYPRINT, it does not modify the definition of FN in the process of producing a "clean" version of the definition; it works on a copy.

If FLG = T, as for the compiler and DEFINE, it physically restores the function to its original state, and prints the changes it is making, e.g., FOO UNBROKEN, FOO UNADVISED, FOO NAMES RESTORED, etc.

Returns the virgin function definition.

Advising

The operation of advising gives you a way of modifying a function without necessarily knowing how the function works or even what it does. Advising consists of modifying the interface between functions as opposed to modifying the function definition itself, as in editing. BREAK, TRACE, and BREAKDOWN, are examples of the use of this technique: they each modify user functions by placing relevant computations between the function and the rest of the programming environment.

The principal advantage of advising, aside from its convenience, is that it allows you to treat anyone’s functions as “black boxes,” and to modify them without concern for their contents or details of operations. For example, you could modify SYSOUT to set SYSDATE to the time and date of creation by (ADVISE 'SYSOUT '(SETQ SYSDATE (DATE))).

As with BREAK, advising works equally well on compiled and interpreted functions. Similarly, it is possible to make a change which only operates when a function is called from some other specified function. For example, you can modify the interface between two particular functions, instead of the
interface between one function and the rest of the world. This latter feature is especially useful for changing the *internal* workings of a system function.

For example, suppose you wanted `TIME` (Chapter 22) to print the results of your measurements to the file `FOO` instead of the terminal. You can accomplish this by `(ADVISE '(((PRIN1 PRINT SPACES) IN TIME) 'BEFORE '(SETQQ U FOO))`.

Advising `PRIN1`, `PRINT`, or `SPACES` directly would have affected all calls to these frequently used functions, whereas advising `(((PRIN1 PRINT SPACES) IN TIME)` affects just those calls to `PRIN1`, `PRINT`, and `SPACES` from `TIME`.

Advice can also be specified to operate after a function has been evaluated. The value of the body of the original function can be obtained from the variable `!VALUE`, as with `BREAK1`.

**Implementation of Advising**

After a function has been modified several times by `ADVISE`, it will look like:

```
(LAMBDA arguments
  (PROG (!VALUE)
    (SETQ !VALUE
      (PROG NIL
        advice1
          .                     ; advice before
          .
          advicen
            (RETURN BODY)))
    advice1
      .                     ; advice after
      .
    advicem
      (RETURN !VALUE)))
```

where `BODY` is equivalent to the original definition. If `FN` was originally an expr definition, `BODY` is the body of the definition, otherwise a form using a `GENSYM` which is defined with the original definition.

The structure of a function modified by `ADVISE` allows a piece of advice to bypass the original definition by using the function `RETURN`. For example, if `(COND ((ATOM X) (RETURN Y)))` were one of the pieces of advice before a function, and this function was entered with `X` atomic, `Y` would be returned as the value of the inner `PROG`, `!VALUE` would be set to `Y`, and control passed to the advice, if any, to be executed after the function. If this same piece of advice appeared after the function, `Y` would be returned as the value of the entire advised function.

The advice `(COND ((ATOM X) (SETQ !VALUE Y)))` after the function would have a similar effect, but the rest of the advice after the function would still be executed.

**Note:** Actually, `ADVISE` uses its own versions of `PROG`, `SETQ`, and `RETURN`, (called `ADV-PROG`, `ADV-SETQ`, and `ADV-RETURN`) to enable advising these functions.
Advise Functions

ADVISE is a function of four arguments: FN, WHEN, WHERE, and WHAT. FN is the function to be modified by advising, WHAT is the modification, or piece of advice. WHEN is either BEFORE, AFTER, or AROUND, and indicates whether the advice is to operate BEFORE, AFTER, or AROUND the body of the function definition. WHERE specifies exactly where in the list of advice the new advice is to be placed, e.g., FIRST, or (BEFORE PRINT) meaning before the advice containing PRINT, or (AFTER 3) meaning after the third piece of advice, or even (: TTY:). If WHERE is specified, ADVISE first checks to see if it is one of LAST, BOTTOM, END, FIRST, or TOP, and operates accordingly. Otherwise, it constructs an appropriate edit command and calls the editor to insert the advice at the corresponding location.

Both WHEN and WHERE are optional arguments, in the sense that they can be omitted in the call to ADVISE. In other words, ADVISE can be thought of as a function of two arguments (ADVISE FN WHAT), or a function of three arguments: (ADVISE FN WHEN WHAT), or a function of four arguments: (ADVISE FN WHEN WHERE WHAT). Note that the advice is always the last argument. If WHEN = NIL, BEFORE is used. If WHERE = NIL, LAST is used.

(ADVISE FN WHEN WHERE WHAT)  [Function]

FN is the function to be advised, WHEN = BEFORE, AFTER, or AROUND, WHERE specifies where in the advice list the advice is to be inserted, and WHAT is the piece of advice.

If FN is of the form (FN, IN, FN2), FN is changed to FN1-IN-FN2 throughout FN2, as with break, and then FN1-IN-FN2 is used in place of FN. If FN1 and/or FN2 are lists, they are distributed as with BREAK0.

If FN is broken, it is unbroken before advising.

If FN is not defined, an error is generated, NOT A FUNCTION.

If FN is being advised for the first time, i.e., if (GETP FN 'ADVISED) = NIL, a GENSYM is generated and stored on the property list of FN under the property ADVISED, and the GENSYM is defined with the original definition of FN. An appropriate expr definition is then created for FN, using private versions of PROG, SETQ, and RETURN, so that these functions can also be advised. Finally, FN is added to the (front of) ADVISEDFNS, so that (UNADVISE T) always unadvises the last function advised.

If FN has been advised before, it is moved to the front of ADVISEDFNS.

If WHEN = BEFORE or AFTER, the advice is inserted in FN’s definition either BEFORE or AFTER the original body of the function. Within that context, its position is determined by WHERE. If WHERE = LAST, BOTTOM, END, or NIL, the advice is added following all other advice, if any. If WHERE = FIRST or TOP, the advice is inserted as the first piece of advice. Otherwise, WHERE is treated as a command for the editor, similar to BREAKIN, e.g., (BEFORE 3), (AFTER PRINT).

If WHEN = AROUND, the body is substituted for * in the advice, and the result becomes the new body, e.g., (ADVISE ‘FOO ‘AROUND ‘(RESETFORM (OUTPUT T) *))]. Note that if several pieces of AROUND advice are specified, earlier ones will be embedded inside later ones. The value of WHERE is ignored.
Finally (LIST WHEN WHERE WHAT) is added (by ADDPROP) to the value of property ADVICE on the property list of FN, so that a record of all the changes is available for subsequent use in readvising. Note that this property value is a list of the advice in order of calls to ADVISE, not necessarily in order of appearance of the advice in the definition of FN.

The value of ADVISE is FN.

If FN is non-atomic, every function in FN is advised with the same values (but copies) for WHEN, WHERE, and WHAT. In this case, ADVISE returns a list of individual functions.

Note: Advised functions can be broken. However if a function is broken at the time it is advised, it is first unbroken. Similarly, advised functions can be edited, including their advice. UNADVISE will still restore the function to its unadvised state, but any changes to the body of the definition will survive. Since the advice stored on the property list is the same structure as the advice inserted in the function, editing of advice can be performed on either the function’s definition or its property list.

(UNADVISE X) [NLambda NoSpread Function]

An nlambda nospread like UNBREAK. It takes an indefinite number of functions and restores them to their original unadvised state, including removing the properties added by ADVISE. UNADVISE saves on the list ADVINFOLST enough information to allow restoring a function to its advised state using READVISE. ADVINFOLST and READVISE thus correspond to BRKINFOLST and REBREAK. If a function contains the property READVICE, UNADVISE moves the current value of the property ADVICE to READVICE.

(UNADVISE) unadvises all functions on ADVISEDFNS in reverse order, so that the most recently advised function is unadvised last. It first sets ADVINFOLST to NIL.

(UNADVISE T) unadvises the first function of ADVISEDFNS, i.e., the most recently advised function.

(READVISE X) [NLambda NoSpread Function]

An nlambda nospread like REBREAK for restoring a function to its advised state without having to specify all the advise information. For each function on X, READVISE retrieves the advise information either from the property READVICE for that function, or from ADVINFOLST, and performs the corresponding advise operation(s). It also stores this information on the property ADVISE if not already there. If no information is found for a particular function, value is (FN - NO ADVICE SAVED).

(READVISE) readvises everything on ADVINFOLST.

(READVISE T) readvises the first function on ADVINFOLST, i.e., the function most recently unadvised.

A difference between ADVISE, UNADVISE, and READVISE versus BREAK, UNBREAK, and REBREAK, is that if a function is not rebroken between successive (UNBREAK)s, its break information is forgotten. However, once READVISE is called on a function, that function’s advice is permanently saved on its property list (under READVICE); subsequent calls to
UNADVISE will not remove it. In fact, calls to UNADVISE update the property READVICE with the current value of the property ADVICE, so that the sequence READVICE, ADVISE, UNADVISE causes the augmented advice to become permanent. The sequence READVICE, ADVISE, READVICE removes the "intermediate advice" by restoring the function to its earlier state.

(ADVISEDUMP X FLG) [Function]

Used by PRETTYDEF when given a command of the form (ADVISE ...) or (ADVICE ...). If FLG = T, ADVISEDUMP writes both a DEFLIST and a READVICE; this corresponds to (ADVISE ...). If FLG = NIL, only the DEFLIST is written; this corresponds to (ADVICE ...). In either case, ADVISEDUMP copies the advise information to the property READVICE, thereby making it "permanent" as described above.
Medley’s code editors are “structure” editors—they know how to take advantage of Lisp code being represented as lists. One is a display editor named SEdit and the other is a TTY-based editor.

**Starting the Editor**

The editor is normally called using the following functions:

- `(DF FN)` [NLambda NoSpread Function]
  
  Edit the definition of the function `FN`. RF handles exceptional cases (the function is broken or advised, the definition is on the property list, the function needs to be loaded from a file, etc.) the same as EDITF (see below).

  If you call DF with a name that has no function definition, you are prompted with a choice of definers to use.

- `(DV VAR)` [NLambda NoSpread Function]
  
  Edit the value of the variable `VAR`.

- `(DP NAME PROP)` [NLambda NoSpread Function]
  
  Edit property `PROP` of the symbol `NAME`. If `PROP` is not given, the whole property list of `NAME` is edited.

- `(DC FILE)` [NLambda NoSpread Function]
  
  Edit the file package commands (or “filecoms,” see Chapter 17) for the file `FILE`.

- `(ED NAME OPTIONS)` [Function]
  
  This function finds out what kind of definition `NAME` has and lets you edit it. If `NAME` has more than one definition (e.g., it’s both a function and a macro), you will be prompted for the right one. If `NAME` has no definition, you’ll be asked what kind of definition to create.

**Choosing Your Editor**

The default editor may be set with EDITMODE:
(EDITMODE NEWMODE) [Function]

If NEWMODE is DISPLAY, sets the default editor to be SEdit; or the teletype editor (if NEWMODE is TELETYPE). Returns the previous setting. If NEWMODE is NIL, returns the previous setting without setting a new editor.

SEdit - The Structure Editor

SEdit is a structure editor. You use a structure editor when you want to edit objects instead of text. SEdit is a part of the environment and operates directly on objects in the system you are running. SEdit behaves differently depending on the type of objects you are editing.

Common Lisp definitions: SEdit always edits a copy of a Common Lisp definition. The changes made while you edit a function will not be installed until the edit session is complete.

For example, when you edit a Common Lisp function, you edit the definition of the function and not the executable version of the function. When you end the session the comments will be stripped of the definition and the definition will be installed as the executable version of the function.

Interlisp functions and macros: SEdit edits the actual structure that will be run, except editing the source for a compiled function. In this case, changes are made and the function is unsaved when you complete the edit session.

All other structures: Variables, property lists and other structures are edited directly in place, i.e. SEdit installs all changes as they are made.

If you make a severe editing error, you can abort the edit session with an Abort command (see Command Keys, below). This command undoes all changes from the beginning of the edit session and exits from SEdit without changing your environment.

If you change the definition of an object that is being edited in an SEdit window, Medley will ask you if you want to throw away the changes made there.

SEdit supports the standard Copy-Select mechanism in Medley.

An SEdit Session

Whenever you call SEdit, a new SEdit window is created. This SEdit window has its own process. You can make edits in the window, shrink it while you do something else, expand it and edit some more, and finally close the window when you are done.
Throughout an edit session, SEdit remembers everything that you do IN a change history. You can undo and redo edits sequentially. When you end the edit session, SEdit forgets this information and installs the changes in the system.

You signal the end of the session in the following ways:

- Close the window.
- Shrink the window. If you expand the window again, you can continue editing.
- Issue a Completion Command, see below.

**SEdit Carets**

There are two carets in SEdit, the edit caret and the structure caret. The edit caret appears when characters are edited within a single symbol, string, or comment. Anything you type will appear at the edit caret as part of the item it’s in. The edit caret looks like this:

\[(a \_b)\]

The structure caret appears when the edit point is between symbols (or strings or comments), so that anything you type will go into a new one. It looks like this:

\[(a \_b)\]

SEdit changes the caret frequently, depending on where the caret is positioned. The left mouse button positions the edit caret. The middle mouse button positions the structure caret.

**The Mouse**

The left mouse button selects parts of Lisp structures. The middle mouse button selects whole Lisp structures.

For example; select the \(Q\) in \(\text{LEQ}\) below by pressing the left mouse button when the pointer is over the \(Q\).

\[(\text{LEQ} n 1)\]
Any characters you type in now will be appended to the symbol \texttt{LEQ}.

Selecting the same letter with the middle mouse button selects the whole symbol (this matches TEdit's character/word selection convention), and sets a structure caret between the \texttt{LEQ} and the \texttt{n}:

\[
(\text{LEQ} \; n \; 1)
\]

Any characters you type in now will form a new symbol between the \texttt{LEQ} and the \texttt{n}.

Larger structures can be selected in two ways. Use the middle mouse button to position the mouse cursor on the parenthesis of the list you want to edit. Press the mouse button multiple times, without moving the mouse, extends the selection. In the previous example, if the middle button was pressed twice, the list \((\text{LEQ} \; \ldots)\) would be selected:

\[
(\text{LEQ} \; n \; 1)
\]

Press the button a third time and you will select the list containing the \((\text{LEQ} \; n \; 1)\) to be selected.

The right mouse button positions the mouse cursor for selecting sequences of structures or substructures. Extended selections are indicated by a box enclosing the structures selected. The selection extends in the same mode as the original selection. That is, if the original selection was a character selection, the right button will be used to select more characters in the same atom. Extended selections also have the property of being marked for pending deletion. That is, the selection takes the place of the caret, and anything typed in is inserted in place of the selection.

For example, selecting the \texttt{E} by pressing the left mouse button and selecting the \texttt{Q} by pressing the right mouse button will produce:

\[
(\text{LEQ} \; n \; 1)
\]

Similarly, pressing the middle mouse button and then selecting with the right mouse button extends the selection by whole structures. In our example, pressing the middle mouse button to select \texttt{LEQ} and pressing the right mouse button to select the \texttt{1} will produce:

\[
(\text{LEQ} \; n \; 1)
\]

This is not the same as selecting the entire list, as above. Instead, the elements in the list are collectively selected, but the list itself is not.
**Gaps**

SEdit requires that everything edited must have an underlying Lisp structure at all times. Some characters, such as single quote ‘”’ have no meaning by themselves, but must be followed by something more. When you type such a character, SEdit puts a “gap” where the rest of the input should go. When you type, the gap is automatically replaced.

A gap looks like:  –</当地的考点>

After you type a quote, the gap looks like this:  with the gap marked for pending deletion.

**Broken Atoms**

When you type an atom (a symbol or a number), SEdit saves the characters you type until you are finished. Typing any character that cannot belong to an atom, like a space or open parenthesis, ends the atom. SEdit then tries to create an atom with the characters you just typed, just as if they were read by the Lisp reader. The atom then becomes part of the structure you’re editing.

If an error occurs when SEdit reads the atom, SEdit creates a structure called a Broken-Atom. A Broken-Atom looks and behaves just like a normal atom, but is printed in italics to tell you that something is wrong.

SEdit creates a Broken-Atom when the characters typed don’t make a legal atom. For example, the characters "DECLARE:" can’t be a symbol because the colon is a package specifier, but the form is not correct for a package-qualified symbol. Similarly, the characters "#b123" cannot represent an integer in base two, because 2 and 3 aren’t legal digits in base two, so SEdit would make a Broken-Atom that looks like #b123.

You can edit Broken-Atoms just like real atoms. Whenever you finish editing a Broken-Atom, SEdit again tries to create an atom from the characters. If SEdit succeeds, it reprints the atom in SEdit’s default font, rather than in italics. Be sure to correct any Broken-Atoms you create before exiting SEdit, since Broken-Atoms do not behave in any useful way outside SEdit.

**Special Characters**

Some characters have special meanings in Lisp, and are therefore treated specially by SEdit. SEdit must always have a complete structure to work on at any level of the edit. This means that SEdit needs a special way to type in structures such as lists, strings, and quoted objects. In most instances these structures can be typed in just as they would be to a regular Exec, but in the following cases this is not possible.
Lists: ( )

Lists begin with an open parenthesis character "('. Typing an open parenthesis gives a balanced list. SEdit inserts both an open and a close parenthesis. The structure caret is placed between the two parentheses. List elements can be typed in at the structure caret. When a close parenthesis, ")" is typed, the caret will be moved outside the list, effectively finishing the list. Square bracket characters, "[" and "]", have no special meaning in SEdit, as they have no special meaning in Common Lisp.

Single Quote: '
Backquote: '
Comma: ,
At Sign: @
Dot: .
Hash Quote: #'

All these characters are special macro characters in Common Lisp. When you type one, SEdit will echo the character followed by a gap, which you should then fill in.

Dotted Lists: ( . )

Use period to enter dotted pairs. After you type a dot, SEdit prints a dot and a gap to fill in for the tail of the list. To dot an existing list, point the cursor between the last and second to last elements, and type a dot. To undot a list, select the tail of the list before the dot while holding down the SHIFT key.

Single escape: \
Percent: %

Use the single escape characters to make symbols with special characters. The single escape character for Interlisp is "%". The single escape character for Common Lisp is "\".

When you want to create a symbol with a special character in it you have to type a single escape character before you type the character itself. SEdit does not echo the single escape character until you type the following character.

For example; create the Common Lisp symbol APAREN- (. Since SEdit normally will treat the "(" as the start of a new list you have to tell SEdit to treat it as an ordinary character. You do this by typing a "\" before you type the "(".

Multiple Escape: |

Use the multiple escape character when you enter symbols with many special characters. SEdit always balances multiple escape characters. When you type one, SEdit adds another, with the caret between them. If you type a second vertical bar, the caret moves after it, but is still in the same symbol, so you can add more unescaped characters.
Comment:  ;  A semicolon starts a comment. When you type a semicolon, an empty comment is inserted with the caret in position to type the comment. Comments can be edited like strings.

There are three levels of comments supported by SEdit: single-, double-, and triple-semicolon. Single-semicolon comments are formatted at the comment column, about three-quarters of the way across the window. Double-semicolon comments are formatted at the current indentation of the code they are in. Triple semicolon comments are formatted against the left margin. The level of a comment can be increased or decreased by pointing after the semicolon, and either typing another semicolon, or backspacing over the preceding semicolon. Comments can be placed anywhere in your Common Lisp code. However, in Interlisp code, they must follow the placement rules for Interlisp comments.

String:  "  Enter strings in SEdit by typing a double quote. SEdit balances the double quotes: When one is typed, SEdit produces a second, with the caret between the two. If you type a double-quote in the middle of a string, SEdit breaks the string in two, leaving the caret between them.

SEdit Commands

Enter SEdit commands either from the keyboard or from the SEdit menu. When possible, SEdit uses a named key on the keyboard, e.g., the DELETE key. Other commands are combinations of Meta, Control, and alphabetic keys. For the alphabetic command keys, either uppercase or lowercase will work.

There are two menus available, as an alternative means of invoking commands. They are the middle button popup menu, and the attached command menu. These menus are described in more detail below.

Meta-A  Abort the session. Throw away the changes made to the form.
Meta-B  Change the Print Base. Prompts for entry of the desired Print Base, in decimal. SEdit redisplays fixed point numbers in this new base.
Control-C  Tell SEdit that this session is complete and compiles the definition being edited. The variable *COMPILE-FN* determines which function to use as compiler. See the Options section below.
Control-Meta-C  Signals the system that this edit is complete, compiles the definition being editing, and closes the window.
DELETE  Deletes the current selection.
Meta-E  Evaluate the current selection. If the result is a structure, the inspector is called on it, allowing the user to choose how to look at the result. Otherwise, the result is printed in the SEdit prompt window. The evaluation is done in the process from which the edit session was started. Thus, while editing a function from a break window, evaluations are done in the context of the break.

FIND  
Meta-F  Find a specified structure, or sequence of structures. If there is a current selection, SEdit looks for the next occurrence of the selected structure. If there is no selection, SEdit prompts for the structure to find, and searches forward from the position of the caret. The found structure will be selected, so the Find command can be used to easily find the same structure again.

If a sequence of structures are selected, SEdit will look for the next occurrence of the same sequence. Similarly, when SEdit prompts for the structure to find, you can type a sequence of structures to look for.

The variable *WRAP-SEARCH* controls whether or not SEdit wraps around from the end of the structure being edited and continues searching from the beginning.

Control-Meta-F  Find a specified structure, searching in reverse from the position of the caret.

HELP  
Meta-H  Show the argument list for the function currently selected, or currently being typed in, in the SEdit prompt window. If the argument list will not fit in the SEdit prompt window, it is displayed in the main Prompt Window.

Meta-I  Inspect the current selection.

Meta-J  Join any number of sequential Lisp objects of the same type into a single object of that type. Join is supported for atoms, strings, lists, and comments. In addition, SEdit permits joining of a sequence of atoms and strings, since either type can easily be coerced into the other. In this case, the result of the Join will be an atom if the first object in the selection is an atom, otherwise the result will be a string.

Control-L  Redisplay the structure being edited.

SKIP-NEXT  
Meta-N  Select next gap in the structure.

Meta-O  Edit the definition of the current selection. If the selected name has more than one type of definition, SEdit asks for the type to edit. If the selection has no definition, a menu pops up. This menu lets you specify the type of definition to create.

Control-Meta-O  Perform a fast edit by calling ED with the CURRENT option.

Meta-P  Change the current package for this edit. Prompt the user for a new package name. SEdit will redisplay atoms with respect to that package.

AGAIN  
Meta-R  Redo the edit change that was just undone. Redo only works directly following an Undo. Any number of Undo commands can be sequentially redone.

SHIFT-FIND
Meta-S  Substitute a structure, or sequence of structures within the current selection.
SEdit prompts you in the SEdit prompt window for the structures to replace, and
the structures to replace with. The selection to substitute within must be a
structure selection.

Control-Meta-S  Remove all occurrences of a structure or sequence of structures within the current
selection. SEdit prompts you for the structures to delete.

UNDO
Meta-U  Undo the last edit. All changes in the the edit session are remembered, and can
be undone sequentially.

Control-W  Delete the previous atom or structure. If the caret is in the middle of an atom,
deletes backward to the beginning of the atom only.

Control-X  Tell SEdit that this session is complete. The SEdit window remains open.

EXPAND
Meta-X  Replaces the current selection with its definition. This command can be used to
expand macros and translate CLISP.

Control-Meta-X  Tell SEdit that this session is complete Close the SEdit window.

Meta-Z  Mutate. Prompt for a function and call this function with the current selection as
the argument. The result is inserted into SEdit and made the current selection.

For example, you can replace a structure with its value by selecting it and
mutating by EVAL.

Meta-;  Convert old style comments in the selected structure to new style comments.
The converter notices any list that begins with the symbol IL:* as an old style
comment. Section 16.1.18, Options, describes the converter options.

Control-Meta-;  Put the contents of a structure selection into a comment. This provides an easy
way to "comment out" a chunk of code. The Extract command can be used to
reverse this process, returning the comment to the structures contained therein.

Meta-/  Extract one level of structure from the current selection. If there is no selection,
but there is a structure caret, the list containing the caret is used. This command
can be used to strip the parentheses off a list, or to unquote a quoted structure,
or to replace a comment with the contained structures.

Meta-’
Meta-`
Meta-,
Meta-.
Meta-@  or Meta-2
Meta-#  or Meta-3
Meta-.  Quote the current selection with the specified kind of quote.

Meta-Space
Meta-Return  Scroll the current selection to the center of the window. Similarly, the Space or
Return key can be used to normalize the caret.

Meta-)
Meta-0  Parenthesize the current selection, position the caret after the new list.
Meta-() Parenthesize the current selection, position the caret at the beginning of the new list.

Meta-9 Attach a menu of common commands to the top of the SEdit window. Each SEdit window can have its own menu.

SEdit Command Menu

When the mouse cursor is in the SEdit title bar and you press middle mouse button, a Help Menu of commands pops up. The menu looks like this:
The Help Menu lists each command and its corresponding Command Key. (C- stands for Control, M- for Meta.) The menu pops up with the mouse cursor next to the last command you used from the menu. This makes it easy to repeat a command.

### SEedit Attached Menu

SEedit’s Attached Command Menu contains the commonly used commands. Use the Meta-M keyboard command to bring up this menu. The menu can be closed, independently of the SEedit window. The menu looks like:

<table>
<thead>
<tr>
<th>Menu commands</th>
<th>Command key</th>
</tr>
</thead>
<tbody>
<tr>
<td>Set Print-base</td>
<td>M-B</td>
</tr>
<tr>
<td>Set Package</td>
<td>M-P</td>
</tr>
<tr>
<td>Attach Menu</td>
<td>M-M</td>
</tr>
</tbody>
</table>

Menu commands work like the corresponding keyboard commands, except for Find and Substitute.
For Find, SEdit prompts in the menu window, next to the Find button, for the structures to find. Type in the structures then select Find again. The search begins from the caret position in the SEdit window.

Similarly, Substitute prompts next to the Find button for the structures to find, and next to the Substitute button for the structures to replace them with. After both have been typed in, selecting Substitute replaces all occurrences of the Find structures with the Substitute structures, within the current selection.

To selectively substitute, use Find to find the next potential substitution target. If you want to replace it, select Substitute. Otherwise, select Find again to go on.

Selecting either Find or Substitute with the right mouse button erases the old structure to find or substitute from the menu, and prompts for a new one.

SEdit Programmer’s Interface

The following sections describe SEdit’s programmer’s interface. All symbols are external in the package SEDIT.

SEdit Window Region Manager

SEdit provides user redefinable functions which control how SEdit chooses the region for a new edit window. In the followin there are a few concepts that you will have to be familiar with. They are:

The region stack. This is a stack of old used regions. The reason to keep these around is that the user probably was comfortable with the old position of the window, so when he starts a new SEdit it is a good bet that he will be happy with the old placement.

SEdit uses the respective value of the symbols SEDIT::DEFAULT-FONT, SEDIT::ITALIC-FONT, SEDIT::KEYWORD-FONT, SEDIT::COMMENT-FONT, and SEDIT::BROKEN-ATOM-FONT when displaying an expression. The value of these symbols have to be font descriptors.

(GET-WINDOW-REGION context reason name type) [Function]

This function is called when SEdit wants to know where to place a window it is about to open. This happens whenever the user starts a new SEdit or expands an Sedit icon. The default behavior is to pop a window region off SEdit’s stack of regions that have been used in the past. If the stack is empty, SEdit prompts for a new region.

context is the current editor context.

reason is one of :CREATE or :EXPAND depending on what action prompted the call to GET-WINDOW-REGION

name is the name of the structure to be edited.
type is the edit type of the calling context.

(SAVE-WINDOW-REGION context reason name type region) [Function]

This function is called whenever SEdit is finished with a region and wants to make the region available for other SEdits. This happens whenever an SEdit window is closed or shrunk, or when an SEdit Icon is closed. The default behavior is simply to push the region onto SEdit’s stack of regions.

category is the current editor context.

reason is one of :CLOSE, :SHRINK, or :CLOSE-ICON or depending on what action prompted the call to SAVE-WINDOW-REGION

name is the name of the structure to be edited.

type is the edit type of the calling context.

region is the region to be pushed onto the region stack. If region is NIL the old region of the SEdit will be pushed top the region stack.

KEEP-WINDOW-REGION [Variable]

Default T. This flag determines the behavior of the default SEdit region manager, explained above, for shrinking and expanding windows. When set to T, shrinking an SEdit window will not give up that window’s region; the icon will always expand back into the same region. When set to NIL, the window’s region is made available for other SEdits when the window is shrunk. Then when an SEdit icon is expanded, the window will be reshaped to the next available region.

This variable is only used by the default implementations of the functions get-window-region and save-window-region. If these functions are redefined, this flag is no longer used.

Options

The following parameters can be set as desired.

*WRAP-PARENS* [Variable]

This SEdit pretty printer flag determines whether or not trailing close parenthesis characters, ), are forced to be visible in the window without scrolling. By default it is set to NIL, meaning that close parens are allowed to "fall off" the right edge of the window. If set to T, the pretty printer will start a new line before the structure preceding the close parens, so that all the parens will be visible.

*WRAP-SEARCH* [Variable]

This flag determines whether or not SEdit find will wrap around to the top of the structure when it reaches the end, or vice versa in the case of reverse find. The default is NIL.
**INTERLISP-D REFERENCE MANUAL**

*CLEAR-LINEAR-ON-COMPLETION*  [Variable]

This flag determines whether or not SEdit completely re-pretty prints the structure being edited when you complete the edit. The default value is NIL, meaning that SEdit reuses the pretty printing.

*IGNORE-CHANGES-ON-COMPLETION*  [Variable]

Sometimes the structure that you are editing is changed by the system upon completion. Editdates are an example of this behavior. When this flag is NIL, the default, SEdit will redisplay the new structure, capturing the changes. When T, SEdit will ignore the fact that changes were made by the system and keep the old structure.

CONVERT-UPGRADE  [Variable]

Default 100. When using Meta-; to convert old-style single-asterisk comments, if the length of the comment exceeds convert-upgrade characters, the comment is converted into a double semicolon comment. Otherwise, the comment is converted into a single semicolon comment. Old-style double-asterisk comments are always converted into new-style triple-semicolon comments.

Control Functions

(RESET)  [Function]

This function recomputes the SEdit edit environment. Any changes made in the font profile, or any changes made to SEdit’s commands are captured by resetting. Close all SEdit windows before calling this function.

(ADD-COMMAND key-code form &optional scroll? key-name command-name help-string)  [Function]

This function allows you to write your own SEdit keyboard commands. You can add commands to new keys, or you can redefine keys that SEdit already uses as command keys. If you mistakenly redefine an SEdit command, the function Reset-Commands will remove all user-added commands, leaving SEdit with its default set of commands.

*key-code* can be a character code, or any form acceptable to il:charcode.

*form* determines the function to be called when the key command is typed. It can be a symbol naming a function, or a list, whose first element is a symbol naming a function and the rest of the elements are extra arguments to the function. When the command is invoked, SEdit will apply the function to the edit context (SEdit’s main data structure), the charcode that was typed, and any extra arguments supplied in form. The extra arguments do not get evaluated, but are useful as keywords or flags, depending on how the command was invoked. The command function must return T if it handled the command. If the function returns NIL, SEdit will ignore the command and insert the character typed.
The first optional argument, `scroll?`, determines whether or not SEdit scrolls the window after running the command. This argument defaults to `NIL`, meaning don’t scroll. If the value of `scroll?` is `T`, SEdit will scroll the window to ensure that the caret is visible.

The rest of the optional arguments are used to add this command to SEdit’s middle button menu. When the item is selected from the menu, the command function will be called as described above, with the charcode argument set to `NIL`.

`key-name` is a string to identify the key (combination) to be typed to invoke the command. For example "M-A" to represent the Meta-A key combination, and "C-M-A" for Control-Meta-A.

`command-name` is a string to identify the command function, and will appear in the menu next to the `key-name`.

`help-string` is a string to be printed in the prompt window when a mouse button is held down over the menu item.

After adding all the commands that you want, you must call `Reset-Commands` to install them.

For example:

```lisp
(ADD-COMMAND "^U" (MY-CHANGE-CASE T))
(ADD-COMMAND "^Y" (MY-CHANGE-CASE NIL))
(ADD-COMMAND "1,R" MY-REMOVE-NIL
 "M-R" "REMOVE NIL"
 "REMOVE NIL FROM THE SELECTED STRUCTURE")
(RESET-COMMANDS)
```

will add three commands.

Suppose `MY-CHANGE-CASE` takes the arguments `context`, `charcode`, and `upper-case?`. `upper-case?` will be set to `T` when `MY-CHANGE-CASE` is called from Control-U, and `NIL` when called from Control-Y. `MY-REMOVE-NIL` will be called with only `context` and `charcode` arguments when you type Meta-R.

`RESET-COMMANDS` [Function]

This function installs all commands added by `add-command`. SEdits which are open at the time of the reset-commands will not see the new commands; only new SEdits will have the new commands available.

`DEFAULT-COMMANDS` [Function]

This function removes all commands added by `add-command`, leaving SEdit with its default set of commands. As in reset-commands, open SEdits will not be changed; only new SEdits will have the user commands removed.
(GET-PROMPT-WINDOW context) [Function]

Returns the attached prompt window for a particular SEdit.

(GET-SELECTION context) [Function]

This function returns two values: the selected structure, and the type of selection, one of NIL, T, or :SUB-LIST. The selection type NIL means there is not a valid selection (in this case the structure is meaningless). T means the selection is one complete structure. :SUB-LIST means a series of elements in a list is selected, in which case the structure returned is a list of the elements selected.

(REPLACE-SELECTION context structure selection-type ) [Function]

This function replaces the current selection with a new structure, or multiple structures, by deleting the selection and then inserting the new structure(s). The selection-type argument must be one of T or :SUB-LIST. If T, the structure is inserted as one complete structure. If :SUB-LIST, the structure is treated as a list of elements, each of which is inserted.

*EDIT-FN* [Variable]

This function is called with the selected structure and the edit specified as arguments to Sedit options as its arguments from the Edit (M-O) command. It should start the editor as appropriate, or generate an error if the selection is not editable.

*COMPILE-FN* [Variable]

This function is called with the arguments name, type, and body, from the compile/completion commands. It should compile the definition, body, and install the code as appropriate.

(SEEDIT structure props options) [Function]

This function provides a means of starting SEdit directly. structure is the structure to be edited.

props is a property list, which may specify the following properties:

:NAME - the name of the object being edited

:TYPE - the file manager type of the object being edited. If NIL, SEdit will not call the file manager when it tries to refetch the definition it is editing. Instead, it will just continue to use the structure that it has.

:COMPLETION-FN - the function to be called when the edit session is completed. This function is called with the context, structure, and changed? arguments. context is SEdit's main data structure. structure is the structure being edited. changed? specifies if any changes have been made, and is one of NIL, T, or :ABORT, where :ABORT means the user is aborting the edit and throwing away any changes made. If the value of this property is a list, the first element is treated as the function, and the rest of the elements are extra arguments for the function.
:ROOT-CHANGED-FN - the function to be called when the entire structure being edited is replaced with a new structure. This function is called with the new structure as its argument. If the value of this property is a list, the first element is treated as the function, and the rest of the elements are extra arguments that the function is applied to following the structure argument.

options is one or a list of any number of the following keywords:

:CLOSE-ON-COMPLETION - This option specifies that SEdit cannot remain active for multiple completions. That is, the SEdit window cannot be shrunk, and the completion commands that normally leave the window open will in this case close the window and terminate the edit.

:COMPILE-ON-COMPLETION - This option specifies that SEdit should call the *COMPILE-FN* to compile the definition being edited upon completion, regardless of the completion command used.

The TTY Editor

This editor the main code editor in pre-window-system versions of Interlisp. For that task, it has been replaced by SEdit.

However, the TTY Editor provides an excellent language for manipulating list structure and making large-scale code changes. For example, several tools for cleaning up code are written using TTY Editor calls to do the actual work.

TTY Editor Local Attention-Changing Commands

This section describes commands that change the current expression (i.e., change the edit chain) thereby "shifting the editor’s attention.” These commands depend only on the structure of the edit chain, as compared to the search commands (presented later), which search the contents of the structure.

UP

UP modifies the edit chain so that the old current expression (i.e., the one at the time UP was called) is the first element in the new current expression. If the current expression is the first element in the next higher expression UP simply does a 0. Otherwise UP adds the corresponding tail to the edit chain.

If a P command would cause the editor to type ... before typing the current expression, i.e., the current expression is a tail of the next higher expression, UP has no effect.

For example:
The execution of UP is straightforward, except in those cases where the current expression appears more than once in the next higher expression. For example, if the current expression is (A NIL B NIL C NIL) and you perform 4 followed by UP, the current expression should then be ... NIL C NIL). UP can determine which tail is the correct one because the commands that descend save the last tail on an internal editor variable, LASTAIL. Thus after the 4 command is executed, LASTAIL is (NIL C NIL). When UP is called, it first determines if the current expression is a tail of the next higher expression. If it is, UP is finished. Otherwise, UP computes (MEMB CURRENT-EXPRESSION NEXT-HIGHER-EXPRESSION) to obtain a tail beginning with the current expression. The current expression should always be either a tail or an element of the next higher expression. If it is neither, for example you have directly (and incorrectly) manipulated the edit chain, UP generates an error. If there are no other instances of the current expression in the next higher expression, this tail is the correct one. Otherwise UP uses LASTAIL to select the correct tail.

Occasionally you can get the edit chain into a state where LASTAIL cannot resolve the ambiguity, for example if there were two non-atomic structures in the same expression that were EQ, and you descended more than one level into one of them and then tried to come back out using UP. In this case, UP prints LOCATION UNCERTAIN and generates an error. Of course, we could have solved this problem completely in our implementation by saving at each descent both elements and tails. However, this would be a costly solution to a situation that arises infrequently, and when it does, has no detrimental effects. The LASTAIL solution is cheap and resolves almost all of the ambiguities.

$ N (N \geq 1) $  

[Editor Command]

Adds the $N$th element of the current expression to the front of the edit chain, thereby making it be the new current expression. Sets LASTAIL for use by UP. Generates an error if the current expression is not a list that contains at least $N$ elements.
$-N (N> = 1)$  

[Editor Command]

Adds the $N$th element from the end of the current expression to the front of the edit chain, thereby making it be the new current expression. Sets $\text{LASTAIL}$ for use by $\text{UP}$. Generates an error if the current expression is not a list that contains at least $N$ elements.

$0$  

[Editor Command]

Sets the edit chain to $\text{CDR}$ of the edit chain, thereby making the next higher expression be the new current expression. Generates an error if there is no higher expression, i.e., $\text{CDR}$ of edit chain is $\text{NIL}$.

Note that $0$ usually corresponds to going back to the next higher left parenthesis, but not always. For example:

```plaintext
*P
(A B C D E F B)
*3 UP P
... C D E F G)
*3 UP P
... E F G)
*0 P
... C D E F G)
```

If the intention is to go back to the next higher left parenthesis, regardless of any intervening tails, the command $!0$ can be used.

$!0$  

[Editor Command]

Does repeated $0$’s until it reaches a point where the current expression is not a tail of the next higher expression, i.e., always goes back to the next higher left parenthesis.

$\uparrow$  

[Editor Command]

Sets the edit chain to $\text{LAST}$ of edit chain, thereby making the top level expression be the current expression. Never generates an error.

$\text{NX}$  

[Editor Command]

Effectively does an $\text{UP}$ followed by a 2, thereby making the current expression be the next expression. Generates an error if the current expression is the last one in a list. (However, $!\text{NX}$ described below will handle this case.)

$\text{BK}$  

[Editor Command]

Makes the current expression be the previous expression in the next higher expression. Generates an error if the current expression is the first expression in a list.
For example:

```
*PP
  (COND ((NULL X) (RETURN Y)))
*F RETURN P
  (RETURN Y)
*BK P
  (NULL X)
```

Both \texttt{NX} and \texttt{BK} operate by performing a \texttt{!0} followed by an appropriate number, i.e., there won’t be an extra tail above the new current expression, as there would be if \texttt{NX} operated by performing an \texttt{UP} followed by a \texttt{2}.

\[(\text{NX } N)\]  
\[\text{[Editor Command]}\]

\[(N \geq 1)\] Equivalent to \texttt{N NX} commands, except if an error occurs, the edit chain is not changed.

\[(\text{BK } N)\]  
\[\text{[Editor Command]}\]

\[(N \geq 1)\] Equivalent to \texttt{N BK} commands, except if an error occurs, the edit chain is not changed.

Note: \texttt{(NX -N)} is equivalent to \texttt{(BK N)}, and vice versa.

\texttt{!NX}

\[\text{[Editor Command]}\]

Makes the current expression be the next expression at a higher level, i.e., goes through any number of right parentheses to get to the next expression. For example:

```
*PP
  (PROG ((L L)
    (UF L))
  LP  (COND
    ((NULL (SETQ L (CDR L)))
      (ERROR!))
    ((NULL (CDR (FMEMB (CAR L) (CADR L)
      (GO LP)))))
      (EDITCOM (QUOTE NX))
    (SETQ UNFIND UF)
      (RETURN L))
  *F CDR P
    (CDR L)
  *NX

NX \ ?
*!NX P
  (ERROR!)
*!NX P
  ((NULL &.) (GO LP))
*!NX P
  (EDITCOM (QUOTE NX))
*```
!NX operates by doing 0’s until it reaches a stage where the current expression is *not* the last expression in the next higher expression, and then does a NX. Thus !NX always goes through at least one unmatched right parenthesis, and the new current expression is always on a different level, i.e., !NX and NX always produce different results. For example using the previous current expression:

```
*F CAR P
(CAR L)
!*NX P
(GO LP)
*
\P P
(CAR L)
*NX P
(CADR L)
*
```

(NTH N) [Editor Command]

(N <= 0) Equivalent to N followed by UP, i.e., causes the list starting with the Nth element of the current expression (or Nth from the end if N < 0) to become the current expression. Causes an error if current expression does not have at least N elements.

(NTH 1) is a no-op, as is (NTH -L) where L is the length of the current expression.

line-feed [Editor Command]

Moves to the “next” expression and prints it, i.e. performs a NX if possible, otherwise performs a !NX. (The latter case is indicated by first printing “>”.)

Control-X [Editor Command]

Control-X moves to the “previous” thing and then prints it, i.e. performs a BK if possible, otherwise a !0 followed by a BK.

Control-Z [Editor Command]

Control-Z moves to the last expression and prints it, i.e. does -1 followed by P.

Line-feed, Control-X, and Control-Z are implemented as *immediate* read macros; as soon as they are read, they abort the current printout. They thus provide a convenient way of moving around in the editor. To facilitate using different control characters for those macros, the function SETTERMCHARS is provided (see below).
Commands That Search

All of the editor commands that search use the same pattern matching routine (the function \texttt{EDIT4E}, below). We will therefore begin our discussion of searching by describing the pattern match mechanism. A pattern\texttt{PAT} matches with \texttt{X} if any of the following conditions are true:

1. If \texttt{PAT} is \texttt{EQ} to \texttt{X}
2. If \texttt{PAT} is \&
3. If \texttt{PAT} is a number and \texttt{EQP} to \texttt{X}
4. If \texttt{PAT} is a string and \texttt{(STREQUAL PAT X)} is true
5. If \texttt{(CAR PAT)} is the atom \texttt{*\textasteriskcentered*}, \texttt{(CDR PAT)} is a list of patterns, and one of the patterns on \texttt{(CDR PAT)} matches \texttt{X}.
6. If \texttt{PAT} is a literal atom or string containing one or more \$\$s (escapes), each $ can match an indefinite number (including 0) of contiguous characters in the atom or string \texttt{X}, e.g., \texttt{VER$}$ matches both \texttt{VERYLONGATOM} and "\texttt{VERYLONGSTRING}" as do \texttt{$LONG}$ (but not \texttt{$LONG$}), and \texttt{$V$L$T$}. Note: the litatom $ (escape) matches only with itself.
7. If \texttt{PAT} is a literal atom or string ending in $$ (escape, escape), \texttt{PAT} matches with the atom or string \texttt{X} if it is "close" to \texttt{PAT}, in the sense used by the spelling corrector (see Chapter 20). For example, \texttt{CONSS$$} matches with \texttt{CONS}, \texttt{CNONC$$} with \texttt{NCONC} or \texttt{NCONC1}.

The pattern matching routine always types a message of the form =\texttt{MATCHING-ITEM} to inform you of the object matched by a pattern of the above two types, unless \texttt{EDITQUIETFLG = T}. For example, if \texttt{VER$} matches \texttt{VERYLONGATOM}, the editor would print \texttt{=VERYLONGATOM}.

8. If \texttt{(CAR PAT)} is the atom \texttt{--}, \texttt{PAT} matches \texttt{X} if \texttt{(CDR PAT)} matches with some tail of \texttt{X}. For example, \texttt{(A \texttt{-- \&\textasteriskcentered})} will match with \texttt{(A B C (D))}, but not \texttt{(A B C D)}, or \texttt{(A B C (D) E)}. However, note that \texttt{(A \texttt{-- \&\textasteriskcentered} \texttt{--})} will match with \texttt{(A B C (D) E)}. In other words, -- can match any interior segment of a list.

9. If \texttt{(CAR PAT)} is the atom \texttt{==}, \texttt{PAT} matches \texttt{X} if and only if \texttt{(CDR PAT)} is \texttt{EQ} to \texttt{X}.

This pattern is for use by programs that call the editor as a subroutine, since any nonatomic expression in a command \textit{typed} in by you obviously cannot be \texttt{EQ} to already existing structure.

10. If \texttt{(CDR PAT)} is the atom \texttt{\&\textasteriskcentered} (two periods), \texttt{PAT} matches \texttt{X} if \texttt{(CAR PAT)} matches \texttt{(CAR X)} and \texttt{(CDDR PAT)} is contained in \texttt{X}, as described below.

11. Otherwise if \texttt{X} is a list, \texttt{PAT} matches \texttt{X} if \texttt{(CAR PAT)} matches \texttt{(CAR X)}, and \texttt{(CDR PAT)} matches \texttt{(CDR X)}.
When the editor is searching, the pattern matching routine is called to match with elements in the structure, unless the pattern begins with ... (three periods), in which case CDR of the pattern is matched against proper tails in the structure. Thus,

```
*P
  (A B C (B C))  
*F (B --)     
*P           
  (B C)     
*0 F (... B --) 
*P           
    ... B C (B C) 
```

Matching is also attempted with atomic tails (except for NIL). Thus,

```
*P
  (A (B . C))  
*F C       
*P           
    ... . C 
```

Although the current expression is the atom C after the final command, it is printed as ... . C) to alert you to the fact that C is a tail, not an element. Note that the pattern C will match with either instance of C in (A C (B . C)), whereas (... . C) will match only the second C. The pattern NIL will only match with NIL as an element, i.e., it will not match in (A B), even though CDDR of (A B) is NIL. However, (... . NIL) (or equivalently (...) ) may be used to specify a NIL tail, e.g., (... . NIL) will match with CDR of the third subexpression of ((A . B) (C . D) (E)).

**Search Algorithm**

Searching begins with the current expression and proceeds in print order. Searching usually means find the next instance of this pattern, and consequently a match is not attempted that would leave the edit chain unchanged. At each step, the pattern is matched against the next element in the expression currently being searched, unless the pattern begins with ... (three periods) in which case it is matched against the next tail of the expression.

If the match is not successful, the search operation is recursive first in the CAR direction, and then in the CDR direction, i.e., if the element under examination is a list, the search descends into that list before attempting to match with other elements (or tails) at the same level. Note: A find command of the form (F PATTERN NIL) will only attempts matches at the top level of the current expression, i.e., it does not descend into elements, or ascend to higher expressions.

However, at no point is the total recursive depth of the search (sum of number of CARs and CDRs descended into) allowed to exceed the value of the variable MAXLEVEL. At that point, the search of that element or tail is abandoned, exactly as though the element or tail had been completely searched without finding a match, and the search continues with the element or tail for which the recursive depth is below MAXLEVEL. This feature is designed to enable you to search circular list structures (by setting MAXLEVEL small), as well as protecting him from accidentally encountering a circular list.
structure in the course of normal editing. \texttt{MAXLEVEL} can also be set to \texttt{NIL}, which is equivalent to infinity. \texttt{MAXLEVEL} is initially set to 300.

If a successful match is not found in the current expression, the search automatically ascends to the next higher expression, and continues searching there on the next expression after the expression it just finished searching. If there is none, it ascends again, etc. This process continues until the entire edit chain has been searched, at which point the search fails, and an error is generated. If the search fails (or is aborted by Control-E), the edit chain is not changed (nor are any \texttt{CONS}es performed).

If the search is successful, i.e., an expression is found that the pattern matches, the edit chain is set to the value it would have had had you reached that expression via a sequence of integer commands.

If the expression that matched was a list, it will be the final link in the edit chain, i.e., the new current expression. If the expression that matched is not a list, e.g., is an atom, the current expression will be the tail beginning with that atom, unless the atom is a tail, e.g., \texttt{B} in \texttt{(A . B)}. In this case, the current expression will be \texttt{B}, but will print as \ldots \texttt{B}). In other words, the search effectively does an \texttt{UP} (unless \texttt{UPFINDFLG = NIL} (initially \texttt{T}). See "Form Oriented Editing" in this chapter).

\textbf{Search Commands}

All of the commands below set \texttt{LASTAIL} for use by \texttt{UP}, set \texttt{UNFIND} for use by \texttt{\} (below), and do not change the edit chain or perform any \texttt{CONS}es if they are unsuccessful or aborted.

\texttt{F PATTERN} \hfill [Editor Command]

Actually two commands: the \texttt{F} informs the editor that the next command is to be interpreted as a pattern. This is the most common and useful form of the find command. If successful, the edit chain always changes, i.e., \texttt{F PATTERN} means find the next instance of \texttt{PATTERN}.

If \texttt{(MEMB PATTERN CURRENT-EXPRESSION)} is true, \texttt{F} does not proceed with a full recursive search. If the value of the \texttt{MEMB} is \texttt{NIL}, \texttt{F} invokes the search algorithm described above.

If the current expression is \texttt{(PROG NIL LP (COND (-- (GO LP1))) \ldots LP1 \ldots)}, then \texttt{F LP1} will find the \texttt{PROG} label, not the \texttt{LP1} inside of the \texttt{GO} expression, even though the latter appears first (in print order) in the current expression. Typing 1 (making the atom \texttt{PROG} be the current expression) followed by \texttt{F LP1} \textit{would} find the first \texttt{LP1}.

\texttt{F PATTERN N} \hfill [Editor Command]

Same as \texttt{F PATTERN}, i.e., finds the Next instance of \texttt{PATTERN}, except that the \texttt{MEMB} check of \texttt{F PATTERN} is not performed.
**F PATTERN T**  
[Editor Command]

Similar to **F PATTERN**, except that it may succeed without changing the edit chain, and it does not perform the MEME check. For example, if the current expression is `(COND ...)`, **F COND** will look for the next **COND**, but `(F COND T)` will "stay here".

**(F PATTERN N)**  
[Editor Command]

`(N >= 1)` Finds the `N`th place that `PATTERN` matches. Equivalent to `(F PATTERN T)` followed by `(F PATTERN N)` repeated `N`-1 times. Each time `PATTERN` successfully matches, `N` is decremented by 1, and the search continues, until `N` reaches 0. Note that `PATTERN` does not have to match with `N` identical expressions; it just has to match `N` times. Thus if the current expression is `(FOO1 FOO2 FOO3)`, `(F FOO$ 3)` will find `FOO3`.

If `PATTERN` does not match successfully `N` times, an error is generated and the edit chain is unchanged (even if `PATTERN` matched `N`-1 times).

**(F PATTERN)**  
[Editor Command]

**F PATTERN NIL**  
[Editor Command]

Similar to **F PATTERN**, except that it only matches with elements at the top level of the current expression, i.e., the search will not descend into the current expression, nor will it go outside of the current expression. May succeed without changing the edit chain.

For example, if the current expression is `(PROG NIL (SETQ X (COND & &)) (COND &) ... )`, the command `F COND` will find the **COND** inside the **SETQ**, whereas `(F (COND --))` will find the top level **COND**, i.e., the second one.

**(FS PATTERN₁ ... PATTERNₙ)**  
[Editor Command]

Equivalent to `F PATTERN₁` followed by `F PATTERN₂` ... followed by `F PATTERNₙ` so that if `F PATTERNₙ` fails, the edit chain is left at the place `PATTERNₙ-₁` matched.

**(F= EXPRESSION X)**  
[Editor Command]

Equivalent to `(F (== . EXPRESSION) X)`, i.e., searches for a structure **EQ** to **EXPRESSION** (see above).

**(ORF PATTERN₁ ... PATTERNₙ)**  
[Editor Command]

Equivalent to `(F (*ANY* PATTERN₁ ... PATTERNₙ) N)`, i.e., searches for an expression that is matched by either `PATTERN₁`, `PATTERN₂`, ... or `PATTERNₙ` (see above).
BF PATTERN

"Backwards Find". Searches in reverse print order, beginning with the expression immediately before the current expression (unless the current expression is the top level expression, in which case BF searches the entire expression, in reverse order).

BF uses the same pattern match routine as F, and MAXLEVEL and UPFINDFLG have the same effect, but the searching begins at the end of each list, and descends into each element before attempting to match that element. If unsuccessful, the search continues with the next previous element, etc., until the front of the list is reached, at which point BF ascends and backs up, etc.

For example, if the current expression is

(PROG NIL (SETQ X (SETQ Y (LIST Z))) (COND ((SETQ W --) --)) --),

the command F LIST followed by BF SETQ will leave the current expression as (SETQ Y (LIST Z)), as will F COND followed by BF SETQ.

BF PATTERN T

Similar to BF PATTERN, except that the search always includes the current expression, i.e., starts at the end of current expression and works backward, then ascends and backs up, etc.

Thus in the previous example, where F COND followed by BF SETQ found (SETQ Y (LIST Z)), F COND followed by (BF SETQ T) would find the (SETQ W --) expression.

GO LABEL

Makes the current expression be the first thing after the PROG label LABEL, i.e. goes where an executed GO would go.

Location Specification

Many of the more sophisticated commands described later in this chapter use a more general method of specifying position called a "location specification." A location specification is a list of edit commands that are executed in the normal fashion with two exceptions. First, all commands not recognized by the editor are interpreted as though they had been preceded by F; normally such commands would cause errors. For example, the location specification (COND 2 3) specifies the 3rd element in the first clause of the next COND. Note that you could always write F COND followed by 2.
and 3 for (COND 2 3) if you were not sure whether or not COND was the name of an atomic command.

Secondly, if an error occurs while evaluating one of the commands in the location specification, and the edit chain had been changed, i.e., was not the same as it was at the beginning of that execution of the location specification, the location operation will continue. In other words, the location operation keeps going unless it reaches a state where it detects that it is "looping", at which point it gives up. Thus, if (COND 2 3) is being located, and the first clause of the next COND contained only two elements, the execution of the command 3 would cause an error. The search would then continue by looking for the next COND. However, if a point were reached where there were no further CONDs, then the first command, COND, would cause the error; the edit chain would not have been changed, and so the entire location operation would fail, and cause an error.

The IF command (see above) in conjunction with the ## function (see below) provide a way of using arbitrary predicates applied to elements in the current expression. IF and ## will be described in detail later in the chapter, along with examples illustrating their use in location specifications.

Throughout this chapter, the meta-symbol @ is used to denote a location specification. Thus @ is a list of commands interpreted as described above. @ can also be atomic, in which case it is interpreted as (LIST @).

(LC . @) [Editor Command]

Provides a way of explicitly invoking the location operation, e.g., (LC COND 2 3) will perform the the search described above.

(LCL . @) [Editor Command]

Same as LC except the search is confined to the current expression, i.e., the edit chain is rebound during the search so that it looks as though the editor were called on just the current expression. For example, to find a COND containing a RETURN, one might use the location specification (COND (LCL RETURN) \) where the \ would reverse the effects of the LCL command, and make the final current expression be the COND.

(2ND . @) [Editor Command]

Same as (LC . @) followed by another (LC . @) except that if the first succeeds and second fails, no change is made to the edit chain.

(3ND . @) [Editor Command]

Similar to 2ND.

(← PATTERN) [Editor Command]

Ascends the edit chain looking for a link which matches PATTERN. In other words, it keeps doing 0's until it gets to a specified point. If PATTERN is atomic, it is matched with the first
element of each link, otherwise with the entire link. If no match is found, an error is
generated, and the edit chain is unchanged.

If PATTERN is of the form (IF EXPRESSION), EXPRESSION is evaluated at each link, and if
its value is NIL, or the evaluation causes an error, the ascent continues.

For example:

*PP
 [PROG NIL
  (COND
   [(NULL (SETQ L (CDR L)))]
    (COND
     (FLG (RETURN L))
     [(NULL (CDR (FMEMB (CAR L) (CADR L)])]
    *F CADR
   * (← COND)
   *P
    (COND (& &) (& &))
   *

Note that this command differs from BF in that it does not search inside of each link, it simply
ascends. Thus in the above example, F CADR followed by BF COND would find (COND
(FLG (RETURN L))), not the higher COND.

(BELOW COM X) [Editor Command]

Ascends the edit chain looking for a link specified by COM, and stops X links below that (only
links that are elements are counted, not tails). In other words BELOW keeps doing 0’s until it
gets to a specified point, and then backs off X 0’s.

Note that X is evaluated, so one can type (BELOW COM (IPLUS X Y)).

(BELOW COM) [Editor Command]

Same as (BELOW COM 1).

For example, (BELOW COND) will cause the COND clause containing the current expression
to become the new current expression. Thus if the current expression is as shown above, F
CADR followed by (BELOW COND) will make the new expression be ([NULL (CDR (FMEMB
(CAR L) (CADR L)) (GO LP)]), and is therefore equivalent to 0 0 0 0.

The BELOW command is useful for locating a substructure by specifying something it
contains. For example, suppose you are editing a list of lists, and want to find a sublist that
contains a FOO (at any depth). He simply executes F FOO (BELOW \).
(NEX COM) [Editor Command]

Same as (BELOW COM) followed by NX.

For example, if you are deep inside of a SELECTQ clause, you can advance to the next clause with (NEX SELECTQ).

NEX [Editor Command]

Same as (NEX ←).

The atomic form of NEX is useful if you will be performing repeated executions of (NEX COM). By simply marking (see the next section) the chain corresponding to COM, you can use NEX to step through the sublists.

(NTH COM) [Editor Command]

Generalized NTH command. Effectively performs (LCL . COM), followed by (BELOW \), followed by UP.

If the search is unsuccessful, NTH generates an error and the edit chain is not changed.

Note that (NTH NUMBER) is just a special case of (NTH COM), and in fact, no special check is made for COM a number; both commands are executed identically.

In other words, NTH locates COM, using a search restricted to the current expression, and then backs up to the current level, where the new current expression is the tail whose first element contains, however deeply, the expression that was the terminus of the location operation. For example:

```
*P
(PROG (& &) LP (COND & &) (EDITCOM &) (SETQ UNFIND UF) (RETURN L))
* (NTH UF)
*P
... (SETQ UNFIND UF) (RETURN L))
*
```

PATTERN ... @ [Editor Command]

For example, (COND .. RETURN). Finds a COND that contains a RETURN, at any depth. Equivalent to (but more efficient than) (F PATTERN N), (LCL . @) followed by (← PATTERN).
An infix command, ".." is not a meta-symbol, it is the name of the command. @ is CDDR of the command. Note that (PATTERN .. @) can also be used directly as an edit pattern as described above, e.g. F (PATTERN .. @).

For example, if the current expression is

(PROG NIL [COND ((NULL L) (COND (FLG (RETURN L) --)),

then (COND .. RETURN) will make (COND (FLG (RETURN L))) be the current expression. Note that it is the innermost COND that is found, because this is the first COND encountered when ascending from the RETURN. In other words, (PATTERN .. @) is not always equivalent to (F PATTERN), followed by (LCL . @) followed by \.

Note that @ is a location specification, not just a pattern. Thus (RETURN .. COND 2 3) can be used to find the RETURN which contains a COND whose first clause contains (at least) three elements. Note also that since @ permits any edit command, you can write commands of the form (COND .. (RETURN .. COND)), which will locate the first COND that contains a RETURN that contains a COND.

Commands That Save and Restore the Edit Chain

Several facilities are available for saving the current edit chain and later retrieving it: MARK, which marks the current chain for future reference, ←, which returns to the last mark without destroying it, and ←←, which returns to the last mark and also erases it.

MARK

[Editor Command]

Adds the current edit chain to the front of the list MARKLST.

←

[Editor Command]

Makes the new edit chain be (CAR MARKLST). Generates an error if MARKLST is NIL, i.e., no MARKS have been performed, or all have been erased.

This is an atomic command; do not confuse it with the list command (← PATTERN).

←←

[Editor Command]

Similar to ← but also erases the last MARK, i.e., performs (SETQ MARKLST (CDR MARKLST)).

If you have two chains marked, and wish to return to the first chain, you must perform ←←, which removes the second mark, and then ←. However, the second mark is then no longer
accessible. If you want to be able to return to either of two (or more) chains, you can use the following generalized MARK:

\[ \text{(MARK SYMBOL)} \quad \text{[Editor Command]} \]

Sets SYMBOL to the current edit chain,

\[ \text{(\ SYMBOL)} \quad \text{[Editor Command]} \]

Makes the current edit chain become the value of SYMBOL.

If you did not prepare in advance for returning to a particular edit chain, you may still be able to return to that chain with a single command by using \ or \P.

\[ \quad \text{[Editor Command]} \]

Makes the edit chain be the value of UNFIND. Generates an error if UNFIND = NIL.

UNFIND is set to the current edit chain by each command that makes a "big jump", i.e., a command that usually performs more than a single ascent or descent, namely ↑, ←, ←←, !NX, all commands that involve a search, e.g., P, LC, .., BELOW, et al and \ and \P themselves. One exception is that UNFIND is not reset when the current edit chain is the top level expression, since this could always be returned to via the ↑ command.

For example, if you type F COND, and then F CAR, \ would take you back to the COND. Another \ would take you back to the CAR, etc.

\[ \P \quad \text{[Editor Command]} \]

Restores the edit chain to its state as of the last print operation, i.e., P, ?, or PP. If the edit chain has not changed since the last printing, \P restores it to its state as of the printing before that one, i.e., two chains are always saved.

For example, if you type P followed by 3 2 1 P, \P returns to the first P, i.e., would be equivalent to 0 0 0. Another \P would then take you back to the second P, i.e., you could use \P to flip back and forth between the two edit chains.

If you had typed P followed by F COND, you could use either \ or \P to return to the P, i.e., the action of \ and \P are independent.

\[ S \text{ SYMBOL } @ \quad \text{[Editor Command]} \]

Sets SYMBOL (using SETQ) to the current expression after performing (LC . @). The edit chain is not changed.
INTERLISP-D REFERENCE MANUAL

Thus (S FOO) will set FOO to the current expression, and (S FOO -1 1) will set FOO to the first element in the last element of the current expression.

Commands That Modify Structure

The basic structure modification commands in the editor are:

\[(N \quad (N >= 1))\]  
[Editor Command]

Deletes the corresponding element from the current expression.

\[(N \ E_1 \ ... \ E_M) \quad (N >= 1)\]  
[Editor Command]

Replaces the \(N\)th element in the current expression with \(E_1 \ ... \ E_M\).

\[(-N \ E_1 \ ... \ E_M) \quad (N >= 1)\]  
[Editor Command]

Inserts \(E_1 \ ... \ E_M\) before the \(N\)th element in the current expression.

\[(N \ E_1 \ ... \ E_M)\]  
[Editor Command]

Attaches \(E_1 \ ... \ E_M\) at the end of the current expression.

As mentioned earlier: all structure modification done by the editor is destructive, i.e., the editor uses RPLACA and RPLACD to physically change the structure it was given. However, all structure modification is undoable, see UNDO.

All of the above commands generate errors if the current expression is not a list, or in the case of the first three commands, if the list contains fewer than \(N\) elements. In addition, the command \((1)\), i.e., delete the first element, will cause an error if there is only one element, since deleting the first element must be done by replacing it with the second element, and then deleting the second element. Or, to look at it another way, deleting the first element when there is only one element would require changing a list to an atom (i.e., to NIL) which cannot be done. However, the command DELETE will work even if there is only one element in the current expression, since it will ascend to a point where it can do the deletion.

If the value of CHANGESARRAY is a hash array, the editor will mark all structures that are changed by doing (PUTHASH STRUCTURE FN CHANGESARRAY), where \(FN\) is the name of the function. The algorithm used for marking is as follows:

1. If the expression is inside of another expression already marked as being changed, do nothing.
2. If the change is an insertion of or replacement with a list, mark the list as changed.

3. If the change is an insertion of or replacement with an atom, or a deletion, mark the parent as changed.

CHANGESARRAY is primarily for use by PRETTYPRINT (Chapter 26). When the value of CHANCECHAR is non-NIL, PRETTYPRINT, when printing to a file or display terminal, prints CHANCECHAR in the right margin while printing an expression marked as having been changed. CHANCECHAR is initially |

**Implementation**

*Note: Since all commands that insert, replace, delete or attach structure use the same low level editor functions, the remarks made here are valid for all structure changing commands.*

For all replacement, insertion, and attaching at the end of a list, unless the command was typed in directly to the editor, copies of the corresponding structure are used, because of the possibility that the exact same command, (i.e., same list structure) might be used again. Thus if a program constructs the command (1 (A B C)) e.g., via (LIST 1 FOO), and gives this command to the editor, the (A B C) used for the replacement will not be EQ to FOO. You can circumvent this by using the I command, which computes the structure to be used. In the above example, the form of the command would be (I 1 FOO), which would replace the first element with the value of FOO itself.

*Note: Some editor commands take as arguments a list of edit commands, e.g., (LP F FOO (1 (CAR FOO))). In this case, the command (1 (CAR FOO)) is not considered to have been "typed in" even though the LP command itself may have been typed in. Similarly, commands originating from macros, or commands given to the editor as arguments to EDITP, EDITV, et al, e.g., EDITP(FOO F COND (N --)) are not considered typed in.*

The rest of this section is included for applications wherein the editor is used to modify a data structure, and pointers into that data structure are stored elsewhere. In these cases, the actual mechanics of structure modification must be known in order to predict the effect that various commands may have on these outside pointers. For example, if the value of FOO is CDR of the current expression, what will the commands (2), (3), (2 X Y Z), (-2 X Y Z), etc. do to FOO?

Deletion of the first element in the current expression is performed by replacing it with the second element and deleting the second element by patching around it. Deletion of any other element is done by patching around it, i.e., the previous tail is altered. Thus if FOO is EQ to the current expression which is (A B C D), and FIE is CDR of FOO, after executing the command (1), FOO will be (B C D) (which is EQUAL but not EQ to FIE). However, under the same initial conditions, after executing (2) FIE will be unchanged, i.e., FIE will still be (B C D) even though the current expression and FOO are now (A C D).

A general solution of the problem isn’t possible, as it would require being able to make two lists EQ to each other that were originally different. Thus if FIE is CDR of the current expression, and FUM is CDDDR of the current expression, performing (2) would have to make FIE be EQ to FUM if all subsequent operations were to update both FIE and FUM correctly.
Both replacement and insertion are accomplished by smashing both CAR and CDR of the corresponding tail. Thus, if FOO were EQ to the current expression, \((A \ B \ C \ D)\), after \((1 \ X \ Y \ Z)\), FOO would be \((X \ Y \ Z \ B \ C \ D)\). Similarly, if FOO were EQ to the current expression, \((A \ B \ C \ D)\), then after \((-1 \ X \ Y \ Z)\), FOO would be \((X \ Y \ Z \ A \ B \ C \ D)\).

The \(N\) command is accomplished by smashing the last CDR of the current expression a la NCONC. Thus if FOO were EQ to any tail of the current expression, after executing an \(N\) command, the corresponding expressions would also appear at the end of FOO.

In summary, the only situation in which an edit operation will not change an external pointer occurs when the external pointer is to a *proper tail* of the data structure, i.e., to CDR of some node in the structure, and the operation is deletion. If all external pointers are to *elements* of the structure, i.e., to CAR of some node, or if only insertions, replacements, or attachments are performed, the edit operation will *always* have the same effect on an external pointer as it does on the current expression.

**The A, B, and : Commands**

In the \((N)\), \((N \ E_1 \ldots \ E_M)\), and \((-N \ E_1 \ldots \ E_M)\) commands, the sign of the integer is used to indicate the operation. As a result, there is no direct way to express insertion after a particular element (hence the necessity for a separate \(N\) command). Similarly, you cannot specify deletion or replacement of the \(N\)th element from the end of a list without first converting \(N\) to the corresponding positive integer. Accordingly, we have:

\[
\text{\(B \ E_1 \ldots \ E_M\)} \quad \text{[Editor Command]}
\]

Inserts \(E_1 \ldots E_M\) before the current expression. Equivalent to UP followed by \((-1 \ E_1 \ldots \ E_M)\).

For example, to insert FOO before the last element in the current expression, perform -1 and then \((B \ \text{FOO})\).

\[
\text{\(A \ E_1 \ldots \ E_M\)} \quad \text{[Editor Command]}
\]

Inserts \(E_1 \ldots E_M\) after the current expression. Equivalent to UP followed by \((-2 \ E_1 \ldots \ E_M)\) or \((N \ E_1 \ldots \ E_M)\), whichever is appropriate.

\[
\text{\(: \ E_1 \ldots \ E_M\)} \quad \text{[Editor Command]}
\]

Replaces the current expression by \(E_1 \ldots E_M\). Equivalent to UP followed by \((1 \ E_1 \ldots \ E_M)\).
DELETE

Deletes the current expression.

DELETE first tries to delete the current expression by performing an UP and then a (1). This works in most cases. However, if after performing UP, the new current expression contains only one element, the command (1) will not work. Therefore, DELETE starts over and performs a BK, followed by UP, followed by (2). For example, if the current expression is (COND ((MEMB X Y)) (T Y)), and you perform -1, and then DELETE, the BK-UP-(2) method is used, and the new current expression will be ... ((MEMB X Y)).

However, if the next higher expression contains only one element, BK will not work. So in this case, DELETE performs UP, followed by (: NIL), i.e., it replaces the higher expression by NIL. For example, if the current expression is (COND ((MEMB X Y)) (T Y)) and you perform F MEMB and then DELETE, the new current expression will be ... NIL (T Y)) and the original expression would now be (COND NIL (T Y)). The rationale behind this is that deleting (MEMB X Y) from ((MEMB X Y)) changes a list of one element to a list of no elements, i.e., () or NIL.

If the current expression is a tail, then B, A, ; and DELETE all work exactly the same as though the current expression were the first element in that tail. Thus if the current expression were ... (PRINT Y) (PRINT Z)), (B (PRINT X)) would insert (PRINT X) before (PRINT Y), leaving the current expression ... (PRINT X) (PRINT Y) (PRINT Z)).

The following forms of the A, B, and : commands incorporate a location specification:

(INsert E1 ... EM BEFORE . @)

(@ is (CDR (MEMBER 'BEFORE COMMAND))) Similar to (LC .@) followed by (B E1 ... EM).

Warning: If @ causes an error, the location process does not continue as described above. For example, if @ = (COND 3) and the next COND does not have a thirdelement, the search stops and the INSERT fails. You can always write (LC COND 3) if you intend the search to continue.

*P
(PROG (& & X) **COMMENT** (SELECTQ ATM & NIL) (OR & &) (PRIN1 & T) (PRIN1 & T) (SETQ X &

*(INSERT LABEL BEFORE PRIN1)

*P

16 - 35
Current edit chain is not changed, but UNFIND is set to the edit chain after the \ was performed, i.e., \ will make the edit chain be that chain where the insertion was performed.

\( (\text{INSERT} \ E_1 \ldots \ E_M \ \text{AFTER} \ . \ @) \)  
[Editor Command]

Similar to \text{INSERT BEFORE} except uses \( A \) instead of \( B \).

\( (\text{INSERT} \ E_1 \ldots \ E_M \ \text{FOR} \ . \ @) \)  
[Editor Command]

Similar to \text{INSERT BEFORE} except uses : for \( B \).

\( (\text{REPLACE} \ \@ \ \text{BY} \ E_1 \ldots \ E_M) \)  
[Editor Command]

\( (\text{REPLACE} \ \@ \ \text{WITH} \ E_1 \ldots \ E_M) \)  
[Editor Command]

Here \( @ \) is the segment of the command between REPLACE and WITH. Same as \( (\text{INSERT} \ E_1 \ldots \ E_M \ \text{FOR} \ . \ @) \).

Example: \( (\text{REPLACE} \ \text{COND} \ -1 \ \text{WITH} \ (\text{T} \ (\text{RETURN} \ L))) \)

\( (\text{CHANGE} \ \@ \ \text{TO} \ E_1 \ldots \ E_M) \)  
[Editor Command]

Same as REPLACE WITH.

\( (\text{DELETE} \ . \ @) \)  
[Editor Command]

Does a \( (\text{LC} \ . \ @) \) followed by DELETE (see warning about INSERT above). The current edit chain is not changed, but UNFIND is set to the edit chain after the DELETE was performed.

Note: The edit chain will be changed if the current expression is no longer a part of the expression being edited, e.g., if the current expression is \( \ldots \ C \) and you perform \( (\text{DELETE} \ 1) \), the tail, \( (C) \), will have been cut off. Similarly, if the current expression is \( (\text{CDR} \ Y) \) and you perform \( (\text{REPLACE} \ \text{WITH} \ (\text{CAR} \ X)) \).

Example: \( (\text{DELETE} \ -1) \), \( (\text{DELETE} \ \text{COND} \ 3) \)

Note: If \( @ \) is NIL (i.e., empty), the corresponding operation is performed on the current edit chain.
For example, (REPLACE WITH (CAR X)) is equivalent to (: (CAR X)). For added readability, HERE is also permitted, e.g., (INSERT (PRINT X) BEFORE HERE) will insert (PRINT X) before the current expression (but not change the edit chain).

Note: @ does not have to specify a location within the current expression, i.e., it is perfectly legal to ascend to INSERT, REPLACE, or DELETE.

For example, (INSERT (RETURN) AFTER ^ PROG -1) will go to the top, find the first PROG, and insert a (RETURN) at its end, and not change the current edit chain.

The A, B, and : commands, commands, (and consequently INSERT, REPLACE, and CHANGE), all make special checks in E1 thru E1 for expressions of the form (## . COMS). In this case, the expression used for inserting or replacing is a copy of the current expression after executing COMS, a list of edit commands (the execution of COMS does not change the current edit chain). For example, (INSERT (## F COND -1 -1) AFTER 3) will make a copy of the last form in the last clause of the next COND, and insert it after the third element of the current expression. Note that this is not the same as (INSERT F COND -1 (## -1) AFTER 3), which inserts four elements after the third element, namely F, COND, -1, and a copy of the last element in the current expression.

Form Oriented Editing and the Role of UP

The UP that is performed before A, B, and : commands (and therefore in INSERT, CHANGE, REPLACE, and DELETE commands after the location portion of the operation has been performed) makes these operations form-oriented. For example, if you type F SETQ, and then DELETE, or simply (DELETE SETQ), you will delete the entire SETQ expression, whereas (DELETE X) if X is a variable, deletes just the variable X. In both cases, the operation is performed on the corresponding form, and in both cases is probably what you intended. Similarly, if you type (INSERT (RETURN Y) BEFORE SETQ), you mean before the SETQ expression, not before the atom SETQ. A consequent of this procedure is that a pattern of the form (SETQ Y --) can be viewed as simply an elaboration and further refinement of the pattern SETQ. Thus (INSERT (RETURN Y) BEFORE SETQ) and (INSERT (RETURN Y) BEFORE (SETQ Y --)) perform the same operation (assuming the next SETQ is of the form (SETQ Y --)) and, in fact, this is one of the motivations behind making the current expression after F SETQ, and F (SETQ Y --) be the same.

Note: There is some ambiguity in (INSERT EXPR AFTER FUNCTIONNAME), as you might mean make EXPR be the function’s first argument. Similarly, you cannot write (REPLACE SETQ WITH SETQQ) meaning change the name of the function. You must in these cases write (INSERT EXPR AFTER FUNCTIONNAME 1), and (REPLACE SETQ 1 WITH SETQQ).

Occasionally, however, you may have a data structure in which no special significance or meaning is attached to the position of an atom in a list, as Interlisp attaches to atoms that appear as CAR of a list, versus those appearing elsewhere in a list. In general, you may not even know whether a particular atom is at the head of a list or not. Thus, when you write (INSERT EXPR BEFORE FOO), you mean before the atom FOO, whether or not it is CAR of a list. By setting the variable UPFINDPLG to NIL
(initially T), you can suppress the implicit UP that follows searches for atoms, and thus achieve the desired effect. With UPFINDFLG = NIL, following F FOO, for example, the current expression will be the atom FOO. In this case, the A, B, and : operations will operate with respect to the atom FOO. If you intend the operation to refer to the list which FOO heads, use the pattern (FOO --) instead.

**Extract and Embed**

Extraction involves replacing the current expression with one of its subexpressions (from any depth).

```
(XTR . @)
```

Replaces the original current expression with the expression that is current after performing (LCL . @) (see warning about INSERT above). If the current expression after (LCL . @) is a tail of a higher expression, its first element is used.

If the extracted expression is a list, then after XTR has finished, the current expression will be that list. If the extracted expression is not a list, the new current expression will be a tail whose first element is that non-list.

For example, if the current expression is (COND ((NULL X) (PRINT Y))), (XTR PRINT) will replace the COND by the PRINT. The current expression after the XTR would be (PRINT Y).

If the current expression is (COND ((NULL X) Y) (T Z)), then (XTR Y) will replace the COND with Y, even though the current expression after performing (LCL Y) is ... Y). The current expression after the XTR would be ... Y followed by whatever followed the COND.

If the current expression *initially* is a tail, extraction works exactly the same as though the current expression were the first element in that tail. Thus if the current expression is ... (COND ((NULL X) (PRINT Y))) (RETURN Z)), then (XTR PRINT) will replace the COND by the PRINT, leaving (PRINT Y) as the current expression.

The extract command can also incorporate a location specification:

```
(EXTRACT @1 FROM . @2)
```

Performs (LC . @2) and then (XTR . @1) (see warning about INSERT). The current edit chain is not changed, but UNFIND is set to the edit chain after the XTR was performed.

**Note:** @1 is the *segment* between EXTRACT and FROM.

For example: If the current expression is (PRINT (COND ((NULL X) Y) (T Z))) then following (EXTRACT Y FROM COND), the current expression will be (PRINT Y). (EXTRACT 2 -1 FROM COND), (EXTRACT Y FROM 2), and (EXTRACT 2 -1 FROM 2) will all produce the same result.
While extracting replaces the current expression by a subexpression, embedding replaces the current expression with one containing it as a subexpression.

\[(\text{MBD } E_1 \ldots E_M)\]  

[Editor Command]

\(\text{MBD}\) substitutes the current expression for all instances of the atom & in \(E_1 \ldots E_M\) and replaces the current expression with the result of that substitution. As with \(\text{SUBST}\), a fresh copy is used for each substitution.

If & does not appear in \(E_1 \ldots E_M\) the \(\text{MBD}\) is interpreted as \((\text{MBD} (E_1 \ldots E_M &))\).

\(\text{MBD}\) leaves the edit chain so that the larger expression is the new current expression.

Examples:

If the current expression is \((\text{PRINT} \ Y)\), \((\text{MBD} \ (\text{COND} ((\text{NULL} \ X) \ & \ ((\text{NULL} \ (\text{CAR} \ Y)) \ & \ (\text{GO} \ \text{LP}))))))\) would replace \((\text{PRINT} \ Y)\) with \((\text{COND} ((\text{NULL} \ X) \ (\text{PRINT} \ Y)) \ ((\text{NULL} \ (\text{CAR} \ Y)) \ (\text{PRINT} \ Y) \ (\text{GO} \ \text{LP}))))\).

If the current expression is \((\text{RETURN} \ X)\), \((\text{MBD} \ (\text{PRINT} \ Y) \ (\text{AND} \ FLG \ &))\) would replace it with the two expressions \((\text{PRINT} \ Y)\) and \((\text{AND} \ FLG \ (\text{RETURN} \ X))\), i.e., if the \((\text{RETURN} \ X)\) appeared in the cond clause \((\text{T} \ (\text{RETURN} \ X))\), after the \(\text{MBD}\), the clause would be \((\text{T} \ (\text{PRINT} \ Y) \ (\text{AND} \ FLG \ (\text{RETURN} \ X)))).\)

If the current expression is \((\text{PRINT} \ Y)\), then \((\text{MBD} \ \text{SETQ} \ X)\) will replace it with \((\text{SETQ} \ X \ (\text{PRINT} \ Y))\). If the current expression is \((\text{PRINT} \ Y)\), \((\text{MBD} \ \text{RETURN})\) will replace it with \((\text{RETURN} \ (\text{PRINT} \ Y))\).

If the current expression initially is a tail, embedding works exactly the same as though the current expression were the first element in that tail. Thus if the current expression were \(\ldots \ (\text{PRINT} \ Y) \ (\text{PRINT} \ Z))\), \((\text{MBD} \ \text{SETQ} \ X)\) would replace \((\text{PRINT} \ Y)\) with \((\text{SETQ} \ X \ (\text{PRINT} \ Y))\).

The embed command can also incorporate a location specification:

\[(\text{EMBED} @ \ \text{IN} \ . \ X)\]  

[Editor Command]

\(@\) is the segment between \(\text{EMBED}\) and \(\text{IN}\.) \(\text{Does} \ (\text{LC} \ . \ @)\) and then \((\text{MBD} \ . \ X)\) (see warning about \(\text{INSERT}\)). Edit chain is not changed, but \text{UNFIND} is set to the edit chain after the \(\text{MBD}\) was performed.

Examples: \((\text{EMBED} \ \text{PRINT} \ \text{IN} \ \text{SETQ} \ X), \ (\text{EMBED} \ 3 \ 2 \ \text{IN} \ \text{RETURN}), \ (\text{EMBED} \ \text{COND} \ 3 \ 1 \ \text{IN} \ (\text{OR} \ & \ (\text{NULL} \ X)))).\)
WITH can be used for IN, and SURROUND can be used for EMBED, e.g., (SURROUND NUMBERP WITH (AND & (MINUSP X))).

EDITEMBEDTOKEN

The special atom used in the MBD and EMBED commands is the value of this variable, initially &.

The MOVE Command

The MOVE command allows you to specify the expression to be moved, the place it is to be moved to, and the operation to be performed there, e.g., insert it before, insert it after, replace, etc.

(MOVE @1 TO COM . @2)

[@1 is the segment between MOVE and TO.] COM is BEFORE, AFTER, or the name of a list command, e.g., :, N, etc. Performs (LC . @1) (see warning about INSERT), and obtains the current expression there (or its first element, if it is a tail), which we will call EXPR; MOVE then goes back to the original edit chain, performs (LC . @2) followed by (COM EXPR) (setting an internal flag so EXPR is not copied), then goes back to @1 and deletes EXPR. The edit chain is not changed. UNFINISH is set to the edit chain after (COM EXPR) was performed.

If @2 specifies a location inside of the expression to be moved, a message is printed and an error is generated, e.g., (MOVE 2 TO AFTER X), where X is contained inside of the second element.

For example, if the current expression is (A B C D), (MOVE 2 TO AFTER 4) will make the new current expression be (A C D B). Note that 4 was executed as of the original edit chain, and that the second element had not yet been removed.

As the following examples taken from actual editing will show, the MOVE command is an extremely versatile and powerful feature of the editor.

*?
(PROG ((L L)) (EDLOC (CDDR C)) (RETURN (CAR L))))
*(MOVE 3 TO : CAR)
*?
(PROG ((L L)) (RETURN (EDLOC (CDDR C)))))
*P
... (SELECTQ OBJPR & &) (RETURN &) LP2 (COND & &))
*(MOVE 2 TO N 1)
*P
... (SELECTQ OBJPR & & &) LP2 (COND & &))
*P
*P
In the last example, you could have added the PROG label \texttt{NXT} and moved the \texttt{COND} in one operation by performing \texttt{(MOVE 4 TO N \texttt{← PROG})}. Similarly, in the next example, in the course of specifying \texttt{@2}, the location where the expression was to be moved to, you also perform a structure modification, via \texttt{(N \texttt{T})}, thus creating the structure that will receive the expression being moved.

If \texttt{a2} is \texttt{NIL}, or \texttt{(HERE)}, the current position specifies where the operation is to take place. In this case, \texttt{UNFIND} is set to where the expression that was moved was originally located, i.e., \texttt{a1}. For example:

\begin{verbatim}
*P (TENEX) *(MOVE ↑ F APPLY TO N HERE) *P (TENEX (APPLY & &)) *
 *P (PROG (↑ & & ATM IND VAL) (OR & &) **COMMENT** (OR & &) (PRIN1 & T) (PRIN1 & T) (SETQ IND *user typed Control-E

* (MOVE * TO BEFORE HERE) *P (PROG (↑ & & & ATM IND VAL) (OR & &) (OR & &) (PRIN1 &
\end{verbatim}
Finally, if \( \odot_1 \) is \texttt{NIL}, the \texttt{MOVE} command allows you to specify where the \textit{current expression} is to be moved to. In this case, the edit chain is changed, and is the chain where the current expression was moved to; \texttt{UNFIND} is set to where it was.

*P
\((\texttt{SELECTQ OBJPR} \ (\&)) \ (\texttt{PROGN} \ \&))\)*P
\((\texttt{MOVE TO BEFORE LOOP})\)*P
\(\ldots \ (\texttt{SELECTQ OBJPR} \ \&) \ \texttt{LOOP} \ (\texttt{FRPLACA DFPRP} \ \&) \ (\texttt{FRPLACD DFPRP} \ \&)) \ (\texttt{SELECTQ} \ \textit{user typed Control-E})\)*

### Commands That Move Parentheses

The commands presented in this section permit modification of the list structure itself, as opposed to modifying components thereof. Their effect can be described as inserting or removing a single left or right parenthesis, or pair of left and right parentheses. Of course, there will always be the same number of left parentheses as right parentheses in any list structure, since the parentheses are just a notational guide to the structure provided by \texttt{PRINT}. Thus, no command can insert or remove just one parenthesis, but this is suggestive of what actually happens.

In all six commands, \( N \) and \( M \) are used to specify an element of a list, usually of the current expression. In practice, \( N \) and \( M \) are usually positive or negative integers with the obvious interpretation. However, all six commands use the generalized \texttt{NTH} command (\texttt{NTH COM}) to find their element(s), so that \( N \)th element means the first element of the tail found by performing \( \texttt{NTH N} \). In other words, if the current expression is \( (\texttt{LIST} \ \texttt{(CAR X)} \ \texttt{(SETQ Y} \ \texttt{(CONS W Z)})) \), then \( \texttt{(BI 2 CONS)}, \ (\texttt{BI X -1}), \) and \( \texttt{(BI X Z)} \) all specify the exact same operation.

All six commands generate an error if the element is not found, i.e., the \texttt{NTH} fails. All are undoable.

\((\texttt{BI } N \ M)\) [Editor Command]

"Both In". Inserts a left parentheses before the \( N \)th element and after the \( M \)th element in the current expression. Generates an error if the \( M \)th element is not contained in the \( N \)th tail, i.e., the \( M \)th element must be "to the right" of the \( N \)th element.

Example: If the current expression is \( (A \ B \ (C \ D \ E) \ F \ G) \), then \( \texttt{(BI 2 4)} \) will modify it to be \( (A \ (B \ (C \ D \ E) \ F) \ G) \).

\((\texttt{BI } N)\) [Editor Command]

Same as \( \texttt{(BI } N \ N) \).
Example: If the current expression is \((A \ B \ (C \ D \ E) \ F \ G)\), then \((BI \ -2)\) will modify it to be \((A \ B \ (C \ D \ E) \ (F) \ G)\).

\((BO \ N)\)  
[Editor Command]

"Both Out". Removes both parentheses from the \(N\)th element. Generates an error if \(N\)th element is not a list.

Example: If the current expression is \((A \ B \ (C \ D \ E) \ F \ G)\), then \((BO \ D)\) will modify it to be \((A \ B \ C \ D \ E \ F \ G)\).

\((LI \ N)\)  
[Editor Command]

"Left In". Inserts a left parenthesis before the \(N\)th element (and a matching right parenthesis at the end of the current expression), i.e. equivalent to \((BI \ N-1)\).

Example: if the current expression is \((A \ B \ (C \ D \ E) \ F \ G)\), then \((LI \ 2)\) will modify it to be \((A \ (B \ (C \ D \ E) \ F \ G))\).

\((LO \ N)\)  
[Editor Command]

"Left Out". Removes a left parenthesis from the \(N\)th element. \textit{All elements following the \(N\)th element are deleted}. Generates an error if \(N\)th element is not a list.

Example: If the current expression is \((A \ B \ (C \ D \ E) \ F \ G)\), then \((LO \ 3)\) will modify it to be \((A \ B \ C \ D \ E)\).

\((RI \ N \ M)\)  
[Editor Command]

"Right In". Inserts a right parenthesis after the \(M\)th element of the \(N\)th element. The rest of the \(N\)th element is brought up to the level of the current expression.

Example: If the current expression is \((A \ (B \ C \ D \ E) \ F \ G)\), \((RI \ 2 \ 2)\) will modify it to be \((A \ (B \ C \ D \ E \ F \ G)\). Another way of thinking about \(RI\) is to read it as "move the right parenthesis at the end of the \(N\)th element \textit{in} to after its \(N\)th element."

\((RO \ N)\)  
[Editor Command]

"Right Out". Removes the right parenthesis from the \(N\)th element, moving it to the end of the current expression. All elements following the \(N\)th element are moved inside of the \(N\)th element. Generates an error if \(N\)th element is not a list.
Example: If the current expression is \( (A \ B \ (C \ D \ E) \ F \ G) \), \( (RO \ 3) \) will modify it to be \( (A \ B \ (C \ D \ E \ F \ G)) \). Another way of thinking about \( RO \) is to read it as “move the right parenthesis at the end of the \( N \)th element out to the end of the current expression.”

**TO and THRU**

**EXTRACT**, **EMBED**, **DELETE**, **REPLACE**, and **MOVE** can be made to operate on several contiguous elements, i.e., a segment of a list, by using in their respective location specifications the **TO** or **THRU** command.

\[
(@_1 \ \text{THRU} \ @_2)
\]

[Editor Command]

Does a \( (LC \ . \ @_1) \), followed by an **UP**, and then a \( (BI \ 1 \ @_2) \), thereby grouping the segment into a single element, and finally does a **1**, making the final current expression be that element.

For example, if the current expression is \( (A \ (B \ (C \ D) \ (E) \ (F \ G \ H) \ I) \ J \ K) \), following \( (C \ \text{THRU} \ G) \), the current expression will be \( ((C \ D) \ (E) \ (F \ G \ H)) \).

\[
(@_1 \ \text{TO} \ @_2)
\]

[Editor Command]

Same as **THRU** except the last element not included, i.e., after the **BI**, an \( (RI \ 1 \ -2) \) is performed.

If both \( @_1 \) and \( @_2 \) are numbers, and \( @_2 \) is greater than \( @_1 \), then \( @_2 \) counts from the beginning of the current expression, the same as \( @_1 \). In other words, if the current expression is \( (A \ B \ C \ D \ E \ F \ G) \), \( (3 \ \text{THRU} \ 5) \) means \( (C \ \text{THRU} \ E) \) not \( (C \ \text{THRU} \ G) \). In this case, the corresponding **BI** command is \( (BI \ 1 \ @_2-@_1+1) \).

**THRU** and **TO** are not very useful commands by themselves; they are intended to be used in conjunction with **EXTRACT**, **EMBED**, **DELETE**, **REPLACE**, and **MOVE**. After **THRU** and **TO** have operated, they set an internal editor flag informing the above commands that the element they are operating on is actually a segment, and that the extra pair of parentheses should be removed when the operation is complete. Thus:

\[
*p
\]

\[
\text{(PROG} \ (& \ & \ \text{ATM IND VAL WORD}) \ (PRIN1 \ & \ T) \ (PRIN1 \ & \ T) \ (SETQ \ \text{IND} \ &)
\]
\[
(SETQ \ \text{VAL} \ &} \ **\text{COMMENT}** \ (SETQQ \ \text{user typed Control-E}
\]

\[
*p
\]

\[
\text{(MOVE} \ (3 \ \text{THRU} \ 4) \ \text{TO} \ \text{BEFORE} \ 7)\]
\[

*...

*PP

(PROG (RF TEMP1 TEMP2)
  (COND
    ((NOT (MEMB REMARG LISTING))
     (SETQ TEMP1 (ASSOC REMARG NAMEDREMARKS)))
    **COMMENT**
     (SETQ TEMP2 (CADR TEMP1))
     (GO SKIP))
    **COMMENT**
     (SETQ TEMP1 REMARG)))
  (NCONC1 LISTING REMARG)
  (COND
    ((NOT (SETQ TEMP2 (SASSOC

*(EXTRACT (SETQ THRU CADR) FROM COND)

*(PROG (RF TEMP1 TEMP2) (SETQ TEMP1 &) **COMMENT** (SETQ TEMP2 &)) (NCONC1 LISTING REMARG) (COND & & user typed Control-E

TO and THRU can also be used directly with XTR, because XTR involves a location specification while A, B, :, and MBD do not. Thus in the previous example, if the current expression had been the COND, e.g., you had first performed F COND, you could have used (XTR (SETQ THRU CADR)) to perform the extraction.
Both are the same as \( @1 \text{ THRU} -1 \), i.e., from \( @1 \) through the end of the list.

Examples:

```
*P
(VALUE (RPLACA DEPRP &) (RPLACD &) (RPLACA VARSWORD &) (RETURN))
*(MOVE (2 TO) TO N (← PROG))

     (NOTICECL (CAR A)))
```
The R Command

(R X Y) [Editor Command]

Replaces all instances of $X$ by $Y$ in the current expression, e.g., (R CAADR CADAR).
Generates an error if there is not at least one instance.

The R command operates in conjunction with the search mechanism of the editor. The search proceeds as described in the Search Algorithm section above, and $X$ can employ any of the patterns shown in the Commands That Search section above. Each time $X$ matches an element of the structure, the element is replaced by (a copy of) $Y$; each time $X$ matches a tail of the structure, the tail is replaced by (a copy of) $Y$.

For example, if the current expression is (A (B C) (B . C)),

(R C D) will change it to (A (B D) (B . D)),

(R (... C) D) will change it to (A (B C) (B . D)),

(R C (D E)) will change it to (A (B C) (B . D)), and

(R (... NIL) D) will change it to (A (B C . D) (B . C) . D).

If $X$ is an atom or string containing $\$s$ (escapes), $\$s$ appearing in $Y$ stand for the characters matched by the corresponding $\$ in $X$. For example, (R FOO$ FIE$) means for all atoms or strings that begin with FOO, replace the characters "FOO" by "FIE". Applied to the list (FOO FOO2 XFOO1), (R FOO$ FIE$) would produce (FIE FIE2 XFOO1), and (R $POO$ $FIE$) would produce (FIE FIE2 XFOE1). Similarly, (R $D$ $A$) will change (LIST (CAADR Y)) to (LIST (CAAR X) (CAADR)). Note that CADDR was not changed to CAAR, i.e., (R $D$ $A$) does not mean replace every D with A, but replace the first D in every atom or string by A. If you wanted to replace every D by A, you could perform (LP (R $D$ $A$)).

You will be informed of all such $ replacements by a message of the form $X$->$Y$, e.g., CADR->CAAR.

If $X$ matches a string, it will be replaced by a string. It does not matter whether $X$ or $Y$ themselves are strings, i.e. (R $D$ $A$), (R "$D" "$A"$), (R $D$ "$A"$), and (R "$D" "$A"$) are equivalent. $X$ will never match with a number, i.e., (R $1$ $2$) will not change 11 to 12.

The $ (escape) feature can be used to delete or add characters, as well as replace them. For example, (R $1$ $1$) will delete the terminating 1's from all literal atoms and strings.
Similarly, if an $ in X does not have a mate in Y, the characters matched by the $ are effectively deleted. For example, \( (R \ $/\ $) \) will change AND/OR to AND. There is no similar operation for changing AND/OR to OR, since the first $ in Y always corresponds to the first $ in X, the second $ in Y to the second in X, etc. Y can also be a list containing $s, e.g., \( (R \ $1 (CAR $)) \) will change FOO1 to (CAR FOO), FIE1 to (CAR FIE).

If X does not contain $s, $ appearing in Y refers to the entire expression matched by X, e.g., \( (R \ LONGATOM \ '$) \) changes LONGATOM to ‘LONGATOM, \( (R \ (SETQ \ X \ &) \ (PRINT \ $)) \) changes every \( (SETQ \ X \ &) \) to \( (PRINT \ (SETQ \ X \ &)) \). If X is a pattern containing an $ pattern somewhere within it, the characters matched by the $s are not available, and for the purposes of replacement, the effect is the same as though X did not contain any $s. For example, if you type \( (R \ (CAR \ F$) \ (PRINT \ $)) \), the second $ will refer to the entire expression matched by \( (CAR \ F$).

Since \( (R \ $X$ $SY$) \) is a frequently used operation for Replacing Characters, the following command is provided:

\[
(R \ XY) \quad \text{[Editor Command]}
\]

Equivalent to \( (R \ $X$ $SY$) \)

R and RC change all instances of X to Y. The commands R1 and RC1 are available for changing just one, (i.e., the first) instance of X to Y.

\[
(R1 \ XY) \quad \text{[Editor Command]}
\]

Find the first instance of X and replace it by Y.

\[
(RC1 \ XY) \quad \text{[Editor Command]}
\]

Equivalent to \( (R1 \ $X$ $SY$) \).

In addition, while R and RC only operate within the current expression, R1 and RC1 will continue searching, a la the F command, until they find an instance of x, even if the search carries them beyond the current expression.

\[
(SW \ NM) \quad \text{[Editor Command]}
\]

Switches the Nth and Mth elements of the current expression.

For example, if the current expression is \( (LIST \ \CONS \ (CAR \ X) \ (CAR \ Y)) \ \CONS \ \CONS \ \CONS \ \CONS \ (CDR \ X) \ (CDR \ Y)) \), (SW 2 3) will modify it to be \( (LIST \ \CONS \ (CONS \ \CONS \ (CDR \ X) \ (CDR \ Y)) \ (CONS \ (CAR \ X) \ (CAR \ Y))) \). The relative order of N and M is not important, i.e., \( (SW \ 3 \ 2) \) and \( (SW \ 2 \ 3) \) are equivalent.
SW uses the generalized NTH command \((\texttt{NTH COM})\) to find the \(N\)th and \(M\)th elements, a la the BI-BO commands.

Thus in the previous example, \((\texttt{SW CAR CDR})\) would produce the same result.

\[(\texttt{SWAP \_1 \_2})\] \hspace{1cm} \text{[Editor Command]}

Like SW except switches the expressions specified by \(_1\) and \(_2\), not the corresponding elements of the current expression, i.e. \(_1\) and \(_2\) can be at different levels in current expression, or one or both be outside of current expression.

Thus, using the previous example, \((\texttt{SWAP CAR CDR})\) would result in \((\texttt{LIST (CONS (CDR X) (CAR Y)) (CONS (CAR X) (CDR Y))})\).

### Commands That Print

\textbf{PP} \hspace{1cm} \text{[Editor Command]}

Prettyprints the current expression.

\textbf{P} \hspace{1cm} \text{[Editor Command]}

Prints the current expression as though PRINTLEVEL (Chapter 25) were set to 2.

\[(P \ M)\] \hspace{1cm} \text{[Editor Command]}

Prints the \(M\)th element of the current expression as though PRINTLEVEL were set to 2.

\[(P \ 0)\] \hspace{1cm} \text{[Editor Command]}

Same as P.

\[(P \ M N)\] \hspace{1cm} \text{[Editor Command]}

Prints the \(M\)th element of the current expression as though PRINTLEVEL were set to \(N\).

\[(P \ 0 \ N)\] \hspace{1cm} \text{[Editor Command]}

Prints the current expression as though PRINTLEVEL were set to \(N\).

? \hspace{1cm} \text{[Editor Command]}

Same as \((P \ 0 \ 100)\).
Both \((P\ M)\) and \((P\ M\ N)\) use the generalized \texttt{NTH} command \((\texttt{NTH} \ \texttt{COM})\) to obtain the corresponding element, so that \(M\) does not have to be a number, e.g., \((P\ \texttt{COND} \ 3)\) will work. \texttt{PP} causes all comments to be printed as \texttt{**COMMENT**} (see Chapter 26). \texttt{P} and \texttt{?} print as \texttt{**COMMENT**} only those comments that are (top level) elements of the current expression. Lower expressions are not really seen by the editor; the printing command simply sets \texttt{PRINTLEVEL} and calls \texttt{PRINT}.

\texttt{PP}\*  
[Editor Command]

Prettyprints current expression, \textit{including} comments.

\texttt{PP}\* is equivalent to \texttt{PP} except that it first resets \texttt{**COMMENT**FLG} to \texttt{NIL} (see Chapter 26).

\texttt{PPV}  
[Editor Command]

Prettyprints the current expression as a variable, i.e., no special treatment for \texttt{LAMBDA}, \texttt{COND}, \texttt{SETQ}, etc., or for \texttt{CLISP}.

\texttt{PPT}  
[Editor Command]

Prettyprints the current expression, printing \texttt{CLISP} translations, if any.

\texttt{?=}  
[Editor Command]

Prints the argument names and corresponding values for the current expression. Analagous to the \texttt{?= break} command (Chapter 14). For example,

\begin{verbatim}
  *P
  (STRPOS "A0???" X N (QUOTE ?) T)
  *=
  X = "A0???"
  Y = X
  START = N
  SKIP = (QUOTE ?)
  ANCHOR = T
  TAIL =
\end{verbatim}

The command \texttt{MAKE} (see below) is an imperative form of \texttt{?=}. It allows you to specify a change to the element of the current expression that corresponds to a particular argument name.

All printing functions print to the terminal, regardless of the primary output file. All use the readtable \texttt{T}. No printing function ever changes the edit chain. All record the current edit chain for use by \texttt{\textbackslash P} (above). All can be aborted with Control-E.
Commands for Leaving the Editor

OK [Editor Command]

Exits from the editor.

STOP [Editor Command]

Exits from the editor with an error. Mainly for use in conjunction with TTY: commands (see next section) that you want to abort.

Since all of the commands in the editor are errorset protected, you must exit from the editor via a command. STOP provides a way of distinguishing between a successful and unsuccessful (from your standpoint) editing session. For example, if you are executing (MOVE 3 TO AFTER COND TTY:), and you exits from the lower editor with an OK, the MOVE command will then complete its operation. If you want to abort the MOVE command, you must make the TTY: command generate an error. Do this by exiting from the lower editor with a STOP command. In this case, the higher editor's edit chain will not be changed by the TTY: command.

Actually, it is also possible to exit the editor by typing Control-D. STOP is preferred even if you are editing at the EVALQT level, as it will perform the necessary "wrapup" to insure that the changes made while editing will be undoable.

SAVE [Editor Command]

Exits from the editor and saves the "state of the edit" on the property list of the function or variable being edited under the property EDIT-SAVE. If the editor is called again on the same structure, the editing is effectively "continued," i.e., the edit chain, mark list, value of UNFIND and UNDOLST are restored.

For example:

```
P (NULL X)  
*F COND P  
(COND (\ & &) (T \))  
*SAVE  
FOO  
← .  
.  
.  
←EDITF (FOO)  
EDIT  
P (COND (\ & &) (T \))  
\ P  
(NULL X)  
* 
```
SAVE is necessary only if you are editing many different expressions; an exit from the editor via OK always saves the state of the edit of that call to the editor on the property list of the atom EDIT, under the property name LASTVALUE. OK also remprops EDIT-SAVE from the property list of the function or variable being edited.

Whenever the editor is entered, it checks to see if it is editing the same expression as the last one edited. In this case, it restores the mark list and UNDOLST, and sets UNFIND to be the edit chain as of the previous exit from the editor. For example:

```
←EDITF(FOO)
EDIT
*p
(LAMBDA (X) (PROG & & LP & & & &))
.
.
.*
(COND & &)
*OK
FOO
←
.
.
←EDITF(FOO)
EDIT
*p
(LAMBDA (X) (PROG & & LP & & & &))
* \ p
(COND & &)
*
```

```
\hspace*{0.7cm}any number of LISPX inputs
\hspace*{0.7cm}except for calls to the editor
```

Furthermore, as a result of the history feature, if the editor is called on the same expression within a certain number of LISPX inputs (namely, the size of the history list, which can be changed with CHANGESLICE, Chapter 13) the state of the edit of that expression is restored, regardless of how many other expressions may have been edited in the meantime. For example:

```
←EDITF(FOO)
EDIT
* 
.
.
.*
(COND (& &) (& &) (&) (T &))
*OK
FOO
.
.
.
←EDITF(FOO)
EDIT
* \ p
(COND (& &) (& &) (&) (T &))
*
```

```
\hspace*{1cm}a small number of LISPX inputs,
\hspace*{1cm}including editing
```
Thus you can always continue editing, including undoing changes from a previous editing session, if one of the following occurs:

1. No other expressions have been edited since that session (since saving takes place at exit time, intervening calls that were aborted via Control-D or exited via STOP will not affect the editor's memory).

2. That session was "sufficiently" recent.

3. It was ended with a SAVE command.

**Nested Calls to Editor**

TTY: [Editor Command]

Calls the editor recursively. You can then type in commands, and have them executed. The TTY: command is completed when you exit from the lower editor (see OK and STOP above).

The TTY: command is extremely useful. It enables you to set up a complex operation, and perform interactive attention-changing commands part way through it. For example, the command (MOVE 3 TO AFTER COND 3 P TTY:) allows you to interact, in effect, within the MOVE command. You can then verify for yourself that the correct location has been found, or complete the specification "by hand." In effect, TTY: says "I'll tell you what you should do when you get there."

The TTY: command operates by printing TTY: and then calling the editor. The initial edit chain in the lower editor is the one that existed in the higher editor at the time the TTY: command was entered. Until you exit from the lower editor, any attention changing commands you execute only affect the lower editor's edit chain. Of course, if you perform any structure modification commands while under a TTY: command, these will modify the structure in both editors, since it is the same structure. When the TTY: command finishes, the lower editor's edit chain becomes the edit chain of the higher editor.

EF [Editor Command]
EV [Editor Command]
EP [Editor Command]

Calls EDITF or EDITV or EDITP on CAR of current expression.
Manipulating the Characters of an Atom or String

**RAISE**

[Editor Command]

An edit macro defined as UP followed by `(I 1 (U-CASE (## 1)))`, i.e., it raises to uppercase the current expression, or if a tail, the first element of the current expression.

**LOWER**

Similar to RAISE, except uses `L-CASE`.

**CAP**

First does a RAISE, and then lowers all but the first character, i.e., the first character is left capitalized.

RAISE, LOWER, and CAP are all no-ops if the corresponding atom or string is already in that state.

**(RAISE X)**

[Editor Command]

Equivalent to `(I R (L-CASE X) X)`, i.e., changes every lowercase X to uppercase in the current expression.

**(LOWER X)**

Similar to RAISE, except performs `(I R X (L-CASE X))`.

In both (RAISE X) and (LOWER X), X should be typed in uppercase.

**REPACK**

[Editor Command]

Permits the "editing" of an atom or string.

REPACK operates by calling the editor recursively on UNPACK of the current expression, or if it is a list, on UNPACK of its first element. If the lower editor is exited successfully, i.e., via OK as opposed to STOP, the list of atoms is made into a single atom or string, which replaces the atom or string being "repacked." The new atom or string is always printed.

Example:

```
(P
  ... "THIS IS A LOGN STRING")
*REPACK
*EDIT
P
(T H I S % I S % A % L O G N % S T R I N G)
```
This could also have been accomplished by (R $GN$ $NG$) or simply (RC GN NG).

(REPACK @)  
[Editor Command]

Does (LC . @) followed by REPACK, e.g. (REPACK THIS$).

Manipulating Predicates and Conditional Expressions

JOINC  
[Editor Command]

Used to join two neighboring CONDs together, e.g. (COND CLAUSE₁ CLAUSE₂) followed by (COND CLAUSE₃ CLAUSE₄) becomes (COND CLAUSE₁ CLAUSE₂ CLAUSE₃ CLAUSE₄).

JOINC does an (F COND T) first so that you don’t have to be at the first COND.

(SPLITC X)  
[Editor Command]

Splits one COND into two. X specifies the last clause in the first COND, e.g. (SPLITC 3) splits (COND CLAUSE₁ CLAUSE₂ CLAUSE₃ CLAUSE₄) into (COND CLAUSE₁ CLAUSE₂) (COND CLAUSE₃ CLAUSE₄). Uses the generalized NTH command (NTH COM), so that X does not have to be a number, e.g., you can say (SPLITC RETURN), meaning split after the clause containing RETURN. SPLITC also does an (F COND T) first.

NEGATE  
[Editor Command]

Negates the current expression, i.e. performs (MBD NOT), except that is smart about simplifying. For example, if the current expression is: (OR (NULL X) (LISTP X)), NEGATE would change it to (AND X (NLISTP X)).

NEGATE is implemented via the function NEGATE (Chapter 3).

SWAPC  
[Editor Command]

Takes a conditional expression of the form (COND (A B) (T C)) and rearranges it to an equivalent (COND ((NOT A) C) (T B)), or (COND (A B) (C D)) to (COND ((NOT A) (COND (C D))) (T B)).
SWAPC is smart about negations (uses NEGATE) and simplifying CONDs. It always produces an equivalent expression. It is useful for those cases where one wants to insert extra clauses or tests.

**History Commands in the Editor**

All of your inputs to the editor are stored on the history list EDITHISTORY (see Chapter 13, the editor’s history list, and all of the programmer’s assistant commands for manipulating the history list, e.g. REDO, USE, FIX, NAME, etc., are available for use on events on EDITHISTORY. In addition, the following four history commands are recognized specially by the editor. They always operate on the last, i.e. most recent, event.

**DO COM**

[Editor Command]

Allows you to supply the command name when it was omitted.

**USE** is useful when a command name is incorrect.

For example, suppose you want to perform \((-2 \ (SETQ X \ (LIST Y Z)))\) but instead types just \((SETQ X \ (LIST Y Z))\). The editor will type \(SETQ \ ?\), whereupon you can type **DO -2**. The effect is the same as though you had typed **FIX**, followed by \((LI 1), (-1 -2),\) and **OK**, i.e., the command \((-2 \ (SETQ X \ (LIST Y Z)))\) is executed. **DO** also works if the command is a line command.

**!F**

[Editor Command]

Same as **DO F**.

In the case of **!F**, the previous command is always treated as though it were a line command, e.g., if you type \((SETQ X \ &)\) and then **!F**, the effect is the same as though you had typed **F** \((SETQ X \ &)\), not \((F \ (SETQ X \ &)\).

**!E**

[Editor Command]

Same as **DO E**.

**!N**

[Editor Command]

Same as **DO N**.
Miscellaneous Commands

NIL [Editor Command]

Unless preceded by $F$ or $BF$, is always a no-op. Thus extra right parentheses or square brackets at the ends of commands are ignored.

CL [Editor Command]

Clispifies the current expression (see Chapter 21).

DW [Editor Command]

Dwimifies the current expression (see Chapter 21).

IFY [Editor Command]

If the current statement is a $COND$ statement (Chapter 9), replaces it with an equivalent $IF$ statement.

GET* [Editor Command]

If the current expression is a comment pointer (see Chapter 26), reads in the full text of the comment, and replaces the current expression by it.

(* . X) [Editor Command]

$X$ is the text of a comment. $*$ ascends the edit chain looking for a "safe" place to insert the comment, e.g., in a $COND$ clause, after a $PROG$ statement, etc., and inserts ($* . X$) after that point, if possible, otherwise before. For example, if the current expression is $(FACT \ (SUB1 \ N))$ in

```
(COND
  ((ZEROP N) 1)
  (T (ITIMES N (FACT (SUB1 N)
```

then ($* \ \text{CALL FACT RECURSIVELY})$) would insert ($* \ \text{CALL FACT RECURSIVELY})$ before the $ITIMES$ expression. If inserted after the $ITIMES$, the comment would then be (incorrectly) returned as the value of the $COND$. However, if the $COND$ was itself a $PROG$ statement, and hence its value was not being used, the comment could be (and would be) inserted after the $ITIMES$ expression.

$*$ does not change the edit chain, but $UNFIND$ is set to where the comment was actually inserted.
GETD

[Editor Command]

Essentially "expands" the current expression in line:

1. If (CAR of) the current expression is the name of a macro, expands the macro in line;
2. If a CLISP word, translates the current expression and replaces it with the translation;
3. If CAR is the name of a function for which the editor can obtain a symbolic definition, either in-core or from a file, substitutes the argument expressions for the corresponding argument names in the body of the definition and replaces the current expression with the result;
4. If CAR of the current expression is an open lambda, substitutes the arguments for the corresponding argument names in the body of the lambda, and then removes the lambda and argument list.

Warning: When expanding a function definition or open lambda expression, GETD does a simple substitution of the actual arguments for the formal arguments. Therefore, if any of the function arguments are used in other ways in the function definition (as functions, as record fields, etc.), they will simply be replaced with the actual arguments.

(MAKEFN (FN . ACTUALARGS) ARGLIST N1 N2)

[Editor Command]

The inverse of GETD: makes the current expression into a function. FN is the function name, ARGLIST its arguments. The argument names are substituted for the corresponding argument values in ACTUALARGS, and the result becomes the body of the function definition for FN. The current expression is then replaced with (FN . ACTUALARGS).

If N1 and N2 are supplied, (N1 THRU N2) is used rather than the current expression; if just N1 is supplied, (N1 THRU -1) is used.

If ARGLIST is omitted, MAKEFN will make up some arguments, using elements of ACTUALARGS, if they are literal atoms, otherwise arguments selected from (X Y Z A B C ...), avoiding duplicate argument names.

Example: If the current expression is (COND ((CAR X) (PRINT Y T)) (T (HELP)) ), then (MAKEFN (FOO (CAR X) Y) (A B)) will define FOO as (LAMBDA (A B) (COND (A (PRINT B T)) (T (HELP)) )) and then replace the current expression with (FOO (CAR X) Y).
(MAKE ARGNAME EXP)  

[Editor Command]

Makes the value of ARGNAME be EXP in the call which is the current expression, i.e. a ?= command following a MAKE will always print ARGNAME = EXP. For example:

*P
(JSYS)
*?= JSYS[N;AC1,AC2,AC3,RESULTAC]
*(MAKE N 10)
*(MAKE RESULTAC 3)
*P
(JSYS 10 NIL NIL NIL 3)

Q  

[Editor Command]

Quotes the current expression, i.e. MBD QUOTE.

D  

[Editor Command]

Deletes the current expression, then prints new current expression, i.e. (;) I P.

Commands That Evaluate

E  

[Editor Command]

Causes the editor to call the Interlisp executive LISPX giving it the next input as argument.

Example:

*E BREAK(FIE FUM)
(FIE FUM)
*E (FOO)

(FIE BROKEN)

E only works when when typed in, e.g. (INSERT D BEFORE E) will treat E as a pattern, and search for E.

(E X)  

[Editor Command]

Evaluates X, i.e., performs (EVAL X), and prints the result on the terminal.

(E X T)  

[Editor Command]

Same as (E X) but does not print.
The \((E X)\) and \((E X T)\) commands are mainly intended for use by macros and subroutine calls to the editor; you would probably type in a form for evaluation using the more convenient format of the (atomic) \(E\) command.

\([(I \ C \ X_1 \ \ldots \ X_N)]\)  
[Editor Command]

Executes the editor command \((C \ Y_1 \ \ldots \ Y_N)\) where \(Y_i = (EVAL \ X_i)\). If \(C\) is not an atom, \(C\) is evaluated also.

Examples:

\((I \ 3 \ (GETD \ 'FOO) )\) will replace the third element of the current expression with the definition of \(FOO\).

\((I \ N \ FOO \ (CAR \ FIE))\) will attach the value of \(FOO\) and \(CAR\) of the value of \(FIE\) to the end of the current expression.

\((I \ F = \ FOO \ T)\) will search for an expression \(EQ\) to the value of \(FOO\).

\((I \ (COND \ ((NULL \ FLG) \ '-1) \ (T \ 1)) \ FOO)\), if \(FLG\) is \(NIL\), inserts the value of \(FOO\) before the first element of the current expression, otherwise replaces the first element by the value of \(FOO\).

The \(I\) command sets an internal flag to indicate to the structure modification commands not to copy expression(s) when inserting, replacing, or attaching.

\(EVAL\)  
[Editor Command]

Does an \(EVAL\) of the current expression.

\(EVAL\), line-feed, and the \(GO\) command together effectively allows you to "single-step" a program through its symbolic definition.

\(GETVAL\)  
[Editor Command]

Replaces the current expression by the result of evaluating it.

\((## \ COM_1 \ COM_2 \ \ldots \ COM_N)\)  
[NLambda NoSpread Function]

An nlambda, nospread function (not a command). Its value is what the current expression would be after executing the edit commands \(COM_1\) \ldots \(COM_N\) starting from the present edit chain. Generates an error if any of \(COM_2\) thru \(COM_N\) cause errors. The current edit chain is never changed.
Note: The \( A \), \( B \), \( : \), INSERT, REPLACE, and CHANGE commands make special checks for \#\# forms in the expressions used for inserting or replacing, and use a copy of \#\# form instead (see the \( A \), \( B \), and \( : \) Commands section above). Thus, \( \text{INSERT} (\#\# 3 2) \text{AFTER} 1 \) is equivalent to \( (I \text{ INSERT} (\text{COPY} (\#\# 3 2)) \text{AFTER} 1) \).

Example: \( (I \; R \; 'X \; (\#\# (\text{CONS} .. Z))) \) replaces all \( X \)'s in the current expression by the first \text{CONS} containing a \text{Z}.

The \text{I} command is not very convenient for computing an \textit{entire} edit command for execution, since it computes the command name and its arguments separately. Also, the \text{I} command cannot be used to compute an atomic command. The following two commands provide more general ways of computing commands.

\[ (C\text{OMS} \; X_1 \ldots \; X_M) \]  

Each \( X_j \) is evaluated and its value is executed as a command.

For example, \( (C\text{OMS} \; (C\text{OND} \; (X \; (L\text{IST} \; 1 \; X)))) \) will replace the first element of the current expression with the value of \( X \) if non-NIL, otherwise do nothing. The editor command NIL is a no-op (see the Miscellaneous Commands section above).

\[ (C\text{OMSQ} \; C\text{OM}_1 \ldots \; C\text{OM}_N) \]  

Executes \( \text{COM}_1 \ldots \; \text{COM}_N \).

\( \text{COMSQ} \) is mainly useful in conjunction with the \text{COMS} command. For example, suppose you want to compute an entire list of commands for evaluation, as opposed to computing each command one at a time as does the \text{COMS} command. You would then write \( (C\text{OMS} \; (C\text{ONS} \; 'C\text{OMSQ} \; X)) \) where \( X \) computed the list of commands, e.g., \( (C\text{OMS} \; (C\text{ONS} \; 'C\text{OMSQ} \; (G\text{ETP} \; F\text{OO} \; 'C\text{OMMANDS}))) \).

Commands That Test

\[ (I\text{F} \; X) \]  

Generates an error \textit{unless} the value of \( (E\text{VAL} \; X) \) is true. In other words, if \( (E\text{VAL} \; X) \) causes an error or \( (E\text{VAL} \; X) = \text{NIL} \), IF will cause an error.

For some editor commands, the occurrence of an error has a well defined meaning, i.e., they use errors to branch on, as \text{COND} uses NIL and non-NIL. For example, an error condition in a location specification may simply mean “not this one, try the next.” Thus the location
specification \((\text{IPLUS} (\text{E} (\text{OR} (\text{NUMBERP} (\## 3)) (\text{ERROR})))) \text{T}))\) specifies the first \text{IPLUS} whose second argument is a number. The \text{IF} command, by equating \text{NIL} to error, provides a more natural way of accomplishing the same result. Thus, an equivalent location specification is \((\text{IPLUS} (\text{IF} (\text{NUMBERP} (\## 3))))\).

The \text{IF} command can also be used to select between two alternate lists of commands for execution.

\[(\text{IF} X \text{COMS}_1 \text{COMS}_2)\]  

[Editor Command]

If \((\text{EVAL} X)\) is true, execute \text{COMS}_1; if \((\text{EVAL} X)\) causes an error or is equal to \text{NIL}, execute \text{COMS}_2.

Thus \text{IF} is equivalent to

\[(\text{COMS} (\text{CONS} '\text{COMSQ} \text{COND} ((\text{CAR} (\text{NLSETQ} (\text{EVAL} X))) \text{COMS}_1) (\text{T} \text{COMS}_2))))\]

For example, the command \((\text{IF} (\text{READP} \text{T}) \text{NIL} \text{P}))\) will print the current expression provided the input buffer is empty.

\[(\text{IF} X \text{COMS}_1)\]  

[Editor Command]

If \((\text{EVAL} X)\) is true, execute \text{COMS}_1; otherwise generate an error.

\[(\text{LP} \text{COMS}_1 \ldots \text{COMS}_N)\]  

[Editor Command]

Repeatedly executes \text{COMS}_1 \ldots \text{COMS}_N until an error occurs.

For example, \((\text{LP} \text{F} \text{PRINT} (\text{N} \text{T}))\) will attach a \text{T} at the end of every \text{PRINT} expression. \((\text{LP} \text{F} \text{PRINT} (\text{IF} (\## 3) \text{NIL} ((\text{N} \text{T}))))\) will attach a \text{T} at the end of each print expression which does not already have a second argument. The form \((\## 3)\) will cause an error if the edit command 3 causes an error, thereby selecting \((\text{N} \text{T}))\) as the list of commands to be executed. The \text{IF} could also be written as \((\text{IF} (\text{CDDR} (\##)) \text{NIL} ((\text{N} \text{T}))))\).

When an error occurs, \text{LP} prints \text{N OCCURRENCES} where \text{N} is the number of times the commands were successfully executed. The edit chain is left as of the last complete successful execution of \text{COMS}_1 \ldots \text{COMS}_N.
(LPQ COMS₁ ... COMSN)

Same as LP but does not print the message N OCCURRENCES.

In order to prevent non-terminating loops, both LP and LPQ terminate when the number of iterations reaches MAXLOOP, initially set to 30. MAXLOOP can be set to NIL, which is equivalent to setting it to infinity. Since the edit chain is left as of the last successful completion of the loop, you can simply continue the LP command with REDO (see Chapter 13).

(SHOW X)

X is a list of patterns. SHOW does a LPQ printing all instances of the indicated expression(s), e.g. (SHOW FOO (SETQ FIE &)) will print all FOOs and all (SETQ FIE &)s. Generates an error if there aren't any instances of the expression(s).

(EXAM X)

Like SHOW except calls the editor recursively (via the TTY: command, see above) on each instance of the indicated expression(s) so that you can examine and/or change them.

(ORR COMS₁ ... COMSN)

ORR begins by executing COMS₁, a list of commands. If no error occurs, ORR is finished. Otherwise, ORR restores the edit chain to its original value, and continues by executing COMS₂, etc. If none of the command lists execute without errors, i.e., the ORR "drops off the end", ORR generates an error. Otherwise, the edit chain is left as of the completion of the first command list which executes without an error.

NIL as a command list is perfectly legal, and will always execute successfully. Thus, making the last "argument" to ORR be NIL will insure that the ORR never causes an error. Any other atom is treated as (ATOM), i.e., the above example could be written as (ORR NX !NX NIL).

For example, (ORR (NX) (!NX) NIL) will perform a NX, if possible, otherwise a !NX, if possible, otherwise do nothing. Similarly, DELETE could be written as (ORR (UP (1)) (BK UP (2)) (UP (: NIL))).

Edit Macros

Many of the more sophisticated branching commands in the editor, such as ORR, IF, etc., are most often used in conjunction with edit macros. The macro feature permits you to define new commands and thereby expand the editor's repertoire, or redefine existing commands (to refer to the original
definition of a built-in command when redefining it via a macro, use the ORIGINAL command, below).

Macros are defined by using the $M$ command:

$$(M \ C \ \text{COMS}_1 \ldots \ \text{COMS}_N)$$

[Editor Command]

For $C$ an atom, $M$ defines $C$ as an atomic command. If a macro is redefined, its new definition replaces its old. Executing $C$ is then the same as executing the list of commands $\text{COMS}_1 \ldots \ \text{COMS}_N$.

For example, $(M \ BP \ BK \ UP \ P)$ will define $BP$ as an atomic command which does three things, a $BK$, and $UP$, and a $P$. Macros can use commands defined by macros as well as built in commands in their definitions. For example, suppose $Z$ is defined by $(M \ Z \ -1 \ \text{IF} \ \text{(READP} \ T) \ \text{NIL} \ \text{(P)}))$, i.e., $Z$ does a $-1$, and then if nothing has been typed, a $P$. Now we can define $ZZ$ by $(M \ ZZ \ -1 \ Z)$, and $ZZZ$ by $(M \ ZZZ \ -1 \ -1 \ Z)$ or $(M \ ZZZ \ -1 \ ZZ)$.

Macros can also define list commands, i.e., commands that take arguments.

$$(M \ (\ C) \ \text{ARG}_1 \ldots \ \text{ARG}_N) \ \text{COMS}_1 \ldots \ \text{COMS}_M$$

[Editor Command]

If $C$, ARG are both atoms, this defines $C$ as a list command. Executing $(C \ E_1 \ldots \ E_N)$ is performed by substituting $E_1$ for $\text{ARG}_1$, $\ldots$, $E_N$ for $\text{ARG}_N$ throughout $\text{COMS}_1 \ldots \ \text{COMS}_M$ and then executing $\text{COMS}_1 \ldots \ \text{COMS}_M$.

For example, we could define a more general $BP$ by $(M \ (BP) \ (N) \ (BK \ N) \ \text{UP} \ P)$. Thus, $(BP \ 3)$ would perform $(BK \ 3)$, followed by an $UP$, followed by a $P$.

A list command can be defined via a macro so as to take a fixed or indefinite number of "arguments", as with spread vs. nospread functions. The form given above specified a macro with a fixed number of arguments, as indicated by its argument list. If the "argument list" is atomic, the command takes an indefinite number of arguments.

$$(M \ (\ C) \ \text{ARG} \ \text{COMS}_1 \ldots \ \text{COMS}_M)$$

[Editor Command]

If $C$, ARG are both atoms, this defines $C$ as a list command. Executing $(C \ E_1 \ldots \ E_N)$ is performed by substituting $(E_1 \ldots \ E_N)$, i.e., $\text{CDR}$ of the command, for $\text{ARG}$ throughout $\text{COMS}_1 \ldots \ \text{COMS}_M$ and then executing $\text{COMS}_1 \ldots \ \text{COMS}_M$.

For example, the command $2\text{ND}$ (see the Location Specification section above), could be defined as a macro by $(M \ (2\text{ND}) \ X \ \text{GRR} \ ((\text{LC} \ . \ X) \ (\text{LC} \ . \ X)))$. 
For all editor commands, "built in" commands as well as commands defined by macros as atomic commands and list definitions are completely independent. In other words, the existence of an atomic definition for C in no way affects the treatment of C when it appears as CAR of a list command, and the existence of a list definition for C in no way affects the treatment of C when it appears as an atom. In particular, C can be used as the name of either an atomic command, or a list command, or both. In the latter case, two entirely different definitions can be used.

Once C is defined as an atomic command via a macro definition, it will not be searched for when used in a location specification, unless it is preceded by an F. Thus (INSERT -- BEFORE BP) would not search for BP, but instead perform a BK, and UP, and a P, and then do the insertion. The corresponding also holds true for list commands.

Occasionally, your will want to employ the S command in a macro to save some temporary result. For example, the SW command could be defined as:

\[
(M (SW) (N M)
   (NTH N)
   (S FOO 1)
   MARK
   0
   (NTH M)
   (S FIE 1)
   (I 1 FOO)
   \leftrightarrow
   (I 1 FIE))
\]

Since this version of SW sets FOO and FIE, using SW may have undesirable side effects, especially when the editor was called from deep in a computation, we would have to be careful to make up unique names for dummy variables used in edit macros, which is bothersome. Furthermore, it would be impossible to define a command that called itself recursively while setting free variables. The BIND command solves both problems.

\[
\text{(BIND COMS}_1 \ldots \text{COMS}_N) \quad \text{[Editor Command]}
\]

Binds three dummy variables #1, #2, #3, (initialized to NIL), and then executes the edit commands \text{COMS}_1 \ldots \text{COMS}_n. BIND uses a PROG to make these bindings, so they are only in effect while the commands are being executed and BINDs can be used recursively; the variables #1, #2, and #3 will be rebound each time BIND is invoked.

Thus, we can write SW safely as:

\[
(M (SW) (N M)
   (BIND (NTH N)
      (S #1 1)
      MARK
      0
      (NTH M)
      (S #2 1)
      (I 1 \#1))
\]
INTERLISP-D REFERENCE MANUAL

←←

(I 1 #2)))

(ORIGINAL COMS₁ ... COMSN)

[Editor Command]

Executes COMS₁ ... COMSN without regard to macro definitions. Useful for redefining a built in command in terms of itself, i.e. effectively allows you to "advise" edit commands.

User macros are stored on a list USERMACROS. The file package command USERMACROS (Chapter 17) is available for dumping all or selected user macros.

Undo

Each command that causes structure modification automatically adds an entry to the front of UNDOLST that contains the information required to restore all pointers that were changed by that command.

UNDO

[Editor Command]

Undoes the last, i.e., most recent, structure modification command that has not yet been undone, and prints the name of that command, e.g., MBD undone. The edit chain is then exactly what it was before the "undone" command had been performed. If there are no commands to undo, UNDO types nothing saved.

!UNDO

[Editor Command]

Undoes all modifications performed during this editing session, i.e. this call to the editor. As each command is undone, its name is printed a la UNDO. If there is nothing to be undone, !UNDO prints nothing saved.

Undoing an event containing an I, E, or S command will also undo the side effects of the evaluation(s), e.g., undoing (I 3 (/NCONC FOO FIE)) will not only restore the third element but also restore FOO. Similarly, undoing an S command will undo the set. See the discussion of UNDO in Chapter 13. (If the I command was typed directly to the editor, /NCONC would automatically be substituted for NCONC as described in Chapter 13.)

Since UNDO and !UNDO cause structure modification, they also add an entry to UNDOLST. However, UNDO and !UNDO entries are skipped by UNDO, e.g., if you perform an INSERT, and then an MBD, the first UNDO will undo the MBD, and the second will undo the INSERT. However, you can also specify precisely which commands you want undone by identifying the corresponding entry. In this case, you can undo an UNDO command, e.g., by typing UNDO UNDO, or undo a !UNDO command, or undo a command other than that most recently performed.
Whenever you continue an editing session, the undo information of the previous session is protected by inserting a special blip, called an undo-block, on the front of UNDOLST. This undo-block will terminate the operation of a !UNDO, thereby confining its effect to the current session, and will similarly prevent an UNDO command from operating on commands executed in the previous session.

Thus, if you enter the editor continuing a session, and immediately execute an UNDO or !UNDO, the editor will type BLOCKED instead of NOTHING SAVED. Similarly, if you execute several commands and then undo them all, another UNDO or !UNDO will also cause BLOCKED to be typed.

**UNBLOCK**

[Editor Command]

Removes an undo-block. If executed at a non-blocked state, i.e., if UNDO or !UNDO could operate, types NOT BLOCKED.

**TEST**

[Editor Command]

Adds an undo-block at the front of UNDOLST.

Note that TEST together with !UNDO provide a "tentative" mode for editing, i.e., you can perform a number of changes, and then undo all of them with a single !UNDO command.

**(UNDO Event:Spec)**

[Editor Command]

*Event:Spec* is an event specification (see Chapter 13). Undoes the indicated event on the history list. In this case, the event does not have to be in the current editing session, even if the previous session has not been unblocked as described above. However, you do have to be editing the same expression as was being edited in the indicated event.

If the expressions differ, the editor types the warning message "different expression," and does not undo the event. The editor enforces this to avoid your accidentally undoing a random command by giving the wrong event specification.

**EDITDEFAULT**

Whenever a command is not recognized, i.e., is not "built in" or defined as a macro, the editor calls an internal function, EDITDEFAULT, to determine what action to take. Since EDITDEFAULT is part of the edit block, you cannot advise or redefine it as a means of augmenting or extending the editor. However, you can accomplish this via EDITUSERFN. If the value of the variable EDITUSERFN is T, EDITDEFAULT calls the function EDITUSERFN giving it the command as an argument. If EDITUSERFN returns a non-NIL value, its value is interpreted as a single command and executed. Otherwise, the error correction procedure described below is performed.
If a location specification is being executed, an internal flag informs EDITDEFAULT to treat the command as though it had been preceded by an F.

If the command is a list, an attempt is made to perform spelling correction on the CAR of the command (unless DWIMFLG = NIL) using EDITCOMSL, a list of all list edit commands. If spelling correction is successful, the correct command name is REPLACed into the command, and the editor continues by executing the command. In other words, if you type \((LP \ F \ PRINT \ (MBBD \ AND \ (NULL \ FLG)))\), only one spelling correction will be necessary to change MBBBD to MBD. If spelling correction is not successful, an error is generated.

Note: When a macro is defined via the \(M\) command, the command name is added to EDITCOMSA or EDITCOMSL, depending on whether it is an atomic or list command. The USERMACROS file package command is aware of this, and provides for restoring EDITCOMSA and EDITCOMSL.

If the command is atomic, the procedure followed is a little more elaborate.

1. If the command is one of the list commands, i.e., a member of EDITCOMSL, and there is additional input on the same terminal line, treat the entire line as a single list command. The line is read using READLINE (see Chapter 13), so the line can be terminated by a square bracket, or by a carriage return not preceded by a space. You may omit parentheses for any list command typed in at the top level (provided the command is not also an atomic command, e.g. NX, BK). For example,

```
*P
  (COND (& &) (T &))
  *XTR 3 2]
  *MOVE TO AFTER LP
```

If the command is on the list EDITCOMSL but no additional input is on the terminal line, an error is generated. For example:

```
*P
  (COND (& &) (T &))
  *MOVE
  MOVE ?
```

If the command is on EDITCOMSL, and not typed in directly, e.g., it appears as one of the commands in a LP command, the procedure is similar, with the rest of the command stream at that level being treated as "the terminal line", e.g. \((LP \ F \ (COND \ (T \ &)) \ XTR \ 2 \ 2)\).

If the command is being executed in location context, EDITDEFAULT does not get this far, e.g., \((MOVE \ TO \ AFTER \ COND \ XTR \ 3)\) will search for XTR, not execute it. However, \((MOVE \ TO \ AFTER \ COND \ (XTR \ 3))\) will work.
2. If the command was typed in and the first character in the command is an 8, treat the 8 as a mistyped left parenthesis, and and the rest of the line as the arguments to the command, e.g.,

\[ *P \quad (\text{COND (} \text{&} \text{&} (T \text{&}) \text{)}) \]
\[ *8-2 \quad (Y \quad (\text{RETURN} \quad Z)) \]
\[ = \quad (-2) \]
\[ *P \quad (\text{COND (} Y \text{&} \text{&} (T \text{&}) \text{)}) \]

3. If the command was typed in, is the name of a function, and is followed by \texttt{NIL} or a list \texttt{CAR} of which is not an edit command, assume you forgot to type \texttt{E} and intend to apply the function to its arguments, type \texttt{=E} and the function name, and perform the indicated computation, e.g.

\[ *\text{BREAK(FOO)} \]
\[ =\text{E} \text{ BREAK} \]
\[ (\text{FOO}) \]

4. If the last character in the command is \texttt{P}, and the first \(n-1\) characters comprise a number, assume that you intended two commands, e.g.,

\[ *\text{P} \quad (\text{COND (} \text{&} \text{&} (T \text{&}) \text{)}) \]
\[ *0\text{P} \]
\[ =0\text{ P} \quad (\text{SETQ X (COND & &)}) \]

5. Attempt spelling correction using \texttt{EDITCOMSA}, and if successful, execute the corrected command.

6. If there is additional input on the same line, or command stream, spelling correct using \texttt{EDITCOMSL} as a spelling list, e.g.,

\[ *\text{MBBD SETQ X} \]
\[ =\text{MBD} \]

7. Otherwise, generate an error.

\textbf{Time Stamps}

Whenever a function is edited, and changes were made, the function is time-stamped (by \texttt{EDIT}), which consists of inserting a comment of the form \texttt{(* USERS-INITIALS DATE)}. \texttt{USERS-INITIALS} is the value of the variable \texttt{INITIALS}. After greeting (see Chapter 12), the function \texttt{SETINITIALS} is
setinitials searches initialslst, a list of elements of the form \texttt{(username initials)} or \texttt{(username firstname initials)}. If your name is found, \texttt{initials} is set accordingly. If your username name is \texttt{not} found on \texttt{initialslst}, \texttt{initials} is set to the value of \texttt{defaultinitials}, initially \texttt{edited}. Thus, the default is to always time stamp. To suppress time stamping, you must either include an entry of the form \texttt{(username) on initialslst}, or set \texttt{defaultinitials} to \texttt{nil} before greeting, i.e. in your user profile, or else, after greeting, explicitly set \texttt{initials} to \texttt{nil}.

If you want your functions to be time stamped with your initials when edited, include a file package command command of the form \texttt{(addvars (initialslst \texttt{(username initials))}) in your \texttt{init.lisp} file (see Chapter 12).

The following three functions may be of use for specialized applications with respect to time-stamping: \texttt{(fixeditdate expr)} which, given a lambda expression, inserts orsmashes a time-stamp comment; \texttt{(editdate? comment)} which returns \texttt{T} if \texttt{comment} is a time stamp; and \texttt{(editdate oldate initials)} which returns a new time-stamp comment. If \texttt{oldate} is a time-stamp comment, it will be reused.

**Warning with Declarations**

CAUTION: There is a feature of the BYTECOMPILER that is not supported by SEdit or the XCL compiler. It is possible to insert a comment at the beginning of your function that looks like

\begin{verbatim}
(* DECLARATIONS: --)
\end{verbatim}

The tail, or -- section, of this comment is taken as a set of local record declarations which are then used by the compiler in that function just as if they had been declared globally. See the "Compiler" section in Chapter 3 of these Notes for additional behavior in XCL.

SEdit does not recognize such declarations. Thus, if the "Expand" command is used, the expansion will not be done with these record declarations in effect. The code that you see in SEedit will not be the same code compiled by the BYTECOMPILER.
Warning: The subsystem within Medley used for managing collections of definitions (of functions, variables, etc.) is known as the "File Manager." This terminology is confusing, because the word "file" is also used in the more conventional sense as meaning a collection of data stored on some physical media. Unfortunately, it is not possible to change this terminology at this time, because many functions and variables (MAKEFILE, FILEPKGTYPES, etc.) incorporate the word "file" in their names.

Most implementations of Lisp treat symbolic files as unstructured text, much as they are treated in most conventional programming environments. Function definitions are edited with a character-oriented text editor, and then the changed definitions (or sometimes the entire file) is read or compiled to install those changes in the running memory image. Interlisp incorporates a different philosophy. A symbolic file is considered as a database of information about a group of data objects—function definitions, variable values, record declarations, etc. The text in a symbolic file is never edited directly. Definitions are edited only after their textual representations on files have been converted to data-structures that reside inside the Lisp address space. The programs for editing definitions inside Medley can therefore make use of the full set of data-manipulation capabilities that the environment already provides, and editing operations can be easily intermixed with the processes of evaluation and compilation.

Medley is thus a "resident" programming environment, and as such it provides facilities for moving definitions back and forth between memory and the external databases on symbolic files, and for doing the bookkeeping involved when definitions on many symbolic files with compiled counterparts are being manipulated. The file manager provides those capabilities. It shoulders the burden of keeping track of where things are and what things have changed so that you don't have to. The file manager also keeps track of which files have been modified and need to be updated and recompiled.

The file manager is integrated into many other system packages. For example, if only the compiled version of a file is loaded and you attempt to edit a function, the file manager will attempt to load the source of that function from the appropriate symbolic file. In many cases, if a datum is needed by some program, the file manager will automatically retrieve it from a file if it is not already in your working environment.

Some of the operations of the file manager are rather complex. For example, the same function may appear in several different files, or the symbolic or compiled files may be in different directories, etc. Therefore, this chapter does not document how the file manager works in each and every situation, but instead makes the deliberately vague statement that it does the "right" thing with respect to keeping track of what has been changed, and what file operations need to be performed in accordance with those changes.

For a simple illustration of what the file manager does, suppose that the symbolic file FOO contains the functions FOO1 and FOO2, and that the file BAR contains the functions BAR1 and BAR2. These two files could be loaded into the environment with the function LOAD:

```lisp
(LOAD 'FOO)
```

FILE CREATED 4-MAR-83 09:26:55
Now, suppose that we change the definition of FOO with the editor, and we define two new functions, NEW1 and NEW2. At that point, the file manager knows that the in-memory definition of FOO is no longer consistent with the definition in the file FOO, and that the new functions have been defined but have not yet been associated with a symbolic file and saved on permanent storage. The function FILES? summarizes this state of affairs and enters into an interactive dialog in which we can specify what files the new functions are to belong to.

\[
\text{\texttt{\(\langle\text{FILES?}\rangle\)}}
\]

\[\text{FOO...to be dumped.} \]
\[\text{plus the functions: NEW1,NEW2} \]
\[\text{want to say where the above go? Yes} \]
\[\text{(functions)} \]
\[\text{NEW1 File name: BAR} \]
\[\text{NEW2 File name: ZAP} \]
\[\text{new file? Yes} \]
\[\text{NIL} \]

The file manager knows that the file FOO has been changed, and needs to be dumped back to permanent storage. This can be done with MAKEFILE.

\[
\text{\texttt{\(\langle\text{MAKEFILE 'FOO}\rangle\)}}
\]

\[\text{(DSK)FOO.;2} \]

Since we added NEW1 to the old file BAR and established a new file ZAP to contain NEW2, both BAR and ZAP now also need to be dumped. This is confirmed by a second call to FILES?:

\[
\text{\texttt{\(\langle\text{FILES?}\rangle\)}}
\]

\[\text{BAR, ZAP...to be dumped.} \]
\[\text{FOO...to be listed.} \]
\[\text{FOO...to be compiled} \]
\[\text{NIL} \]

We are also informed that the new version we made of FOO needs to be listed (sent to a printer) and that the functions on the file must be compiled.

Rather than doing several MAKEFILEs to dump the files BAR and ZAP, we can simply call CLEANUP. Without any further user interaction, this will dump any files whose definitions have been modified. CLEANUP will also send any unlisted files to the printer and recompile any files which need to be recompiled. CLEANUP is a useful function to use at the end of a debugging session. It will call FILES? if any new objects have been defined, so you do not lose the opportunity to say explicitly where those belong. In effect, the function CLEANUP executes all the operations necessary to make the your permanent files consistent with the definitions in the current core-image.

\[
\text{\texttt{\(\langle\text{CLEANUP}\rangle\)}}
\]

\[\text{FOO...compiling (DSK)FOO.;2} \]
In addition to the definitions of functions, symbolic files in Interlisp can contain definitions of a variety of other types, e.g. variable values, property lists, record declarations, macro definitions, hash arrays, etc. In order to treat such a diverse assortment of data uniformly from the standpoint of file operations, the file manager uses the concept of a typed definition, of which a function definition is just one example. A typed definition associates with a name (usually a symbol), a definition of a given type (called the file manager type). Note that the same name may have several definitions of different types. For example, a symbol may have both a function definition and a variable definition. The file manager also keeps track of the files that a particular typed definition is stored on, so one can think of a typed definition as a relation between four elements: a name, a definition, a type, and a file.

Symbolic files on permanent storage devices are referred to by names that obey the naming conventions of those devices, usually including host, directory, and version fields. When such definition groups are noticed by the file manager, they are assigned simple root names and these are used by all file manager operations to refer to those groups of definitions. The root name for a group is computed from its full permanent storage name by applying the function ROOTFILENAME; this strips off the host, directory, version, etc., and returns just the simple name field of the file. For each file, the file manager also has a data structure that describes what definitions it contains. This is known as the commands of the file, or its "filecoms". By convention, the filecoms of a file whose root name is X is stored as the value of the symbol XCOMS. For example, the value of FOOCOMS is the filecoms for the file FOO. This variable can be directly manipulated, but the file manager contains facilities such as FILES? which make constructing and updating filecoms easier, and in some cases automatic. See the Functions for Manipulating File Command Lists section.

The file manager is able to maintain its databases of information because it is notified by various other routines in the system when events take place that may change that database. A file is "noticed" when it is loaded, or when a new file is stored (though there are ways to explicitly notice files without completely loading all their definitions). Once a file is noticed, the file manager takes it into account when modifying filecoms, dumping files, etc. The file manager also needs to know what typed definitions have been changed or what new definitions have been introduced, so it can determine which files need to be updated. This is done by "marking changes". All the system functions that perform file manager operations (LOAD, TCOMPL, PRETTYDEF, etc.), as well as those functions that define or change data, (EDITF, EDITV, EDITP, DWIM corrections to user functions) interact with the file manager. Also, typed-in assignment of variables or property values is noticed by the file manager. (Note that modifications to variable or property values during the execution of a function body are not noticed.) In some cases the marking procedure can be subtle, e.g. if you edit a property list using EDITP, only those properties whose values are actually changed (or added) are marked.
All file manager operations can be disabled with FILEPKGFLG.

FILEPKGFLG [Variable]

The file manager can be disabled by setting FILEPKGFLG to NIL. This will turn off noticing files and marking changes. FILEPKGFLG is initially T.

The rest of this chapter goes into further detail about the file manager. Functions for loading and storing symbolic files are presented first, followed by functions for adding and removing typed definitions from files, moving typed definitions from one file to another, determining which file a particular definition is stored in, and so on.

**Loading Files**

The functions below load information from symbolic files into the Interlisp environment. A symbolic file contains a sequence of Interlisp expressions that can be evaluated to establish specified typed definitions. The expressions on symbolic files are read using FILERDTBL as the read table.

The loading functions all have an argument LDFLG. LDFLG affects the operation of DEFINE, DEFINEQ, RPAQ, RPAQ?, and RPAQQ. While a source file is being loaded, DFNFLG (Chapter 10) is rebound to LDFLG. Thus, if LDFLG = NIL, and a function is redefined, a message is printed and the old definition saved. If LDFLG = T, the old definition is simply overwritten. If LDFLG = PROP, the functions are stored as "saved" definitions on the property lists under the property EXPR instead of being installed as the active definitions. If LDFLG = ALLPROP, not only function definitions but also variables set by RPAQQ, RPAQ, RPAQ? are stored on property lists (except when the variable has the value NOBIND, in which case they are set to the indicated value regardless of DFNFLG).

Another option is available for loading systems for others to use and who wish to suppress the saving of information used to aid in development and debugging. If LDFLG = SYSLOAD, LOAD will:
1. Rebind DFNFLG to T, so old definitions are simply overwritten
2. Rebind LISPXHIST to NIL, thereby making the LOAD not be undoable and eliminating the cost of saving undo information (Chapter 13)
3. Rebind ADDSPELLFLG to NIL, to suppress adding to spelling lists
4. Rebind FILEPKGFLG to NIL, to prevent the file from being "noticed" by the file manager
5. Rebind BUILDMAPFLG to NIL, to prevent a file map from being constructed
6. After the load has completed, set the filecoms variable and any filevars variables to NOBIND
7. Add the file name to SYSFILES rather than FILELST

A filevars variable is any variable appearing in a file manager command of the form (FILECOM * VARIABLE) (see the FileVars section). Therefore, if the filecoms includes (FNS * FOOFNS), FOOFNS is set to NOBIND. If you want the value of such a variable to be retained, even when the file is loaded with LDFLG = SYSLOAD, then you should replace the variable with an equivalent, non-atomic expression, such as (FNS * (PROGN FOOFNS)).

All functions that have LDFLG as an argument perform spelling correction using LOADOPTIONS as a spelling list when LDFLG is not a member of LOADOPTIONS. LOADOPTIONS is initially (NIL T PROP ALLPROP SYSLOAD).

(LOAD FILE LDFLG PRINTFLG) [Function]

Reads successive expressions from FILE (with FILERDTBL as read table) and evaluates each as it is read, until it reads either NIL, or the single atom STOP. Note that LOAD can be used to load both symbolic and compiled files. Returns FILE (full name).

If PRINTFLG = T, LOAD prints the value of each expression; otherwise it does not.

(LOAD? FILE LDFLG PRINTFLG) [Function]

Similar to LOAD except that it does not load FILE if it has already been loaded, in which case it returns NIL.

LOAD? loads FILE except when the same version of the file has been loaded (either from the same place, or from a copy of it from a different place). Specifically, LOAD? considers that FILE has already been loaded if the full name of FILE is on LOADEDFILELST (see the Noticing Files section) or the date stored on the FILEDATES property of the root file name of FILE is the same as the FILECREATED expression on FILE.

(LOADFNS FNS FILE LDFLG VARS) [Function]

Permits selective loading of definitions. FNS is a list of function names, a single function name, or T, meaning to load all of the functions on the file. FILE can be either a compiled
or symbolic file. If a compiled definition is loaded, so are all compiler-generated
subfunctions. The interpretation of $LD\_FLG$ is the same as for $LOAD$.

If $FILE = NIL$, $LOAD\_FNS$ will use $WHERE\_IS$ (see the Storing Files section) to determine
where the first function in $FNS$ resides, and load from that file. Note that the file must
previously have been "noticed". If $WHERE\_IS$ returns $NIL$, and the $WHERE\_IS$ library
package has been loaded, $LOAD\_FNS$ will use the $WHERE\_IS$ data base to find the file
containing $FN$.

$VARS$ specifies which non-$DEFINEQ$ expressions are to be loaded (i.e., evaluated). It is
interpreted as follows:

- **T** Means to load all non-$DEFINEQ$ expressions.
- **NIL** Means to load none of the non-$DEFINEQ$ expressions.
- **VARS** Means to evaluate all variable assignment expressions
  (beginning with $RPAQ$, $RPAQQ$, or $RPAQ?$, see the Functions
  Used Within Source Files section).
- Any other symbol Means the same as specifying a list containing that atom.

A list If $VARS$ is a list that is not a valid function definition, each
element in $VARS$ is "matched" against each non-$DEFINEQ$
expression, and if any elements in $VARS$"match" successfully,
the expression is evaluated. "Matching" is defined as follows:
If an element of $VARS$ is an atom, it matches an expression if
it is $EQ$ to either the $CAR$ or the $CADR$ of the expression. If an
element of $VARS$ is a list, it is treated as an edit pattern (see
Chapter 16), and matched with the entire expression (using
EDIT$4E$, described in Chapter 16). For example, if $VARS$ was
($FOOCOMS$ DECLARE: ($DEFLIST$ & $QUOTE$ MACRO))),
this would cause ($RPAQQ$ $FOOCOMS$ ...), all DECLARE:s,
and all DEFLISTS which set up MACROS to be read and
evaluated.

A function definition If $VARS$ is a list and a valid function definition
((FNTYP $VARS$) is true), then $LOAD\_FNS$ will invoke that function on
every non-$DEFINEQ$ expression being considered, applying it
to two arguments, the first and second elements in the
expression. If the function returns $NIL$, the expression will
be skipped; if it returns a non-$NIL$ symbol (e.g., $T$), the
expression will be evaluated; and if it returns a list, this list is
evaluated instead of the expression. The file pointer is set to
the very beginning of the expression before calling the $VARS$
function definition, so it may read the entire expression if
necessary. If the function returns a symbol, the file pointer is
reset and the expression is $READ$ or $SKREAD$. However, the
file pointer is not reset when the function returns a list, so the
function must leave it set immediately after the expression that it has presumably read.

LOADFNS returns a list of:

1. The names of the functions that were found
2. A list of those functions not found (if any) headed by the symbol NOT-FOUND:
3. All of the expressions that were evaluated
4. A list of those members of VARS for which no corresponding expressions were found (if any), again headed by the symbol NOT-FOUND:

For example:

\[(LOADFNS '(FOO FIE FUM) FILE NIL '(BAZ (DEFLIST &)))\]
\=((FOO FIE (NOT-FOUND: FUM) (RPAQ BAZ ...) (NOT-FOUND: (DEFLIST &)))\)

(LOADVARS VARS FILE LDFLG) \[Function\]
Same as (LOADFNS NIL FILE LDFLG VARS).

(LOADFROM FILE FNS LDFLG) \[Function\]
Same as (LOADFNS FNS FILE LDFLG T).

Once the file manager has noticed a file, you can edit functions contained in the file without explicitly loading them. Similarly, those functions which have not been modified do not have to be loaded in order to write out an updated version of the file. Files are normally noticed (i.e., their contents become known to the file manager) when either the symbolic or compiled versions of the file are loaded. If the file is not going to be loaded completely, the preferred way to notice it is with LOADFROM. You can also load some functions at the same time by giving LOADFROM a second argument, but it is normally used simply to inform the file manager about the existence and contents of a particular file.

(LOADBLOCK FN FILE LDFLG) \[Function\]
Calls LOADFNS on those functions contained in the block declaration containing FN (see Chapter 18). LOADBLOCK is designed primarily for use with symbolic files, to load the EXPRs for a given block. It will not load a function which already has an in-core EXPR definition, and it will not load the block name, unless it is also one of the block functions.

(LOADCOMP FILE LDFLG) \[Function\]
Performs all operations on FILE associated with compilation, i.e. evaluates all expressions under a DECLARE: EVAL@COMPILE, and "notices" the function and variable names by adding them to the lists NOFIXFNSLST and NOFIXVARSLST (see Chapter 21).
Thus, if building a system composed of many files with compilation information scattered among them, all that is required to compile one file is to \texttt{LOADCOMP} the others.

\texttt{(LOADCOMP? FILE LDFLG)}  \hspace{1cm} \textbf{[Function]}

Similar to \texttt{LOADCOMP}, except it does not load if file has already been loaded (with \texttt{LOADCOMP}), in which case its value is \texttt{NIL}.

\texttt{LOADCOMP?} will load the file even if it has been loaded with \texttt{LOAD}, \texttt{LOADFNS}, etc. The only time it will not load the file is if the file has already been loaded with \texttt{LOADCOMP}.

\texttt{FILESLOAD} provides an easy way for you to load a series of files, setting various options:

\texttt{(FILESLOAD FILE\_1 \ldots FILE\_N)}  \hspace{1cm} \textbf{[NLambda NoSpread Function]}

Loads the files \texttt{FILE\_1} \ldots \texttt{FILE\_N} (all arguments unevaluated). If any of these arguments are lists, they specify certain loading options for all following files (unless changed by another list). Within these lists, the following commands are recognized:

\textbf{FROM DIR} Search the specified directories for the file. \texttt{DIR} can either be a single directory, or a list of directories to search in order. For example, \texttt{(FILESLOAD \{ERIS\}<LISPCORE>SOURCES)} \ldots will search the directory \{ERIS\}<LISPCORE>SOURCES for the files. If this is not specified, the default is to search the contents of \texttt{DIRECTORIES} (see Chapter 24).

If \texttt{FROM} is followed by the key word \texttt{VALUEOF}, the following word is evaluated, and the value is used as the list of directories to search. For example, \texttt{(FILESLOAD \{ERIS\}<LISPCORE>SOURCES)} \ldots will search the directory \{ERIS\}<LISPCORE>SOURCES for the files. If this is not specified, the default is to search the contents of \texttt{DIRECTORIES} (see Chapter 24).

As a special case, if \texttt{DIR} is a symbol, and the symbol \texttt{DIRODISHERS} is bound, the value of this variable is used as the directory search list. For example, since the variable \texttt{LISPUSSERSDIRECTORIES} (see Chapter 24) is commonly used to contain a list of directories containing "library" packages, \texttt{(FILESLOAD \{ERIS\}<LISPCORE>SOURCES)} \ldots can be used instead of \texttt{(FILESLOAD \{ERIS\}<LISPCORE>SOURCES)} \ldots.

If a \texttt{FILESLOAD} is read and evaluated while loading a file, and it doesn’t contain a \texttt{FROM} expression, the default is to search the directory containing the \texttt{FILESLOAD} expression before the value of \texttt{DIRECTORIES}. \texttt{FILESLOAD} expressions can be dumped on files using the \texttt{FILES} file manager command.
SOURCE  Load the source version of the file rather than the compiled version.

COMPILED  Load the compiled version of the file.

If COMPILED is specified, the compiled version will be loaded, if it is found. The source will not be loaded. If neither SOURCE or COMPILED is specified, the compiled version of the file will be loaded if it is found, otherwise the source will be loaded if it is found.

LOAD  Load the file by calling LOAD, if it has not already been loaded. This is the default unless LOADCOMP or LOADFROM is specified.

If LOAD is specified, FILESLOAD considers that the file has already been loaded if the root name of the file has a non-NIL FILEDATES property. This is a somewhat different algorithm than LOAD? uses. In particular, FILESLOAD will not load a newer version of a file that has already been loaded.

LOADCOMP  Load the file with LOADCOMP? rather than LOAD. Automatically implies SOURCE.

LOADFROM  Load the file with LOADFROM rather than LOAD.

NIL, T, PROP
ALLPROP
SYSLOAD  The loading function is called with its \texttt{LDFLG} argument set to the specified token. \texttt{LDFLG} affects the operation of the loading functions by resetting \texttt{DFNFLG} (see Chapter 10) to \texttt{LDFLG} during the loading. If none of these tokens are specified, the value of the variable \texttt{LDFLG} is used if it is bound, otherwise \texttt{NIL} is used.

NOERROR  If NOERROR is specified, no error occurs when a file is not found.

Each list determines how all further files in the lists are loaded, unless changed by another list. The tokens above can be joined together in a single list. For example,

\begin{verbatim}
(FFILESLOAD (LOADCOMP) NET (SYSLOAD FROM VALUEOF NEWDIRECTORIES) CJSYS)
\end{verbatim}

will call LOADCOMP? to load the file \texttt{NET} searching the value of DIRECTORIES, and then call LOADCOMP? to load the file \texttt{CJSYS} with \texttt{LDFLG} set to SYSLOAD, searching the directory list that is the value of the variable NEWDIRECTORIES.
FILESLOAD expressions can be dumped on files using the FILES file manager command.

### Storing Files

**Function**

\[
\text{(MAKEFILE FILE OPTIONS REPRINTFNS SOURCEFILE)} \quad \text{[Function]}
\]

Makes a new version of the file \text{FILE}, storing the information specified by \text{FILE}'s filecoms. Notices \text{FILE} if not previously noticed. Then, it adds \text{FILE} to \text{NOTLISTEDFILES} and \text{NOTCOMPILEDFILES}.

\text{OPTIONS} is a symbol or list of symbols which specify options. By specifying certain options, \text{MAKEFILE} can automatically compile or list \text{FILE}. Note that if \text{FILE} does not contain any function definitions, it is not compiled even when \text{OPTIONS} specifies \text{C} or \text{RC}. The options are spelling corrected using the list \text{MAKEFILEOPTIONS}. If spelling correction fails, \text{MAKEFILE} generates an error. The options are interpreted as follows:

- **C**
  - After making \text{FILE}, \text{MAKEFILE} will compile \text{FILE} by calling \text{TCOMPL} (if \text{C} is specified) or \text{RECOMPILE} (if \text{RC} is specified). If there are any block declarations specified in the filecoms for \text{FILE}, \text{BCOMPL} or \text{BRECOMPILE} will be called instead.
  - If \text{F}, \text{ST}, \text{STF}, or \text{S} is the next item on \text{OPTIONS} following \text{C} or \text{RC}, it is given to the compiler as the answer to the compiler's question \text{LISTING?} (see Chapter 18). For example, \text{(MAKEFILE 'FOO '(C F LIST))} will dump \text{FOO}, then \text{TCOMPL} or \text{BCOMPL} it specifying that functions are not to be redefined, and finally list the file.

- **LIST**
  - After making \text{FILE}, \text{MAKEFILE} calls \text{LISTFILES} to print a hardcopy listing of \text{FILE}.

- **CLISPIFY**
  - \text{MAKEFILE} calls \text{PRETTYDEF} with \text{CLISPIFYPRETTYFLG} = \text{T} (see Chapter 21). This causes \text{CLISPIFY} to be called on each function defined as an \text{EXPR} before it is prettyprinted.
  - Alternatively, if \text{FILE} has the property \text{FILETYPE} with value \text{CLISP} or a list containing \text{CLISP}, \text{PRETTYDEF} is called with \text{CLISPIFYPRETTYFLG} reset to \text{CHANGES}, which will cause \text{CLISPIFY} to be called on all functions marked as having been changed. If \text{FILE} has property \text{FILETYPE} with value \text{CLISP}, the compiler will \text{DWIMIFY} its functions before compiling them (see Chapter 18).

- **FAST**
  - \text{MAKEFILE} calls \text{PRETTYDEF} with \text{PRETTYFLG} = \text{NIL} (see Chapter 26). This causes data objects to be printed rather than prettyprinted, which is much faster.
REMAKE  MAKEFILE "remakes" FILE: The prettyprinted definitions of functions that have not changed are copied from an earlier version of the symbolic file. Only those functions that have changed are prettyprinted.

NEW  MAKEFILE does not remake FILE. If MAKEFILEREMAKEFLG = T (the initial setting), the default for all calls to MAKEFILE is to remake. The NEW option can be used to override this default.

REPRINTFNS and SOURCEFILE are used when remaking a file.

FILE is not added to NOTLISTEDFILES if FILE has on its property list the property FILETYPE with value DON'TLIST, or a list containing DON'TLIST. FILE is not added to NOTCOMPILEDFILES if FILE has on its property list the property FILETYPE with value DON'TCOMPILE, or a list containing DON'TCOMPILE. Also, if FILE does not contain any function definitions, it is not added to NOTCOMPILEDFILES, and it is not compiled even when OPTIONS specifies C or RC.

If a remake is not being performed, MAKEFILE checks the state of FILE to make sure that the entire source file was actually LOADED. If FILE was loaded as a compiled file, MAKEFILE prints the message CAN'T DUMP: ONLY THE COMPILLED FILE HAS BEEN LOADED. Similarly, if only some of the symbolic definitions were loaded via LOADFNS or LOADFROM, MAKEFILE prints CAN'T DUMP: ONLY SOME OF ITS SYMBOLICS HAVE BEEN LOADED. In both cases, MAKEFILE will then ask you if it should dump anyway; if you decline, MAKEFILE does not call PRETTYDEF, but simply returns (FILE NOT DUMPED) as its value.

You can indicate that FILE must be block compiled together with other files as a unit by putting a list of those files on the property list of each file under the property FILEGROUP. If FILE has a FILEGROUP property, the compiler will not be called until all files on this property have been dumped that need to be.

MAKEFILE operates by rebinding PRETTYFLG, PRETTYTRANFLG, and CLISPIFYPRETTYFLG, evaluating each expression on MAKEFILEFORMS (under errorset protection), and then calling PRETTYDEF.

PRETTYDEF calls PRETTYPRINT with its second argument PRETTYDEFLG = T, so whenever PRETTYPRINT (and hence MAKEFILE) start printing a new function, the name of that function is printed if more than 30 seconds (real time) have elapsed since the last time it printed the name of a function.
(MAKEFILES OPTIONS FILES)  [Function]

Performs (MAKEFILE FILE OPTIONS) for each file on FILES that needs to be dumped. If FILES = NIL, FILELIST is used. For example, (MAKEFILES 'LIST) will make and list all files that have been changed. In this case, if any typed definitions for any items have been defined or changed and they are not contained in one of the files on FILELIST, MAKEFILES calls ADDTOFILES? to allow you to specify where these go. MAKEFILES returns a list of all files that are made.

(CLEANUP FILE1 FILE2 ... FILEN)  [NLambda NoSpread Function]

Dumps, lists, and recompiles (with RECOMPILE or RECOMPILE) any of the specified files (unevaluated) requiring the corresponding operation. If no files are specified, FILELIST is used. CLEANUP returns NIL.

CLEANUP uses the value of the variable CLEANUPOPTIONS as the OPTIONS argument to MAKEFILE. CLEANUPOPTIONS is initially (RC), to indicate that the files should be recompiled. If CLEANUPOPTIONS is set to (RC F), no listing will be performed, and no functions will be redefined as the result of compiling. Alternatively, if FILE1 is a list, it will be interpreted as the list of options regardless of the value of CLEANUPOPTIONS.

.FILES?)  [Function]

Prints on the terminal the names of those files that have been modified but not dumped, dumped but not listed, dumped but not compiled, plus the names of any functions and other typed definitions (if any) that are not contained in any file. If there are any, FILES? then calls ADDTOFILES? to allow you to specify where these go.

(ADDTOFILES? --)  [Function]

Called from MAKEFILES, CLEANUP, and FILES? when there are typed definitions that have been marked as changed which do not belong to any file. ADDTOFILES? lists the names of the changed items, and asks if you want to specify where these items should be put. If you answer N(o), ADDTOFILES? returns NIL without taking any action. If you answer Y, this is taken to be an answer to each question that would be asked, and all the changed items are marked as dummy items to be ignored. Otherwise, ADDTOFILES? prints the name of each changed item, and accepts one of the following responses:

- A file name
- A filevar

If you give a file name or a variable whose value is a list (a filevar), the item is added to the corresponding file or list, using ADDTOFILE.

If your response is not the name of a file on FILELIST or a variable whose value is a list, you will be asked whether it is a new file. If you say no, then ADDTOFILES? will check whether the item is the name of a list, i.e., whether its value is a list. If not, you will be asked whether it is a new list.
The item is marked as a dummy item by adding it to NILCOMS. This tells the file manager simply to ignore this item.

The "definition" of the item in question is prettyprinted to the terminal, and then you are asked again about its disposition.

ADDTOFILES? prompts with "LISTNAME: (", you type in the name of a list, i.e. a variable whose value is a list, terminated by a ). The item will then only be added to (under) a command in which the named list appears as a filevar. If none are found, a message is printed, and you are asked again. For example, you define a new function FOO3. When asked where it goes, you type (FOOFNS). If the command (FNS * FOOFNS) is found, FOO3 will be added to the value of FOOFNS. If instead you type (FOOCOMS), and the command (COMS * FOOCOMS) is found, then FOO3 will be added to a command for dumping functions that is contained in FOOCOMS.

If the named list is not also the name of a file, you can simply type it in without parenthesis as described above.

@ ADDTOFILES? prompts with "Near: (", you type in the name of an object, and the item is then inserted in a command for dumping objects (of its type) that contains the indicated name. The item is inserted immediately after the indicated name.

**LISTFILES FILE1 FILE2 ... FILEN**

[ NLambda NoSpread Function ]

Lists each of the specified files (unevaluated). If no files are given, NOTLISTEDFILES is used. Each file listed is removed from NOTLISTEDFILES if the listing is completed. For each file not found, LISTFILES prints the message FILENAME NOT FOUND and proceeds to the next file.

LISTFILES calls the function LISTFILES1 on each file to be listed. Normally, LISTFILES1 is defined to simply call SEND.FILE.TO.PRINTER (see Chapter 29), but you can advise or redefine LISTFILES1 for more specialized applications.

Any lists inside the argument list to LISTFILES are interpreted as property lists that set the various printing options, such as the printer, number of copies, banner page name, etc (see see Chapter 29). Later properties override earlier ones. For example,

```lisp
(LISTFILES FOO (HOST JEDI) FUM (#COPIES 3) FIE)
```
INTERLISP-D REFERENCE MANUAL

will cause one copy of FOO to be printed on the default printer, and one copy of FUM and three copies of FIE to be printed on the printer JEDI.

(COMPILEFILES FILE1 FILE2 ... FILEN) [NLambda NoSpread Function]

Executes the RC and C options of MAKEFILE for each of the specified files (unevaluated). If no files are given, NOTCOMPILEDFILES is used. Each file compiled is removed from NOTCOMPILEDFILES. If FILE1 is a list, it is interpreted as the OPTIONS argument to MAKEFILES. This feature can be used to supply an answer to the compiler's LISTING? question, e.g., (COMPILEFILES (STF)) will compile each file on NOTCOMPILEDFILES so that the functions are redefined without the EXPRS definitions being saved.

(WHEREIS NAME TYPE FILES FN) [Function]

TYPE is a file manager type. WHEREIS sweeps through all the files on the list FILES and returns a list of all files containing NAME as a TYPE. WHEREIS knows about and expands all file manager commands and file manager macros. TYPE = NIL defaults to FNS (to retrieve function definitions). If FILES is not a list, the value of FILELST is used.

If FN is given, it should be a function (with arguments NAME, FILE, and TYPE) which is applied for every file in FILES that contains NAME as a TYPE. In this case, WHEREIS returns NIL.

If the WHEREIS library package has been loaded, WHEREIS is redefined so that FILES = T means to use the whereis package data base, so WHEREIS will find NAME even if the file has not been loaded or noticed. FILES = NIL always means use FILELST.

Remaking a Symbolic File

Most of the time that a symbolic file is written using MAKEFILE, only a few of the functions that it contains have been changed since the last time the file was written. Rather than prettprinting all of the functions, it is often considerably faster to "remake" the file, copying the prettprinted definitions of unchanged functions from an earlier version of the symbol file, and only prettyprinting those functions that have been changed.

MAKEFILE will remake the symbolic file if the REMAKE option is specified. If the NEW option is given, the file is not remade, and all of the functions are prettprinted. The default action is specified by the value of MAKEFILEREMAKEFLG: if T (its initial value), MAKEFILE will remake files unless the NEW option is given; if NIL, MAKEFILE will not remake unless the REMAKE option is given.

Note: If the file has never been loaded or dumped, for example if the filecoms were simply set up in memory, then MAKEFILE will never attempt to remake the file, regardless of the setting of MAKEFILEREMAKEFLG, or whether the REMAKE option was specified.
When MAKEFILE is remaking a symbolic file, you can explicitly indicate the functions which are to be prettyprinted and the file to be used for copying the rest of the function definitions from via the REPRINTFNS and SOURCEFILE arguments to MAKEFILE. Normally, both of these arguments are defaulted to NIL. In this case, REPRINTFNS will be set to those functions that have been changed since the last version of the file was written. For SOURCEFILE, MAKEFILE obtains the full name of the most recent version of the file (that it knows about) from the FILEDATES property of the file, and checks to make sure that the file still exists and has the same file date as that stored on the FILEDATES property. If it does, MAKEFILE uses that file as SOURCEFILE. This procedure permits you to LOAD or LOADFROM a file in a different directory, and still be able to remake the file with MAKEFILE. In the case where the most recent version of the file cannot be found, MAKEFILE will attempt to remake using the original version of the file (i.e., the one first loaded), specifying as REPRINTFNS the union of all changes that have been made since the file was first loaded, which is obtained from the FILECHANGES property of the file. If both of these fail, MAKEFILE prints the message "CAN'T FIND EITHER THE PREVIOUS VERSION OR THE ORIGINAL VERSION OF FILE, SO IT WILL HAVE TO BE WRITTEN ANEW", and does not remake the file, i.e. will prettyprint all of the functions.

When a remake is specified, MAKEFILE also checks to see how the file was originally loaded. If the file was originally loaded as a compiled file, MAKEFILE will call LOADVARS to obtain those DECLARE: expressions that are contained on the symbolic file, but not the compiled file, and hence have not been loaded. If the file was loaded by LOADFNS (but not LOADFROM), then LOADVARS is called to obtain any non-DEFINEQ expressions. Before calling LOADVARS to re-load definitions, MAKEFILE asks you, e.g. "Only the compiled version of FOO was loaded, do you want to LOADVARS the (DECLARE: .. DONTCOPY ..) expressions from {DSK}<MYDIR>FOO.;3?". You can respond Yes to execute the LOADVARS and continue the MAKEFILE, No to proceed without the MAKEFILE without performing the LOADVARS, or Abort to abort the MAKEFILE. You may wish to skip the LOADVARS if you had circumvented the file manager in some way, and loading the old definitions would overwrite new ones.

Remaking a symbolic file is considerably faster if the earlier version has a file map indicating where the function definitions are located (see the File Maps section), but it does not depend on this information.

**Loading Files in a Distributed Environment**

Each Interlisp source and compiled code file contains the full filename of the file, including the host and directory names, in a FILECREATED expression at the beginning of the file. The compiled code file also contains the full file name of the source file it was created from. In earlier versions of Interlisp, the file manager used this information to locate the appropriate source file when "remaking" or recompiling a file.

This turned out to be a bad feature in distributed environments, where users frequently move files from one place to another, or where files are stored on removable media. For example, suppose you MAKEFILE to a floppy, and then copy the file to a file server. If you loaded and edited the file from a file server, and tried to do MAKEFILE, it would try to locate the source file on the floppy, which is probably no longer loaded.
Currently, the file manager searches for sources file on the connected directory, and on the directory search path (on the variable DIRECTORIES). If it is not found, the host/directory information from the FILECREATED expression be used.

Warning: One situation where the new algorithm does the wrong thing is if you explicitly LOADFROM a file that is not on your directory search path. Future MAKEFILES and CLEANUPS will search the connected directory and DIRECTORIES to find the source file, rather than using the file that the LOADFROM was done from. Even if the correct file is on the directory search path, you could still create a bad file if there is another version of the file in an earlier directory on the search path. In general, you should either explicitly specify the SOURCEFILE argument to MAKEFILE to tell it where to get the old source, or connect to the directory where the correct source file is.

Marking Changes

The file manager needs to know what typed definitions have been changed, so it can determine which files need to be updated. This is done by “marking changes”. All the system functions that perform file manager operations (LOAD, TCOMPL, PRETTYDEF, etc.), as well as those functions that define or change data, (EDITF, EDITV, EDITP, DWIM corrections to user functions) interact with the file manager by marking changes. Also, typed-in assignment of variables or property values is noticed by the file manager. (If a program modifies a variable or property value, this is not noticed.) In some cases the marking procedure can be subtle, e.g. if you edit a property list using EDITP, only those properties whose values are actually changed (or added) are marked.

The various system functions which create or modify objects call MARKASCHANGED to mark the object as changed. For example, when a function is defined via DEFINE or DEFINEQ, or modified via EDITF, or a DWIM correction, the function is marked as being a changed object of type FNS. Similarly, whenever a new record is declared, or an existing record redeclared or edited, it is marked as being a changed object of type RECORDS, and so on for all of the other file manager types.

You can also call MARKASCHANGED directly to mark objects of a particular file manager type as changed:

```
(MARKASCHANGED NAME TYPE REASON) [Function]
```

Marks NAME of type TYPE as being changed. MARKASCHANGED returns NAME. MARKASCHANGED is undoable.

REASON is a symbol that indicated how NAME was changed. MARKASCHANGED recognizes the following values for REASON:

- **DEFINED** Used to indicate the creation of NAME, e.g. from DEFINEQ (Chapter 10).
- **CHANGED** Used to indicate a change to NAME, e.g. from the editor.
DELETED Used to indicate the deletion of NAME, e.g. by DELDEF.

CLISP Used to indicate the modification of NAME by CLISP translation.

For backwards compatibility, MARKASCHANGED also accepts a REASON of T (=DEFINED) and NIL (=CHANGED). New programs should avoid using these values.

The variable MARKASCHANGEDPNS is a list of functions that MARKASCHANGED calls (with arguments NAME, TYPE, and REASON). Functions can be added to this list to "advise" MARKASCHANGED to do additional work for all types of objects. The WHENCHANGED file manager type property (see the Defining New File Manager Types section) can be used to specify additional actions when MARKASCHANGED gets called on specific types of objects.

(UNMARKASCHANGED NAME TYPE) [Function]

Unmarks NAME of type TYPE as being changed. Returns NAME if NAME was marked as changed and is now unmarked, NIL otherwise. UNMARKASCHANGED is undoable.

(FILEPKGCHANGES TYPE LST) [NoSpread Function]

If LST is not specified (as opposed to being NIL), returns a list of those objects of type TYPE that have been marked as changed but not yet associated with their corresponding files (see the File Manager Types section). If LST is specified, FILEPKGCHANGES sets the corresponding list. (FILEPKGCHANGES) returns a list of all objects marked as changed as a list of elements of the form (TYPENAME . CHANGEDOBJECTS).

Some properties (e.g. EXPR, ADVICE, MACRO, I.S.OPR, etc.) are used to implement other file manager types. For example, if you change the value of the property I.S.OPR, you are really changing an object of type I.S.OPR. The effect is the same as though you had redefined the i.s.opr via a direct call to the function I.S.OPR. If a property whose value has been changed or added does not correspond to a specific file manager type, then it is marked as a changed object of type PROPS whose name is (VARIABLENAME PROPNAME) (except if the property name has a property PROPTYPE with value IGNORE).

Similarly, if you change a variable which implements the file manager type ALISTS (as indicated by the appearance of the property VARTYPE with value ALIST on the variable’s property list), only those entries that are actually changed are marked as being changed objects of type ALISTS. The "name" of the object will be (VARIABLENAME KEY) where KEY is CAR of the entry on the alist that is being marked. If the variable corresponds to a specific file manager type other than ALISTS, e.g., USERMACROS, LISPXMACROS, etc., then an object of that type is marked. In this case, the name of the changed object will be CAR of the corresponding entry on the alist. For example, if you edit LISPXMACROS and change a definition for PL, then the object PL of type LISPXMACROS is marked as being changed.
Noticing Files

Already existing files are "noticed" by LOAD or LOADFROM (or by LOADFNS or LOADVARS when the VARS argument is T). New files are noticed when they are constructed by MAKEFILE, or when definitions are first associated with them via FILES? or ADDTOFILES?. Noticing a file updates certain lists and properties so that the file manager functions know to include the file in their operations. For example, CLEANUP will only dump files that have been noticed.

You can explicitly tell the file manager to notice a newly-created file by defining the filecoms for the file, and calling ADDFILE:

\begin{verbatim}
(ADDFILE FILE) [Function]
\end{verbatim}

Tells the file manager that FILE should be recognized as a file; it adds FILE to FILELST, and also sets up the FILE property of FILE to reflect the current set of changes which are "registered against" FILE.

The file manager uses information stored on the property list of the root name of noticed files. The following property names are used:

\textbf{FILE} [Property Name]

When a file is noticed, the property FILE, value \((\{FILECOMS \, LOADTYPE\})\) is added to the property list of its root name. FILECOMS is the variable containing the filecoms of the file. LOADTYPE indicates how the file was loaded, e.g., completely loaded, only partially loaded as with LOADFNS, loaded as a compiled file, etc.

The property FILE is used to determine whether or not the corresponding file has been modified since the last time it was loaded or dumped. CDR of the FILE property records by type those items that have been changed since the last MAKEFILE. Whenever a file is dumped, these items are moved to the property FILECHANGES, and CDR of the FILE property is reset to NIL.

\textbf{FILECHANGES} [Property Name]

The property FILECHANGES contains a list of all changed items since the file was loaded (there may have been several sequences of editing and rewriting the file). When a file is dumped, the changes in CDR of the FILE property are added to the FILECHANGES property.

\textbf{FILEDATES} [Property Name]

The property FILEDATES contains a list of version numbers and corresponding file dates for this file. These version numbers and dates are used for various integrity checks in connection with remaking a file.
The property FILEMAP is used to store the filemap for the file. This is used to directly load individual functions from the middle of a file.

To compute the root name, ROOTFILENAME is applied to the name of the file as indicated in the FILECREATED expression appearing at the front of the file, since this name corresponds to the name the file was originally made under. The file manager detects that the file being noticed is a compiled file (regardless of its name), by the appearance of more than one FILECREATED expressions. In this case, each of the files mentioned in the following FILECREATED expressions are noticed. For example, if you perform (BCOMPL '(FOO FIE)), and subsequently loads FOO.DCOM, both FOO and FIE will be noticed.

When a file is noticed, its root name is added to the list FILELST:

FILELST [Variable]
Contains a list of the root names of the files that have been noticed.

LOADEDFILELST [Variable]
Contains a list of the actual names of the files as loaded by LOAD, LOADFNS, etc. For example, if you perform (LOAD '<NEWLISP>EDITA.COM;3), EDITA will be added to FILELST, but '<NEWLISP>EDITA.COM;3 is added to LOADEDFILELST. LOADEDFILELST is not used by the file manager; it is maintained solely for your benefit.

**Distributing Change Information**

Periodically, the function UPDATEFILES is called to find which file(s) contain the elements that have been changed. UPDATEFILES is called by FILES?, CLEANUP, and MAKEFILES, i.e., any procedure that requires the FILE property to be up to date. This procedure is followed rather than updating the FILE property after each change because scanning FILELST and examining each file manager command can be a time-consuming process; this is not so noticeable when performed in conjunction with a large operation like loading or writing a file.

UPDATEFILES operates by scanning FILELST and interrogating the file manager commands for each file. When (if) any files are found that contain the corresponding typed definition, the name of the element is added to the value of the property FILE for the corresponding file. Thus, after UPDATEFILES has completed operating, the files that need to be dumped are simply those files on FILELST for which CDR of their FILE property is non-NIL. For example, if you load the file FOO containing definitions for FOO1, FOO2, and FOO3, edit FOO2, and then call UPDATEFILES, (GETPROP 'FOO 'FILE) will be ((FOOCOMS . T) (FNS FOO2)). If any objects marked as changed have not been transferred to the FILE property for some file, e.g., you define a new function but forget (or declines) to add it to the file manager commands for the corresponding file, then both FILES? and...
CLEANUP will print warning messages, and then call ADDTOFILES? to permit you to specify on which files these items belong.

You can also invoke UPDATEFILES directly:

```lisp
(UPDATEFILES — —) [Function]
(UPDATEFILES) will update the FILE properties of the noticed files.
```

## File Manager Types

In addition to the definitions of functions and values of variables, source files in Interlisp can contain a variety of other information, e.g. property lists, record declarations, macro definitions, hash arrays, etc. In order to treat such a diverse assortment of data uniformly from the standpoint of file operations, the file manager uses the concept of a typed definition, of which a function definition is just one example. A typed definition associates with a name (usually a symbol), a definition of a given type (called the file manager type). Note that the same name may have several definitions of different types. For example, a symbol may have both a function definition and a variable definition. The file manager also keeps track of the file that a particular typed definition is stored on, so one can think of a typed definition as a relation between four elements: a name, a definition, a type, and a file.

A file manager type is an abstract notion of a class of objects which share the property that every object of the same file manager type is stored, retrieved, edited, copied etc., by the file manager in the same way. Each file manager type is identified by a symbol, which can be given as an argument to the functions that manipulate typed definitions. You may define new file manager types, as described in the Defining New Package Types section.

```lisp
FILEPKGTYPES [Variable]
The value of FILEPKGTYPES is a list of all file manager types, including any that you may have defined.
```

The file manager is initialized with the following built-in file manager types:

```lisp
ADVICE [File Manager Type]
Used to access “advice” modifying a function (see Chapter 15).

ALISTS [File Manager Type]
Used to access objects stored on an association list that is the value of a symbol (see Chapter 3).

A variable is declared to have an association list as its value by putting on its property list the property VARTYPE with value ALIST. In this case, each dotted pair on the list is an object of type ALISTS. When the value of such a variable is changed, only those entries in the association list that are actually changed or added are marked as changed objects of
type **ALISTS** (with "name" (**symbol** **KEY**)). Objects of type **ALISTS** are dumped via the **ALISTS** or **ADDVARS** file manager commands.

Note that some association lists are used to "implement" other file manager types. For example, the value of the global variable **USERMACROS** implements the file manager type **USERMACROS** and the values of **LISPXMACROS** and **LISPXHISTORYMACROS** implement the file manager type **LISPXMACROS**. This is indicated by putting on the property list of the variable the property **VARTYPE** with value a list of the form (**ALIST** **FILEPKGTYPE**). For example, **(GETPROP ‘LISPXHISTORYMACROS ‘VARTYPE)** => (**ALIST** **LISPXMACROS**).

**COURIERPROGRAMS** [File Manager Type]

Used to access Courier programs (see Chapter 31).

**EXPRESSIONS** [File Manager Type]

Used to access lisp expressions that are put on a file by using the **REMEMBER** programmers assistant command (Chapter 13), or by explicitly putting the **p** file manager command on the filecoms.

**FIELDS** [File Manager Type]

Used to access fields of records. The "definition" of an object of type **FIELDS** is a list of all the record declarations which contain the name. See Chapter 8.

**FILEPKGCOMS** [File Manager Type]

Used to access file manager commands and types. A single name can be defined both as a file manager type and a file manager command. The "definition" of an object of type **FILEPKGCOMS** is a list structure of the form (**(COM . COMPROPS)** (**TYPE . TYPEPROPS**)), where **COMPROPS** is a property list specifying how the name is defined as a file manager command by **FILEPKGCOM** (see the Defining New File Manager Commands section), and **TYPEPROPS** is a property list specifying how the name is defined as a file manager type by **FILEPKGTYPE** (see the Defining New File Manager Types section).

**FILES** [File Manager Type]

Used to access files. This file manager type is most useful for renaming files. The "definition" of a file is not a useful structure.

**FILEVARS** [File Manager Type]

Used to access Filevars (see the FileVars section).

**FNS** [File Manager Type]

Used to access function definitions.
I.S.OPRS
[File Manager Type]
Used to access the definitions of iterative statement operators (see Chapter 9).

LISPXMACROS
[File Manager Type]
Used to access programmer’s assistant commands defined on the variables LISPXMACROS and LISPXHISTORYMACROS (see Chapter 13).

MACROS
[File Manager Type]
Used to access macro definitions (see Chapter 10).

PROPS
[File Manager Type]
Used to access objects stored on the property list of a symbol (see Chapter 2). When a property is changed or added, an object of type PROPS, with “name” (SYMBOL PROPNAME) is marked as being changed.

Note that some symbol properties are used to implement other file manager types. For example, the property MACRO implements the file manager type MACROS, the property ADVICE implements ADVICE, etc. This is indicated by putting the property PROPTYPE, with value of the file manager type on the property list of the property name. For example, (GETPROP ‘MACRO ‘PROPTYPE) => MACROS. When such a property is changed or added, an object of the corresponding file manager type is marked. If (GETPROP PROPNAME ‘PROPTYPE) => IGNORE, the change is ignored. The FILE, FILEMAP, FILEDATES, etc. properties are all handled this way. (IGNORE cannot be the name of a file manager type implemented as a property).

RECORDS
[File Manager Type]
Used to access record declarations (see Chapter 8).

RESOURCES
[File Manager Type]
Used to access resources (see Chapter 12).

TEMPLATES
[File Manager Type]
Used to access Masterscope templates (see Chapter 19).

USERNACROS
[File Manager Type]
Used to access user edit macros (see Chapter 16).

VARS
[File Manager Type]
Used to access top-level variable values.
Functions for Manipulating Typed Definitions

The functions described below can be used to manipulate typed definitions, without needing to know how the manipulations are done. For example, (GETDEF 'FOO 'FNS) will return the function definition of FOO, (GETDEF 'FOO 'VARS) will return the variable value of FOO, etc. All of the functions use the following conventions:

1. All functions which make destructive changes are undoable.

2. Any argument that expects a list of symbols will also accept a single symbol, operating as though it were enclosed in a list. For example, if the argument FILES should be a list of files, it may also be a single file.

3. TYPE is a file manager type. TYPE = NIL is equivalent to TYPE = FNS. The singular form of a file manager type is also recognized, e.g. TYPE = VAR is equivalent to TYPE = VARS.

4. FILES = NIL is equivalent to FILES = FILELST.

5. SOURCE is used to indicate the source of a definition, that is, where the definition should be found. SOURCE can be one of:

   CURRENT Get the definition currently in effect.
   SAVED Get the "saved" definition, as stored by SAVEDEF.
   FILE Get the definition contained on the (first) file determined by WHEREIS.

   WHEREIS is called with FILES = T, so that if the WHEREIS library package is loaded, the WHEREIS data base will be used to find the file containing the definition.

   ? Get the definition currently in effect if there is one, else the saved definition if there is one, otherwise the definition from a file determined by WHEREIS. Like specifying CURRENT, SAVED, and FILE in order, and taking the first definition that is found.

   a file name a list of file names Get the definition from the first of the indicated files that contains one.

   NIL In most cases, giving SOURCE = NIL (or not specifying it at all) is the same as giving ?, to get either the current, saved, or filed definition. However, with HASDEF, SOURCE = NIL is interpreted as equal to SOURCE = CURRENT, which only tests if there is a current definition.
The operation of most of the functions described below can be changed or extended by modifying the appropriate properties for the corresponding file manager type using the function FILEPKGTYPE, described in the Defining New File Manager Types section.

(GETDEF NAME TYPE SOURCE OPTIONS)  [Function]

Returns the definition of NAME, of type TYPE, from SOURCE. For most types, GETDEF returns the expression which would be pretty printed when dumping NAME as TYPE. For example, for TYPE = FNS, an EXPR definition is returned, for TYPE = VARS, the value of NAME is returned, etc.

OPTIONS is a list which specifies certain options:

- **NOERROR**
  GETDEF causes an error if an appropriate definition cannot be found, unless OPTIONS is or contains NOERROR. In this case, GETDEF returns the value of the NULLDEF file manager type property (see the Defining New File Manager Types section), usually NIL.

- **a string**
  If OPTIONS is or contains a string, that string will be returned if no definition is found (and NOERROR is not among the options). The caller can thus determine whether a definition was found, even for types for which NIL or NOBIND are acceptable definitions.

- **NOCOPY**
  GETDEF returns a copy of the definition unless OPTIONS is or contains NOCOPY.

- **EDIT**
  If OPTIONS is or contains EDIT, GETDEF returns a copy of the definition unless it is possible to edit the definition "in place." With some file manager types, such as functions, it is meaningful (and efficient) to edit the definition by destructively modifying the list structure, without calling PUTDEF. However, some file manager types (like records) need to be "installed" with PUTDEF after they are edited. The default EDITDEF (see the Defining New File Manager Types section) calls GETDEF with OPTIONS of (EDIT NOCOPY), so it doesn’t use a copy unless it has to, and only calls PUTDEF if the result of editing is not EQUAL to the old definition.

- **NODWIM**
  A FNS definition will be dwimified if it is likely to contain CLISP unless OPTIONS is or contains NODWIM.

(PUTDEF NAME TYPE DEFINITION REASON)  [Function]

Defines NAME of type TYPE with DEFINITION. For TYPE = FNS, does a DEFINE; for TYPE = VARS, does a SAVESET, etc.
For $TYPE = FILES$, PUTDEF establishes the command list, notices $NAME$, and then calls MAKEFILE to actually dump the file $NAME$, copying functions if necessary from the "old" file (supplied as part of DEFINITION).

PUTDEF calls MARKASCHANGED (see the Mrking Changes section) to mark $NAME$ as changed, giving a reason of $REASON$. If $REASON$ is NIL, the default is DEFINED.

If $TYPE = FNS$, PUTDEF prints a warning if you try to redefine a function on the list UNSAFE.TO.MODIFY.FNS (see Chapter 10).

(HASDEF $NAME$ $TYPE$ $SOURCE$ $SPELLFLG$) [Function]

Returns (OR $NAME$ T) if $NAME$ is the name of something of type $TYPE$. If not, attempts spelling correction if $SPELLFLG = T$, and returns the spelling-corrected $NAME$. Otherwise returns NIL. HASDEF for type FNS (or NIL) indicates that $NAME$ has an editable source definition. If $NAME$ is a function that exists on a file for which you have loaded only the compiled version and not the source, HASDEF returns NIL.

(HASDEF NIL $TYPE$) returns T if NIL has a valid definition.

If $SOURCE = NIL$, HASDEF interprets this as equal to $SOURCE = CURRENT$, which only tests if there is a current definition.

(TYPESOF $NAME$ POSSIBLETYPES IMPOSSIBLETYPES $SOURCE$) [Function]

Returns a list of the types in POSSIBLETYPES but not in IMPOSSIBLETYPES for which $NAME$ has a definition. FILEPKGTYPES is used if POSSIBLETYPES is NIL.

(COPYDEF $OLD$ $NEW$ $TYPE$ $SOURCE$ $OPTIONS$) [Function]

Defines $NEW$ to have a copy of the definition of $OLD$ by doing PUTDEF on a copy of the definition retrieved by (GETDEF OLD $TYPE$ $SOURCE$ $OPTIONS$). $NEW$ is substituted for $OLD$ in the copied definition, in a manner that may depend on the $TYPE$.

For example, (COPYDEF 'PDQ 'RST 'FILES) sets up RSTCOMS to be a copy of PDQCOMS, changes things like (VARS * PDQVARS) to be (VARS * RSTVARS) in RSTCOMS, and performs a MAKEFILE on RST such that the appropriate definitions get copied from PDQ.

COPYDEF disables the NOCOPY option of GETDEF, so $NEW$ will always have a copy of the definition of $OLD$.

COPYDEF substitutes $NEW$ for $OLD$ throughout the definition of $OLD$. This is usually the right thing to do, but in some cases, e.g., where the old name appears within a quoted expression but was not used in the same context, you must re-edit the definition.

(DELDEF $NAME$ $TYPE$) [Function]

Removes the definition of $NAME$ as a $TYPE$ that is currently in effect.
(SHOWDEF NAME TYPE FILE) [Function]
Prettyprints the definition of NAME as a TYPE to FILE. This shows you how NAME would be written to a file. Used by ADDTOFILES? (see the Storing Files section).

(EDITDEF NAME TYPE SOURCE EDITCOMS) [Function]
Edits the definition of NAME as a TYPE. Essentially performs
(PUTDEF NAME TYPE
 (EDITE (GETDEF NAME TYPE SOURCE) EDITCOMS))

(SAVEDEF NAME TYPE DEFINITION) [Function]
Sets the "saved" definition of NAME as a TYPE to DEFINITION. If DEFINITION = NIL, the current definition of NAME is saved.

If TYPE = FNS (or NIL), the function definition is saved on NAME's property list under the property EXPR, or CODE (depending on the FNTYP of the function definition). If (GETD NAME) is non-NIL, but (FNTYP FN) = NIL, SAVEDEF saves the definition on the property name LIST. This can happen if a function was somehow defined with an illegal expr definition, such as (LAMMMDA (X) ...).

If TYPE = VARS, the definition is stored as the value of the VALUE property of NAME. For other types, the definition is stored in an internal data structure, from where it can be retrieved by GETDEF or UNSAVEDEF.

(UNSAVEDEF NAME TYPE) [Function]
Restores the "saved" definition of NAME as a TYPE, making it be the current definition. Returns PROP.

If TYPE = FNS (or NIL), UNSAVEDEF unsaves the function definition from the EXPR property if any, else CODE, and returns the property name used. UNSAVEDEF also recognizes TYPE = EXPR, CODE, or LIST, meaning to unsave the definition only from the corresponding property only.

If DFNFLG is not T (see Chapter 10), the current definition of NAME, if any, is saved using SAVEDEF. Thus one can use UNSAVEDEF to switch back and forth between two definitions.

(LOADDEF NAME TYPE SOURCE) [Function]
Equivalent to (PUTDEF NAME TYPE (GETDEF NAME TYPE SOURCE)). LOADDEF is essentially a generalization of LOADFNS, e.g. it enables loading a single record declaration from a file. (LOADDEF FN) will give FN an EXPR definition, either obtained from its property list or a file, unless it already has one.
(CHANGECALLERS OLD NEW TYPES FILES METHOD) [Function]

Finds all of the places where OLD is used as any of the types in TYPES and changes those places to use NEW. For example, (CHANGECALLERS 'NLSETQ 'ERSETQ) will change all calls to NLSETQ to be calls to ERSETQ. Also changes occurrences of OLD to NEW inside the filecoms of any file, inside record declarations, properties, etc.

CHANGECALLERS attempts to determine if OLD might be used as more than one type; for example, if it is both a function and a record field. If so, rather than performing the transformation OLD -> NEW automatically, you are allowed to edit all of the places where OLD occurs. For each occurrence of OLD, you are asked whether you want to make the replacement. If you respond with anything except Yes or No, the editor is invoked on the expression containing that occurrence.

There are two different methods for determining which functions are to be examined. If METHOD = EDITCALLERS, EDITCALLERS is used to search FILES (see Chapter 16). If METHOD = MASTERSCOPE, then the Masterscope database is used instead. METHOD = NIL defaults to MASTERSCOPE if the value of the variable DEFAULTRENAMEMETHOD is MASTERSCOPE and a Masterscope database exists, otherwise it defaults to EDITCALLERS.

(RENAME OLD NEW TYPES FILES METHOD) [Function]

First performs (COPYDEF OLD NEW TYPE) for all TYPE inside TYPES. It then calls CHANGECALLERS to change all occurrences of OLD to NEW, and then "deletes" OLD with DELEDF. For example, if you have a function FOO which you now wish to call FIE, simply perform (RENAME 'FOO 'FIE), and FIE will be given FOO's definition, and all places that FOO are called will be changed to call FIE instead.

METHOD is interpreted the same as the METHOD argument to CHANGECALLERS, above.

(COMPARE NAME1 NAME2 TYPE SOURCE1 SOURCE2) [Function]

Compares the definition of NAME1 with that of NAME2, by calling COMPARELISTS (Chapter 3) on (GETDEF NAME1 TYPE SOURCE1) and (GETDEF NAME2 TYPE SOURCE2), which prints their differences on the terminal.

For example, if the current value of the variable A is (A B C (D E F) G), and the value of the variable B on the file <lisp>FOO is (A B C (D F E) G), then:

←(COMPARE 'A 'B 'VARS 'CURRENT '<lisp>FOO)
A from CURRENT and B from <lisp>TEST differ:
(E -> F) (F -> E)

(T)

(COMPARE DEFS NAME TYPE SOURCES) [Function]

Calls COMPARELISTS (Chapter 3) on all pairs of definitions of NAME as a TYPE obtained from the various SOURCES (interpreted as a list of source specifications).
Defining New File Manager Types

All manipulation of typed definitions in the file manager is done using the type-independent functions \texttt{GETDEF}, \texttt{PUTDEF}, etc. Therefore, to define a new file manager type, it is only necessary to specify (via the function \texttt{FILEPKGTYPE}) what these functions should do when dealing with a typed definition of the new type. Each file manager type has the following properties, whose values are functions or lists of functions:

These functions are defined to take a \texttt{TYPE} argument so that you may have the same function for more than one type.

\textbf{GETDEF} \quad \text{[File Manager Type Property]}  
Value is a function of three arguments, \texttt{NAME}, \texttt{TYPE}, and \texttt{OPTIONS}, which should return the current definition of \texttt{NAME} as a type \texttt{TYPE}. Used by \texttt{GETDEF} (see the Functions for Manipulating Typed Definitions section), which passes its \texttt{OPTIONS} argument.

If there is no \texttt{GETDEF} property, a file manager command for dumping \texttt{NAME} is created (by \texttt{MAKENEWCOM}). This command is then used to write the definition of \texttt{NAME} as a type \texttt{TYPE} onto the file \texttt{FILEPKG.SCRATCH} (in Medley, this file is created on the \{CORE\} device). This expression is then read back in and returned as the current definition.

In some situations, the function \texttt{HASDEF} needs to call \texttt{GETDEF} to determine whether a definition exists. In this case, \texttt{OPTIONS} will include the symbol \texttt{HASDEF}, and it is permissible for a \texttt{GETDEF} function to return \texttt{T} or \texttt{NIL}, rather than creating a complex structure which will not be used.

\textbf{NULLDEF} \quad \text{[File Manager Type Property]}  
The value of the \texttt{NULLDEF} property is returned by \texttt{GETDEF} (see the Functions for Manipulating Typed Definitions section) when there is no definition and the \texttt{NOERROR} option is supplied. For example, the \texttt{NULLDEF} of \texttt{VARS} is \texttt{NOBIND}.

\textbf{FILEGETDEF} \quad \text{[File Manager Type Property]}  
This enables you to provide a way of obtaining definitions from a file that is more efficient than the default procedure used by \texttt{GETDEF} (see the Functions for Manipulating Typed Definitions section). Value is a function of four arguments, \texttt{NAME}, \texttt{TYPE}, \texttt{FILE}, and \texttt{OPTIONS}. The function is applied by \texttt{GETDEF} when it is determined that a typed definition is needed from a particular file. The function must open and search the given file and return any \texttt{TYPE} definition for \texttt{NAME} that it finds.

\textbf{CANFILEDEF} \quad \text{[File Manager Type Property]}  
If the value of this property is non-\texttt{NIL}, this indicates that definitions of this file manager type are not loaded when a file is loaded with \texttt{LOADFROM} (see the Loading Files section). The default is \texttt{NIL}. Initially, only \texttt{FNS} has this property set to non-\texttt{NIL}.
**PUTDEF**

[File Manager Type Property]

Value is a function of three arguments, NAME, TYPE, and DEFINITION, which should store DEFINITION as the definition of NAME as a type TYPE. Used by PUTDEF (see the Functions for Manipulating Typed Definitions section).

**HASDEF**

[File Manager Type Property]

Value is a function of three arguments, NAME, TYPE, and SOURCE, which should return (OR NAME T) if NAME is the name of something of type TYPE. SOURCE is as interpreted by HASDEF (see the Functions for Manipulating Typed Definitions section), which uses this property.

**EDITDEF**

[File Manager Type Property]

Value is a function of four arguments, NAME, TYPE, SOURCE, and EDITCOMS, which should edit the definition of NAME as a type TYPE from the source SOURCE, interpreting the edit commands EDITCOMS. If successful, should return NAME (or a spelling-corrected NAME). If it returns NIL, the "default" editor is called. Used by EDITDEF (see the Functions for Manipulating Typed Definitions section).

**DELDEF**

[File Manager Type Property]

Value is a function of two arguments, NAME, and TYPE, which removes the definition of NAME as a TYPE that is currently in effect. Used by DELDEF (see the Functions for Manipulating Typed Definitions section).

**NEWCOM**

[File Manager Type Property]

Value is a function of four arguments, NAME, TYPE, LISTNAME, and FILE. Specifies how to make a new (instance of a) file manager command to dump NAME, an object of type TYPE. The function should return the new file manager command. Used by ADDTOFILE and SHOWDEF.

If LISTNAME is non-NIL, this means that you specified LISTNAME as the filevar in interaction with ADDTOFILES? (see the FileVars section).

If no NEWCOM is specified, the default is to call DEFAULTMAKENEWCOM, which will construct and return a command of the form (TYPE NAME). You can advise or redefine DEFAULTMAKENEWCOM.

**WHENCHANGED**

[File Manager Type Property]

Value is a list of functions to be applied to NAME, TYPE, and REASON when NAME, an instance of type TYPE, is changed or defined (see MARKASCHANGED, in the Marking Changes section). Used for various applications, e.g. when an object of type I.S.OPRS changes, it is necessary to clear the corresponding translations from CLISPARAY.

The WHENCHANGED functions are called before the object is marked as changed, so that it can, in fact, decide that the object is not to be marked as changed, and execute (RETFROM 'MARKASCHANGED).
The `REASON` argument passed to `WHENCHANGED` functions is either `DEFINED` or `CHANGED`.

**WHENFILED**

[File Manager Type Property]

Value is a list of functions to be applied to `NAME`, `TYPE`, and `FILE` when `NAME`, an instance of type `TYPE`, is added to `FILE`.

**WHENUNFILED**

[File Manager Type Property]

Value is a list of functions to be applied to `NAME`, `TYPE`, and `FILE` when `NAME`, an instance of type `TYPE`, is removed from `FILE`.

**DESCRIPTION**

[File Manager Type Property]

Value is a string which describes instances of this type. For example, for type `RECORDS`, the value of `DESCRIPTION` is the string "record declarations".

The function `FILEPKGTYPE` is used to define new file manager types, or to change the properties of existing types. It is possible to redefine the attributes of system file manager types, such as `FNS` or `PROPS`.

```lisp
(FILEPKGTYPE TYPE PROP VAL_1 ... PROP_N VAL_N)
```

[NoSpread Function]

Nospread function for defining new file manager types, or changing properties of existing file manager types. `PROP_i` is one of the property names given above; `VAL_i` is the value to be given to that property. Returns `TYPE`.

```lisp
(FILEPKGTYPE TYPE PROP)
```

returns the value of the property `PROP`, without changing it.

```lisp
(FILEPKGTYPE TYPE)
```

returns a property list of all of the defined properties of `TYPE`, using the property names as keys.

Specifying `TYPE` as the symbol `TYPE` can be used to define one file manager type as a synonym of another. For example, `(FILEPKGTYPE 'R 'TYPE 'RECORDS)` defines `R` as a synonym for the file manager type `RECORDS`.

### File Manager Commands

The basic mechanism for creating symbolic files is the function `MAKEFILE` (see the Storing Files section). For each file, the file manager has a data structure known as the "filecoms", which specifies what typed descriptions are contained in the file. A filecoms is a list of file manager commands, each of which specifies objects of a certain file manager type which should be dumped. For example, the filecoms

```lisp
((FNS FOO)
 (VARS FOO BAR BAZ)
 (RECORDS XYZZY))
```
has a FNS, a VARS, and a RECORDS file manager command. This filecoms specifies that the function definition for FOO, the variable values of FOO, BAR, and BAZ, and the record declaration for XYZZY should be dumped.

By convention, the filecoms of a file X is stored as the value of the symbol XCOMS. For example, (MAKEFILE 'FOO.;27) will use the value of FOOCOMS as the filecoms. This variable can be directly manipulated, but the file manager contains facilities which make constructing and updating filecoms easier, and in some cases automatic (see the Functions for Manipulating File Command Lists section).

A file manager command is an instruction to MAKEFILE to perform an explicit, well-defined operation, usually printing an expression. Usually there is a one-to-one correspondence between file manager types and file manager commands; for each file manager type, there is a file manager command which is used for writing objects of that type to a file, and each file manager command is used to write objects of a particular type. However, in some cases, the same file manager type can be dumped by several different file manager commands. For example, the file manager commands PROP, IFPROP, and PROPS all dump out objects with the file manager type PROPS. This means if you change an object of file manager type PROPS via EDITP, a typed-in call to PUTPROP, or via an explicit call to MARKASCHANGED, this object can be written out with any of the above three commands. Thus, when the file manager attempts to determine whether this typed object is contained on a particular file, it must look at instances of all three file manager commands PROP, IFPROP, and PROPS, to see if the corresponding atom and property are specified. It is also permissible for a single file manager command to dump several different file manager types. For example, you can define a file manager command which dumps both a function definition and its macro. Conversely, some file manager commands do not dump any file manager types at all, such as the E command.

For each file manager command, the file manager must be able to determine what typed definitions the command will cause to be printed so that the file manager can determine on what file (if any) an object of a given type is contained (by searching through the filecoms). Similarly, for each file manager type, the file manager must be able to construct a command that will print out an object of that type. In other words, the file manager must be able to map file manager commands into file manager types, and vice versa. Information can be provided to the file manager about a particular file manager command via the function FILEPKGCOM (see the Defining New File Manager Commands section), and information about a particular file manager type via the function FILEPKGTYPE (see the prior section). In the absence of other information, the default is simply that a file manager command of the form (X NAME) prints out the definition of NAME as a type X, and, conversely, if NAME is an object of type X, then NAME can be written out by a command of the form (X NAME).

If a file manager function is given a command or type that is not defined, it attempts spelling correction using FILEPKGCOMSPLST as a spelling list (unless DWIMFLG or NOSPELLFLG = NIL; see Chapter 20). If successful, the corrected version of the list of file manager commands is written (again) on the output file, since at this point, the uncorrected list of file manager commands would already have been printed on the output file. When the file is loaded, this will result in FILECOMS being reset, and may cause a message to be printed, e.g., (FOOCOMS RESET). The value of FOOCOMS would then be the corrected version. If the spelling correction is unsuccessful, the file manager functions generate an error, BAD FILE PACKAGE COMMAND.
File package commands can be used to save on the output file definitions of functions, values of
variables, property lists of atoms, advised functions, edit macros, record declarations, etc. The
interpretation of each file manager command is documented in the following sections.

(USERCASOS SYMBOL1 . . . SYMBOLN) [File Manager Command]

Each symbol SYMBOLi is the name of a user edit macro. Writes expressions to add the
edit macro definitions of SYMBOLi to USERMACROS, and adds the names of the commands
to the appropriate spelling lists.

If SYMBOLi is not a user macro, a warning message "no EDIT MACRO for SYMBOLi" is
printed.

Functions and Macros

(FNS FN1 . . . FNN) [File Manager Command]

Writes a DEFINEQ expression with the function definitions of FN1 . . . FNN.

You should never print a DEFINEQ expression directly onto a file (by using the P file
manager command, for example), because MAKEFILE generates the filemap of function
definitions from the FNS file manager commands (see the File Maps section).

(ADVISE FN1 . . . FNN) [File Manager Command]

For each function FNi, writes expressions to reinstate the function to its advised state
when the file is loaded. See Chapter 15.

When advice is applied to a function programmatically or by hand, it is additive. That is,
if a function already has some advice, further advice is added to the already-existing
advice. However, when advice is applied to a function as a result of loading a file with an
ADVISE file manager command, the new advice replaces any earlier advice. ADVISE
works this way to prevent problems with loading different versions of the same advice. If
you really want to apply additive advice, a file manager command such as (P (ADVISE
. . . )) should be used (see the Miscellaneous File Manager Commands section).

(ADVICE FN1 . . . FNN) [File Manager Command]

For each function FNi, writes a PUTPROPS expression which will put the advice back on
the property list of the function. You can then use READVISE (see Chapter 15) to
reactivate the advice.

(MACROS SYMBOL1 . . . SYMBOLN) [File Manager Command]

Each SYMBOLi is a symbol with a MACRO definition (and/or a DMACRO, 10MACRO, etc.).
Writes an expression to restore all of the macro properties for each SYMBOLi,
embedded in a DECLARE: EVAL@COMPILE so the macros will be defined when the file is
compiled. See Chapter 10.
Variables

(VARS VAR₁ . . . VARₙ) [File Manager Command]

For each VARᵢ, writes an expression to set its top level value when the file is loaded. If VARᵢ is atomic, VARS writes out an expression to set VARᵢ to the top-level value it had at the time the file was written. If VARᵢ is non-atomic, it is interpreted as (VAR FORM), and VARS write out an expression to set VAR to the value of FORM (evaluated when the file is loaded).

VARS prints out expressions using RPAQQ and RPAQ, which are like SETQQ and SETQ except that they also perform some special operations with respect to the file manager (see the Functions Used within Source Files section).

VARS cannot be used for putting arbitrary variable values on files. For example, if the value of a variable is an array (or many other data types), a symbol which represents the array is dumped in the file instead of the array itself. The HORBIBLEVARS file manager command provides a way of saving and reloading variables whose values contain re-entrant or circular list structure, user data types, arrays, or hash arrays.

(INITVARS VAR₁ . . . VARₙ) [File Manager Command]

INITVARS is used for initializing variables, setting their values only when they are currently NOBIND. A variable value defined in an INITVARS command will not change an already established value. This means that re-loading files to get some other information will not automatically revert to the initialization values.

The format of an INITVARS command is just like VARS. The only difference is that if VARᵢ is atomic, the current value is not dumped; instead NIL is defined as the initialization value. Therefore, (INITVARS FOO (FUM 2)) is the same as (VARS (FOO NIL) (FUM 2)), if FOO and FUM are both NOBIND.

INITVARS writes out an RPAQ? expression on the file instead of RPAQ or RPAQQ.

(ADDVARS (VAR₁ . LST₁) . . . (VARₙ . LSTₙ)) [File Manager Command]

For each (VARᵢ . LSTᵢ), writes an ADDTOVAR (see the Functions Used Within Source Files section) to add each element of LSTᵢ to the list that is the value of VARᵢ at the time the file is loaded. The new value of VARᵢ will be the union of its old value and LSTᵢ. If the value of VARᵢ is NOBIND, it is first set to NIL.

For example, (ADDVARS (DIRECTORIES LISP LISPUSERS)) will add LISP and LISPUSERS to the value of DIRECTORIES.

If LSTᵢ is not specified, VARᵢ is initialized to NIL if its current value is NOBIND. In other words, (ADDVARS (VAR)) will initialize VAR to NIL if VAR has not previously been set.
**APPENDVARS** (VAR₁ . LST₁) ... (VARₙ . LSTₙ)  

The same as **ADDVARS**, except that the values are added to the end of the lists (using **APPENDTOVAR**, in the Functions Used Within Source Files section), rather than at the beginning.

**UGLYVARS** VAR₁ ... VARₙ  

Like **VARS**, except that the value of each VARᵢ may contain structures for which **READ** is not an inverse of **PRINT**, e.g. arrays, readtables, user data types, etc. Uses **HPRINT** (see Chapter 25).

**HORRIBLEVARS** VAR₁ ... VARₙ  

Like **UGLYVARS**, except structures may also contain circular pointers. Uses **HPRINT** (see Chapter 25). The values of VAR₁ ... VARₙ are printed in the same operation, so that they may contain pointers to common substructures.

**UGLYVARS** does not do any checking for circularities, which results in a large speed and internal-storage advantage over **HORRIBLEVARS**. Thus, if it is known that the data structures do not contain circular pointers, **UGLYVARS** should be used instead of **HORRIBLEVARS**.

**ALISTS** (VAR₁ KEY₁ KEY₂ ... . . . VARₙ KEY₃ KEY₄ ... )  

VARᵢ is a variable whose value is an association list, such as **EDITMACROS**, **BAKTRACELST**, etc. For each VARᵢ, **ALISTS** writes out expressions which will restore the values associated with the specified keys. For example, **(ALISTS (BREAKMACROS BT BTV))** will dump the definition for the BT and BTV commands on **BREAKMACROS**.

Some association lists (**USERMACROS**, **LISPXMACROS**, etc.) are used to implement other file manager types, and they have their own file manager commands.

**SPECVARS** VAR₁ ... VARₙ  

**LOCALVARS** VAR₁ ... VARₙ  

**GLOBALVARS** VAR₁ ... VARₙ  

Outputs the corresponding compiler declaration embedded in a **DECLARE**: **DOEVAL@COMPILE DONTCOPY**. See Chapter 18.

**CONSTANTS** VAR₁ ... VARₙ  

Like **VARS**, for each VARᵢ writes an expression to set its top level value when the file is loaded. Also writes a **CONSTANTS** expression to declare these variables as constants (see Chapter 18). Both of these expressions are wrapped in a **(DECLARE: EVAL@COMPILE . . .)** expression, so they can be used by the compiler.
Like VARS, VAR_i can be non-atomic, in which case it is interpreted as \((VAR\ FORM)\), and passed to \texttt{CONSTANTS} (along with the variable being initialized to \texttt{FORM}).

title: Symbol Properties

\begin{verbatim}
(PROP PROPNAME SYMBOL1 ... SYMBOLN)

Writes a PUTPROPS expression to restore the value of the \texttt{PROPNAME} property of each symbol \texttt{SYMBOL_i} when the file is loaded.

If \texttt{PROPNAME} is a list, expressions will be written for each property on that list. If \texttt{PROPNAME} is the symbol \texttt{ALL}, the values of all user properties (on the property list of each \texttt{SYMBOL_i}) are saved. \texttt{SYSPROPS} is a list of properties used by system functions. Only properties \texttt{not} on that list are dumped when the \texttt{ALL} option is used.

If \texttt{SYMBOL_i} does not have the property \texttt{PROPNAME} (as opposed to having the property with value \texttt{NIL}), a warning message "NO \texttt{PROPNAME} PROPERTY FOR \texttt{SYMBOL_i}" is printed. The command \texttt{IFPROP} can be used if it is not known whether or not an atom will have the corresponding property.

(IFPROP PROPNAME SYMBOL1 ... SYMBOLN)

Same as the \texttt{PROP} file manager command, except that it only saves the properties that actually appear on the property list of the corresponding atom. For example, if \texttt{FOO1} has property \texttt{PROP1} and \texttt{PROP2}, \texttt{FOO2} has \texttt{PROP3}, and \texttt{FOO3} has property \texttt{PROP1} and \texttt{PROP3}, then \texttt{(IFPROP (PROP1 PROP2 PROP3) FOO1 FOO2 FOO3)} will save only those five property values.

(PROPS (SYMBOL1 PROPNAME1) ... (SYMBOLN PROPNAMEN))

Similar to \texttt{PROP} command. Writes a PUTPROPS expression to restore the value of \texttt{PROPNAME_i} for each \texttt{SYMBOL_i} when the file is loaded.

As with the \texttt{PROP} command, if \texttt{SYMBOL_i} does not have the property \texttt{PROPNAME} (as opposed to having the property with \texttt{NIL} value), a warning message "NO \texttt{PROPNAME_i} PROPERTY FOR \texttt{SYMBOL_i}" is printed.

Miscellaneous File Manager Commands

(RECORDS REC1 ... REC_N)

Each \texttt{REC_i} is the name of a record (see Chapter 8). Writes expressions which will redclare the records when the file is loaded.

(INITRECORDS REC1 ... REC_N)

Similar to \texttt{RECORDS}, \texttt{INITRECORDS} writes expressions on a file that will, when loaded, perform whatever initialization/allocation is necessary for the indicated records.
However, the record declarations themselves are not written out. This facility is useful for building systems on top of Interlisp, in which the implementor may want to eliminate the record declarations from a production version of the system, but the allocation for these records must still be done.

**LISPXMACROS SYMBOL₁ ... SYMBOLₙ**  
[File Manager Command]

Each SYMBOLᵢ is defined on LISPXMACROS or LISPXHISTORYMACROS (see Chapter 13). Writes expressions which will save and restore the definition for each macro, as well as making the necessary additions to LISPXCOMS.

**I.S.OPRS OPR₁ ... OPRₙ**  
[File Manager Command]

Each OPRᵢ is the name of a user-defined i.s.opr (see Chapter 9). Writes expressions which will redefine the i.s.oprs when the file is loaded.

**RESOURCES RESOURCE₁ ... RESOURCEₙ**  
[File Manager Command]

Each RESOURCESᵢ is the name of a resource (see Chapter 12). Writes expressions which will redeclare the resource when the file is loaded.

**INITRESOURCES RESOURCE₁ ... RESOURCEₙ**  
[File Manager Command]

Parallel to INITRECORDS, INITRESOURCES writes expressions on a file to perform whatever initialization/allocation is necessary for the indicated resources, without writing the resource declaration itself.

**COURIERPROGRAMS NAME₁ ... NAMEₙ**  
[File Manager Command]

Each NAMEᵢ is the name of a Courier program (see Chapter 31). Writes expressions which will redeclare the Courier program when the file is loaded.

**TEMPLATES SYMBOL₁ ... SYMBOLₙ**  
[File Manager Command]

Each SYMBOLᵢ is a symbol which has a Masterscope template (see Chapter 19). Writes expressions which will restore the templates when the file is loaded.

**FILES FILE₁ ... FILEₙ**  
[File Manager Command]

Used to specify auxiliary files to be loaded in when the file is loaded. Dumps an expression calling FILESLOAD (see the Loading Files section), with FILE₁ ... FILEₙ as the arguments. FILESLOAD interprets FILE₁ ... FILEₙ as files to load, possibly interspersed with lists used to specify certain loading options.

**FILEPKGCOMS SYMBOL₁ ... SYMBOLₙ**  
[File Manager Command]

Each symbol SYMBOLᵢ is either the name of a user-defined file manager command or a user-defined file manager type (or both). Writes expressions which will restore each command/type.
If `SYMBOL_i` is not a file manager command or type, a warning message "no FILE PACKAGE COMMAND for `SYMBOL_i`" is printed.

(`* . TEXT`) [File Manager Command]

Used for inserting comments in a file. The file manager command is simply written on the output file; it will be ignored when the file is loaded.

If the first element of `TEXT` is another `*`, a form-feed is printed on the file before the comment.

(`$ EXP_1 ... EXP_N`) [File Manager Command]

Writes each of the expressions `EXP_1 ... EXP_N` on the output file, where they will be evaluated when the file is loaded.

(`E FORM_1 ... FORM_N`) [File Manager Command]

Each of the forms `FORM_1 ... FORM_N` is evaluated at output time, when `MAKEFILE` interpretes this file manager command.

(`COMS COM_1 ... COM_N`) [File Manager Command]

Each of the commands `COM_1 ... COM_N` is interpreted as a file manager command.

(`ORIGINAL COM_1 ... COM_N`) [File Manager Command]

Each of the commands `COM_i` will be interpreted as a file manager command without regard to any file manager macros (as defined by the `MACRO` property of the `FILEPKGCOM` function, in the Defining New File Manager Commands section). Useful for redefining a built-in file manager command in terms of itself.

Some of the "built-in" file manager commands are defined by file manager macros, so interpreting them (or new user-defined file manager commands) with `ORIGINAL` will fail. `ORIGINAL` was never intended to be used outside of a file manager command macro.

**DECLARE:**

(`DECLARE: . FILEPKGCOMS/FLAGS`) [File Manager Command]

Normally expressions written onto a symbolic file are evaluated when loaded; copied to the compiled file when the symbolic file is compiled (see Chapter 18); and not evaluated at compile time. `DECLARE:` allows you to override these defaults.

`FILEPKGCOMS/FLAGS` is a list of file manager commands, possibly interspersed with "tags". The output of those file manager commands within `FILEPKGCOMS/FLAGS` is embedded in a `DECLARE:` expression, along with any tags that are specified. For example, `(DECLARE: EVAL@COMPILE DONTCOPY (FNS ...) (PROP ...))` would produce `(DECLARE: EVAL@COMPILE DONTCOPY (DEFINEQ ...) (PUTPROPS ...) ...)`
DECLARE is defined as an nlambda nospread function, which processes its arguments by evaluating or not evaluating each expression depending on the setting of internal state variables. The initial setting is to evaluate, but this can be overridden by specifying the DONTEVAL@LOAD tag.

DECLARE: expressions are specially processed by the compiler. For the purposes of compilation, DECLARE: has two principal applications: to specify forms that are to be evaluated at compile time, presumably to affect the compilation, e.g., to set up macros; and/or to indicate which expressions appearing in the symbolic file are not to be copied to the output file. (Normally, expressions are not evaluated and are copied.) Each expression in CDR of a DECLARE: form is either evaluated/not-evaluated and copied/not-copied depending on the settings of two internal state variables, initially set for copy and not-evaluate. These state variables can be reset for the remainder of the expressions in the DECLARE: by means of the tags DONTCOPY, EVAL@COMPILE, etc.

The tags are:

- **EVAL@LOAD**
  Evaluate the following forms when the file is loaded (unless overridden by DONTEVAL@LOAD).

- **DOEVAL@LOAD**
  Do not evaluate the following forms when the file is loaded.

- **DONTEVAL@LOAD**
  This tag can be used to provide conditional evaluation. The value of the expression immediately following the tag determines whether or not to evaluate subsequent expressions when loading. 
  ```
  ... EVAL@LOADWHEN T  
  ... is equivalent to ... EVAL@LOAD ...
  ```

- **COPY**
  When compiling, copy the following forms into the compiled file.

- **DONTCOPY**
  When compiling, do not copy the following forms into the compiled file.

Note: If the file manager commands following DONTCOPY include record declarations for datatypes, or records with initialization forms, it is necessary to include a INITRECORDS file manager command (see the prior section) outside of the DONTCOPY form so that the initialization information is copied. For example, if FOO was defined as a datatype,

```lisp
(DECLARE: DONTCOPY (RECORDS FOO))
(INITRECORDS FOO)
```

would copy the data type declaration for FOO, but would not copy the whole record declaration.
When compiling, if the next form evaluates to non-NIL, copy the following forms into the compiled file.

When compiling, evaluate the following forms.

When compiling, do not evaluate the following forms.

When compiling, if the next form evaluates to non-NIL, evaluate the following forms.

For expressions that are to be copied to the compiled file, the tag FIRST can be used to specify that the following expressions in the DECLARE: are to appear at the front of the compiled file, before anything else except the FILECREATED expressions (see the Symbolic File Format section). For example, (DECLARE: COPY FIRST (PRINT MESS1 T)) NOTFIRST (PRINT MESS2 T)) will cause (PRINT MESS1 T) to appear first in the compiled file, followed by any functions, then (PRINT MESS2 T).

Reverses the effect of FIRST.

The value of DECLARETAGSLST is a list of all the tags used in DECLARE: expressions. If a tag not on this list appears in a DECLARE: file manager command, spelling correction is performed using DECLARETAGSLST as a spelling list.

Note that the function LOADCOMP (see the Loading Files section) provides a convenient way of obtaining information from the DECLARE: expressions in a file, without reading in the entire file. This information may be used for compiling other files.

For each BLOCKi, writes a DECLARE: expression which the block compile functions interpret as a block declaration. See Chapter 18.

Exporting Definitions

When building a large system in Interlisp, it is often the case that there are record definitions, macros and the like that are needed by several different system files when running, analyzing and compiling the source code of the system, but which are not needed for running the compiled code. By using the DECLARE: file manager command with tag DONTCOPY (see the prior section), these definitions can be kept out of the compiled files, and hence out of the system constructed by loading the compiled files files into Interlisp. This saves loading time, space in the resulting system, and whatever other overhead might be incurred by keeping those definitions around, e.g., burden on the record package to consider more possibilities in translating record accesses, or conflicts between system record fields and user record fields.
However, if the implementor wants to debug or compile code in the resulting system, the definitions are needed. And even if the definitions had been copied to the compiled files, a similar problem arises if one wants to work on system code in a regular Interlisp environment where none of the system files had been loaded. One could mandate that any definition needed by more than one file in the system should reside on a distinguished file of definitions, to be loaded into any environment where the system files are worked on. Unfortunately, this would keep the definitions away from where they logically belong. The EXPORT mechanism is designed to solve this problem.

To use the mechanism, the implementor identifies any definitions needed by files other than the one in which the definitions reside, and wraps the corresponding file manager commands in the EXPORT file manager command. Thereafter, GATHEREXPORTS can be used to make a single file containing all the exports.

```
(EXPORT COM1 ... COMN)
```

[File Manager Command]

This command is used for “exporting” definitions. Like COM, each of the commands COM1 ... COMN is interpreted as a file manager command. The commands are also flagged in the file as being “exported” commands, for use with GATHEREXPORTS.

```
(GATHEREXPORTS FROMFILES TOFILE FLG)
```

[Function]

FROMFILES is a list of files containing EXPORT commands. GATHEREXPORTS extracts all the exported commands from those files and produces a loadable file TOFILE containing them. If FLG = EVAL, the expressions are evaluated as they are gathered; i.e., the exports are effectively loaded into the current environment as well as being written to TOFILE.

```
(IMPORTFILE FILE RETURNFLG)
```

[Function]

If RETURNFLG is NIL, this loads any exported definitions from FILE into the current environment. If RETURNFLG is T, this returns a list of the exported definitions (evaluable expressions) without actually evaluating them.

```
(CHECKIMPORTS FILES NOASKFLG)
```

[Function]

Checks each of the files in FILES to see if any exists in a version newer than the one from which the exports in memory were taken (GATHEREXPORTS and IMPORTFILE note the creation dates of the files involved), or if any file in the list has not had its exports loaded at all. If there are any such files, you are asked for permission to IMPORTFILE each such file. If NOASKFLG is non-NIL, IMPORTFILE is performed without asking.

For example, suppose file FOO contains records R1, R2, and R3, macros BAR and BAZ, and constants CON1 and CON2. If the definitions of R1, R2, BAR, and BAZ are needed by files other than FOO, then the file commands for FOO might contain the command

```
(DECLARE: EVAL@COMPIL DONTCOPY
 (EXPORT (RECORDS R1 R2)
 (MACROS BAR BAZ))
 (RECORDS R3)
 (CONSTANTS BAZ))
```
None of the commands inside this `DECLARE:` would appear on `FOO`'s compiled file, but `(GATHEREXPORTS '(FOO) 'MYEXPORTS)` would copy the record definitions for `R1` and `R2` and the macro definitions for `BAR` and `BAZ` to the file `MYEXPORTS`.

**FileVars**

In each of the file manager commands described above, if the symbol `*` follows the command type, the form following the `*`, i.e., `CADDR` of the command, is evaluated and its value used in executing the command, e.g., `(FNS * (APPEND FNS1 FNS2))`. When this form is a symbol, e.g. `(FNS * FOOFNS)`, we say that the variable is a "filevar". Note that `(COMS * FORM)` provides a way of computing what should be done by `MAKEFILE`.

Example:

```
← `(SETQ FOOFNS `(FOO1 FOO2 FOO3))
    (FOO1 FOO2 FOO3)
← `(SETQ FOOCOMS
     '((FNS * FOOFNS)
       (VARS FIE)
       (PROP MACRO FOO1 FOO2)
       (P (MOVD 'FOO1 'FIE1)))
← `(MAKEFILE 'FOO)
```

would create a file `FOO` containing:

```
(FILECREATED "time and date the file was made" . "other information")
(PRETTYCOMPRINT FOOCOMS)
(RPAQQ FOOCOMS ((FNS * FOOFNS) ...)
(RPAQQ FOOFNS (FOO1 FOO3 FOO3))
(DEFINEQ "definitions of FOO1, FOO2, and FOO3")
(RPAQQ FIE "value of FIE")
(PUTPROPS FOO1 MACRO PROPVALUE)
(PUTPROPS FOO2 MACRO PROPVALUE)
(MOVD (QUOTE FOO1) (QUOTE FIE1))
STOP
```

For the `PROP` and `IFPROP` commands (see the Litatom Properties section), the `*` follows the property name instead of the command, e.g., `(PROP MACRO * FOOMACROS)`. Also, in the form `(* * comment ...)`, the word `comment` is not treated as a filevar.

**Defining New File Manager Commands**

A file manager command is defined by specifying the values of certain properties. You can specify the various attributes of a file manager command for a new command, or respecify them for an existing command. The following properties are used:
MACRO

[File Manager Command Property]

Defines how to dump the file manager command. Used by MAKEFILE. Value is a pair (ARGS . COMS). The "arguments" to the file manager command are substituted for ARGs throughout COMS, and the result treated as a list of file manager commands. For example, following (FILEPKGCOM 'FOO 'MACRO '(X Y) . COMS)), the file manager command (FOO A B) will cause A to be substituted for X and B for Y throughout COMS, and then COMS treated as a list of commands.

The substitution is carried out by SUBPAIR (see Chapter 3), so that the "argument list" for the macro can also be atomic. For example, if (X . COMS) was used instead of ((X Y) . COMS), then the command (FOO A B) would cause (A B) to be substituted for X throughout COMS.

Filevars are evaluated before substitution. For example, if the symbol * follows NAME in the command, CADDR of the command is evaluated substituting in COMS.

ADD

[File Manager Command Property]

Specifies how (if possible) to add an instance of an object of a particular type to a given file manager command. Used by ADDTOFILE. Value is FN, a function of three arguments, COM, a file manager command CAR of which is EQ to COMMANDNAME, NAME, a typed object, and TYPE, its type. FN should return T if it (undoably) adds NAME to COM, NIL if not. If no ADD property is specified, then the default is (1) if (CAR COM) = TYPE and (CADR COM) = *, and (CADDR COM) is a filevar (i.e. a literal atom), add NAME to the value of the filevar, or (2) if (CAR COM) = TYPE and (CADR COM) is not *, add NAME to (CDR COM).

Actually, the function is given a fourth argument, NEAR, which if non-NIL, means the function should try to add the item after NEAR. See discussion of ADDTOFILES?, in the Storing Files section.

DELETE

[File Manager Command Property]

Specifies how (if possible) to delete an instance of an object of a particular type from a given file manager command. Used by DELFROMFILES. Value is FN, a function of three arguments, COM, NAME, and TYPE, same as for ADD. FN should return T if it (undoably) deletes NAME from COM, NIL if not. If no DELETE property is specified, then the default is either (CAR COM) = TYPE and (CADR COM) = *, and (CADDR COM) is a filevar (i.e. a literal atom), and NAME is contained in the value of the filevar, then remove NAME from the filevar, or if (CAR COM) = TYPE and (CADR COM) is not *, and NAME is contained in (CDR COM), then remove NAME from (CDR COM).

If FN returns the value of ALL, it means that the command is now "empty", and can be deleted entirely from the command list.
CONTENTS

[File Manager Command Property]

CONTAIN

[File Manager Command Property]

Determines whether an instance of an object of a given type is contained in a given file manager command. Used by WHEREIS and INFILECOMS?. Value is FN, a function of three arguments, COM, a file manager command CAR of which is EQ to COMMANDNAME, NAME, and TYPE. The interpretation of NAME is as follows: if NAME is NIL, FN should return a list of elements of type TYPE contained in COM. If NAME is T, FN should return T if there are any elements of type TYPE contained in COM. If NAME is an atom other than T or NIL, return T if NAME of type TYPE is contained in COM. Finally, if NAME is a list, return a list of those elements of type TYPE contained in COM that are also contained in NAME.

It is sufficient for the CONTENTS function to simply return the list of items of type TYPE in command COM, i.e. it can in fact ignore the NAME argument. The NAME argument is supplied mainly for those situations where producing the entire list of items involves significantly more computation or creates more storage than simply determining whether a particular item (or any item) of type TYPE is contained in the command.

If a CONTENTS property is specified and the corresponding function application returns NIL and (CAR COM) = TYPE, then the operation indicated by NAME is performed on the value of (CADDR COM), if (CADR COM) = *, otherwise on (CDR COM). In other words, by specifying a CONTENTS property that returns NIL, e.g. the function NILL, you specify that a file manager command of name FOO produces objects of file manager type FOO and only objects of type FOO.

If the CONTENTS property is not provided, the command is simply expanded according to its MACRO definition, and each command on the resulting command list is then interrogated.

If COMMANDNAME is a file manager command that is used frequently, its expansion by the various parts of the system that need to interrogate files can result in a large number of CONSes and garbage collections. By informing the file manager as to what this command actually does and does not produce via the CONTENTS property, this expansion is avoided. For example, suppose you have a file manager command called GRAMMARS which dumps various property lists but no functions. The file manager could ignore this command when seeking information about FNS.

The function FILEPKGCOM is used to define new file manager commands, or to change the properties of existing commands. It is possible to redefine the attributes of system file manager commands, such as FNS or PROPS, and to cause unpredictable results.

(FILEPKGCOM COMMANDNAME PROP1 VAL1 ... PROPn VALn) [NoSpread Function]

Nospread function for defining new file manager commands, or changing properties of existing file manager commands. PROP1 is one of the property names described above; VAL1 is the value to be given that property of the file manager command COMMANDNAME. Returns COMMANDNAME.
(FILEPKGCOM COMMANDNAME PROP) returns the value of the property PROP, without changing it.

(FILEPKGCOM COMMANDNAME) returns a property list of all of the defined properties of COMMANDNAME, using the property names as keys.

Specifying TYPE as the symbol COM can be used to define one file manager command as a synonym of another. For example, (FILEPKGCOM 'INITVARIABLES 'COM 'INITVARS) defines INITVARIABLES as a synonym for the file manager command INITVARS.

### Functions for Manipulating File Command Lists

The following functions may be used to manipulate filecoms. The argument COMS does not have to correspond to the filecoms for some file. For example, COMS can be the list of commands generated as a result of expanding a user-defined file manager command.

The following functions will accept a file manager command as a valid value for their TYPE argument, even if it does not have a corresponding file manager type. User-defined file manager commands are expanded as necessary.

**(INFILECOMS? NAME TYPE COMS)**

- **COMS** is a list of file manager commands, or a variable whose value is a list of file manager commands. **TYPE** is a file manager type. INFILECOMS? returns T if NAME of type TYPE is "contained" in COMS.
- If NAME = NIL, INFILECOMS? returns a list of all elements of type TYPE.
- If NAME = T, INFILECOMS? returns T if there are any elements of type TYPE in COMS.

**(ADDTOFILE NAME TYPE FILE NEAR LISTNAME)**

- Adds NAME of type TYPE to the file manager commands for FILE. If NEAR is given and it is the name of an item of type TYPE already on FILE, then NAME is added to the command that dumps NEAR. If LISTNAME is given and is the name of a list of items of TYPE items on FILE, then NAME is added to that list. Uses ADDTOCOMS and MAKENEWCOM. Returns FILE. ADDTOFILE is undoable.

**(DELFROMFILES NAME TYPE FILES)**

- Deletes all instances of NAME of type TYPE from the filecoms for each of the files on FILES. If FILES is a non-NIL symbol, (LIST FILES) is used. FILES = NIL defaults to FILELST. Returns a list of files from which NAME was actually removed. Uses DELFROMCOMS. DELFROMFILES is undoable.

Deleting a function will also remove the function from any BLOCKS declarations in the filecoms.
(ADDTOCOMS COMS NAME TYPE NEAR LISTNAME) [Function]

Adds NAME as a TYPE to COMS, a list of file manager commands or a variable whose value is a list of file manager commands. Returns NIL if ADDTOCOMS was unable to find a command appropriate for adding NAME to COMS. NEAR and LISTNAME are described in the discussion of ADDTOFILE. ADDTOCOMS is undoable.

The exact algorithm for adding commands depends the particular command itself. See discussion of the ADD property, in the description of FILEPKGCOM.

ADDTOCOMS will not attempt to add an item to any command which is inside of a DECLARE: unless you specified a specific name via the LISTNAME or NEAR option of ADDTOFILES?.

(DELFROMCOMS COMS NAME TYPE) [Function]

Deletes NAME as a TYPE from COMS. Returns NIL if DELFROMCOMS was unable to modify COMS to delete NAME. DELFROMCOMS is undoable.

(MAKENEWCOM NAME TYPE) [Function]

Returns a file manager command for dumping NAME of type TYPE. Uses the procedure described in the discussion of NEWCOM, in the Defining New File Manager Types section.

(MOVETOFIELD TOFILE NAME TYPE FROMFILE) [Function]

Moves the definition of NAME as a TYPE from FROMFILE to TOFILE by modifying the file commands in the appropriate way (with DELFROMFILES and ADDTOFILE).

Note that if FROMFILE is specified, the definition will be retrieved from that file, even if there is another definition currently in your environment.

(FILECOMSLST FILE TYPE) [Function]

Returns a list of all objects of type TYPE in FILE.

(FILEFNSLST FILE) [Function]

Same as (FILECOMSLST FILE 'FNS).

(FILECOMS FILE TYPE) [Function]

Returns (PACK* FILE (OR TYPE 'COMS)). Note that (FILECOMS 'FOO) returns the symbol FOOCOMS, not the value of FOOCOMS.

(SMASHFILECOMS FILE) [Function]

Maps down (FILECOMSLST FILE 'FILEVARS) and sets to NOBIND all filevars (see the FileVars section), i.e., any variable used in a command of the form (COMMAND * VARIABLE). Also sets (FILECOMS FILE) to NOBIND. Returns FILE.
Symbolic File Format

The file manager manipulates symbolic files in a particular format. This format is defined so that the information in the file is easily readable when the file is listed, as well as being easily manipulated by the file manager functions. In general, there is no reason for you to manually change the contents of a symbolic file. However, to allow you to extend the file manager, this section describes some of the functions used to write symbolic files, and other matters related to their format.

(PRETTYDEF PRTTYFNS PRTTYFILE PRTTYCOMS REPRINTFNS SOURCEFILE CHANGES)

[Function]

Writes a symbolic file in PRETTYPRINT format for loading, using FILERDTBL as its read table. PRETTYDEF returns the name of the symbolic file that was created.

PRETTYDEF operates under a RESETLST (see Chapter 14), so if an error occurs, or a Control-D is typed, all files that PRETTYDEF has opened will be closed, the (partially complete) file being written will be deleted, and any undoable operations executed will be undone. The RESETLST also means that any RESETSAVEs executed in the file manager commands will also be protected.

PRTTYFNS is an optional list of function names. It is equivalent to including (FNS * PRTTYFNS) in the file manager commands in PRTTYCOMS. PRTTYFNS is an anachronism from when PRETTYDEF did not use a list of file manager commands, and should be specified as NIL.

PRTTYFILE is the name of the file on which the output is to be written. PRTTYFILE has to be a symbol. If PRTTYFILE = NIL, the primary output file is used. PRTTYFILE is opened if not already open, and it becomes the primary output file. PRTTYFILE is closed at end of PRETTYDEF, and the primary output file is restored.

PRTTYCOMS is a list of file manager commands interpreted as described in the File Manager Commands section. If PRTTYCOMS is atomic, its top level value is used and an RPAQQ is written which will set that atom to the list of commands when the file is subsequently loaded. A PRETTYCOMPRINT expression (see below) will also be written which informs you of the named atom or list of commands when the file is subsequently loaded. In addition, if any of the functions in the file are nlambda functions, PRETTYDEF will automatically print a DECLARE: expression suitable for informing the compiler about these functions, in case you recompile the file without having first loaded the nlambda functions (see Chapter 18).

REPRINTFNS and SOURCEFILE are for use in conjunction with remaking a file (see the Remaking a Symbolic File section). REPRINTFNS can be a list of functions to be prettyprinted, or EXPRS, meaning prettyprint all functions with EXPR definitions, or ALL meaning prettyprint all functions either defined as EXPRS, or with EXPR properties. Note that doing a remake with REPRINTFNS = NIL makes sense if there have been changes in the file, but not to any of the functions, e.g., changes to variables or property lists. SOURCEFILE is the name of the file from which to copy the definitions for those functions that are not going to be prettyprinted, i.e., those not specified by REPRINTFNS. SOURCEFILE = T means to use most recent version (i.e., highest number) of
PRETTYFILE, the second argument to PRETTYDEF. If SOURCEFILE cannot be found, PRETTYDEF prints the message "FILE NOT FOUND, SO IT WILL BE WRITTEN ANEW", and proceeds as it does when REPRINTFNS and SOURCEFILE are both NIL.

PRETTYDEF calls PRETTYPRINT with its second argument PRETTYDEFLG = T, so whenever PRETTYPRINT starts a new function, it prints (on the terminal) the name of that function if more than 30 seconds (real time) have elapsed since the last time it printed the name of a function.

Note that normally if PRETTYPRINT is given a symbol which is not defined as a function but is known to be on one of the files noticed by the file manager, PRETTYPRINT will load in the definition (using LOADFNS) and print it. This is not done when PRETTYPRINT is called from PRETTYDEF.

In Medley the SYSPRETTYFLG is ignored in the Interlisp exec.

(PRINTFNS X) [Function]

X is a list of functions. PRINTFNS prettyprints a DEFINEQ expression that defines the functions to the primary output stream using the primary read table. Used by PRETTYDEF to implement the FNS file manager command.

(PRINTDATE FILE CHANGES) [Function]

Prints the FILECREATED expression at beginning of PRETTYDEF files. CHANGES used by the file manager.

(FILECREATED X) [NLambda NoSpread Function]

Prints a message (using LISPXPRINT) followed by the time and date the file was made, which is (CAR X). The message is the value of PRETTYHEADER, initially "FILE CREATED". If PRETTYHEADER = NIL, nothing is printed. (CDR X) contains information about the file, e.g., full name, address of file map, list of changed items, etc.

FILECREATED also stores the time and date the file was made on the property list of the file under the property FILEDATES and performs other initialization for the file manager.

(PRETTYCOMPRINT X) [NLambda Function]

Prints X (unevaluated) using LISPXPRINT, unless PRETTYHEADER = NIL.

PRETTYHEADER [Variable]

Value is the message printed by FILECREATED. PRETTYHEADER is initially "FILE CREATED". If PRETTYHEADER = NIL, neither FILECREATED nor PRETTYCOMPRINT will print anything. Thus, setting PRETTYHEADER to NIL will result in "silent loads". PRETTYHEADER is reset to NIL during greeting (see Chapter 12).
(FILECHANGES FILE TYPE) [Function]

Returns a list of the changed objects of file manager type TYPE from the FILECREATED expression of FILE. If TYPE = NIL, returns an alist of all of the changes, with the file manager types as the CARs of the elements..

(FILEDATE FILE) [Function]

Returns the file date contained in the FILECREATED expression of FILE.

(LISPSOURCEFILEP FILE) [Function]

Returns a non-NIL value if FILE is in file manager format and has a file map, NIL otherwise.

Copyright Notices

The system has a facility for automatically printing a copyright notice near the front of files, right after the FILECREATED expression, specifying the years it was edited and the copyright owner. The format of the copyright notice is:

(* Copyright (c) 1981 by Foo Bars Corporation)

Once a file has a copyright notice then every version will have a new copyright notice inserted into the file without your intervention. (The copyright information necessary to keep the copyright up to date is stored at the end of the file.).

Any year the file has been edited is considered a "copyright year" and therefore kept with the copyright information. For example, if a file has been edited in 1981, 1982, and 1984, then the copyright notice would look like:

(* Copyright (c) 1981,1982,1984 by Foo Bars Corporation)

When a file is made, if it has no copyright information, the system will ask you to specify the copyright owner (if COPYRIGHTFLG = T). You may specify one of the names from COPYRIGHTOWNERS, or give one of the following responses:

- Type a left-square-bracket. The system will then prompt for an arbitrary string which will be used as the owner-string
- Type a right-square-bracket, which specifies that you really do not want a copyright notice.
- Type "NONE" which specifies that this file should never have a copyright notice.

For example, if COPYRIGHTOWNERS has the value

(((BBN "Bolt Beranek and Newman Inc.")
 (XEROX "Xerox Corporation")))
then for a new file FOO the following interaction will take place:

Do you want to Copyright FOO? Yes
Copyright owner: (user typed ?)
one of:
BBN - Bolt Beranek and Newman Inc.
XEROX - Xerox Corporation
NONE - no copyright ever for this file
[ - new copyright owner -- type one line of text
] - no copyright notice for this file now

Copyright owner: BBN

Then "Foo Bars Corporation" in the above copyright notice example would have been "Bolt Beranek and Newman Inc."

The following variables control the operation of the copyright facility:

COPYRIGHTFLG

The value of COPYRIGHTFLG determines whether copyright information is maintained in files. Its value is interpreted as follows:

NIL The system will preserve old copyright information, but will not ask you about copyrighting new files. This is the default value of COPYRIGHTFLG.

T When a file is made, if it has no copyright information, the system will ask you to specify the copyright owner.

NEVER The system will neither prompt for new copyright information nor preserve old copyright information.

DEFAULT The value of DEFAULTCOPYRIGHTOWNER (below) is used for putting copyright information in files that don't have any other copyright. The prompt "Copyright owner for file xx:" will still be printed, but the default will be filled in immediately.

COPYRIGHTOWNERS

COPYRIGHTOWNERS is a list of entries of the form (KEY OWNERSTRING), where KEY is used as a response to ASKUSER and OWNERSTRING is a string which is the full identification of the owner.

DEFAULTCOPYRIGHTOWNER

If you do not respond in DWIMWAIT seconds to the copyright query, the value of DEFAULTCOPYRIGHTOWNER is used.
Functions Used Within Source Files

The following functions are normally only used within symbolic files, to set variable values, property values, etc. Most of these have special behavior depending on file manager variables.

\[(\text{RPAQ} \text{VAR VALUE})\]  
[NLlambda Function]

An nlambda function like \text{SETQ} that sets the top level binding of \text{VAR} (unevaluated) to \text{VALUE}.

\[(\text{RPAQQ} \text{VAR VALUE})\]  
[NLlambda Function]

An nlambda function like \text{SETQQ} that sets the top level binding of \text{VAR} (unevaluated) to \text{VALUE} (unevaluated).

\[(\text{RPAQ?} \text{VAR VALUE})\]  
[NLlambda Function]

Similar to \text{RPAQ}, except that it does nothing if \text{VAR} already has a top level value other than \text{NOBIND}. Returns \text{VALUE} if \text{VAR} is reset, otherwise \text{NIL}.

\text{RPAQ}, \text{RPAQQ}, and \text{RPAQ?} generate errors if \text{X} is not a symbol. All are affected by the value of \text{DFNFLG} (see Chapter 10). If \text{DFNFLG} = \text{ALLPROP} (and the value of \text{VAR} is other than \text{NOBIND}), instead of setting \text{X}, the corresponding value is stored on the property list of \text{VAR} under the property \text{VALUE}. All are undoable.

\[(\text{ADDTOVAR} \text{VAR} X_1 X_2 \ldots X_N)\]  
[NLlambda NoSpread Function]

Each \text{X}_i that is not a member of the value of \text{VAR} is added to it, i.e. after \text{ADDTOVAR} completes, the value of \text{VAR} will be \text{(UNION (LIST X_1 X_2 \ldots X_N) VAR)}. \text{ADDTOVAR} is used by \text{PRETTYDEF} for implementing the \text{ADDVARS} command. It performs some file manager related operations, i.e. "notices" that \text{VAR} has been changed. Returns the atom \text{VAR} (not the value of \text{VAR}).

\[(\text{APPENDTOVAR} \text{VAR} X_1 X_2 \ldots X_N)\]  
[NLlambda NoSpread Function]

Similar to \text{ADDTOVAR}, except that the values are added to the end of the list, rather than at the beginning.

\[(\text{PUTPROPS} \text{ATM} \text{PROP}_1 \text{VAL}_1 \ldots \text{PROP}_N \text{VAL}_N)\]  
[NLlambda NoSpread Function]

Nlambda nospread version of \text{PUTPROP} (none of the arguments are evaluated). For \(i = 1 \ldots N\), puts property \text{PROP}_i, value \text{VAL}_i, on the property list of \text{ATM}. Performs some file manager related operations, i.e., "notices" that the corresponding properties have been changed.

\[(\text{SAVEPUT} \text{ATM} \text{PROP} \text{VAL})\]  
[Function]

Same as \text{PUTPROP}, but marks the corresponding property value as having been changed (used by the file manager).
File Maps

A file map is a data structure which contains a symbolic 'map' of the contents of a file. Currently, this consists of the begin and end byte address (see GETFILEPTR, in Chapter 25) for each DEFINEQ expression in the file, the begin and end address for each function definition within the DEFINEQ, and the begin and end address for each compiled function.

MAKEFILE, PRETTYDEF, LOADFNS, RECOMPILE, and numerous other system functions depend heavily on the file map for efficient operation. For example, the file map enables LOADFNS to load selected function definitions simply by setting the file pointer to the corresponding address using SETFILEPTR, and then performing a single READ. Similarly, the file map is heavily used by the 'remake' option of MAKEFILE (see the Remaking a Symbolic File section): those function definitions that have been changed since the previous version are prettyprinted; the rest are simply copied from the old file to the new one, resulting in a considerable speedup.

Whenever a file is written by MAKEFILE, a file map for the new file is built. Building the map in this case essentially comes for free, since it requires only reading the current file pointer before and after each definition is written or copied. However, building the map does require that PRETTYPRINT know that it is printing a DEFINEQ expression. For this reason, you should never print a DEFINEQ expression onto a file yourself, but should instead always use the FNS file manager command (see the Functions and Macros section).

The file map is stored on the property list of the root name of the file, under the property FILEMAP. In addition, MAKEFILE writes the file map on the file itself. For cosmetic reasons, the file map is written as the last expression in the file. However, the address of the file map in the file is (over)written into the FILECREATED expression that appears at the beginning of the file so that the file map can be rapidly accessed without having to scan the entire file. In most cases, LOAD and LOADFNS do not have to build the file map at all, since a file map will usually appear in the corresponding file, unless the file was written with BUILDMAPFLG = NIL, or was written outside of Interlisp.

Currently, file maps for compiled files are not written onto the files themselves. However, LOAD and LOADFNS will build maps for a compiled file when it is loaded, and store it on the property FILEMAP. Similary, LOADFNS will obtain and use the file map for a compiled file, when available.

The use and creation of file maps is controlled by the following variables:

BUILDMAPFLG [Variable]

Whenever a file is read by LOAD or LOADFNS, or written by MAKEFILE, a file map is automatically built unless BUILDMAPFLG = NIL. (BUILDMAPFLG is initially T.)

While building the map will not help the first reference to a file, it will help in future references. For example, if you perform (LOADFROM 'FOO) where FOO does not contain a file map, the LOADFROM will be (slightly) slower than if FOO did contain a file map, but subsequent calls to LOADFNS for this version of FOO will be able to use the map that was built as the result of the LOADFROM, since it will be stored on FOO's FILEMAP property.
USEMAPFLG  [Variable]

If USEMAPFLG = T (the initial setting), the functions that use file maps will first check the FILEMAP property to see if a file map for this file was previously obtained or built. If not, the first expression on the file is checked to see if it is a FILECREATED expression that also contains the address of a file map. If the file map is not on the FILEMAP property or in the file, a file map will be built (unless BUILDMAPFLG = NIL).

If USEMAPFLG = NIL, the FILEMAP property and the file will not be checked for the file map. This allows you to recover in those cases where the file and its map for some reason do not agree. For example, if you use a text editor to change a symbolic file that contains a map (not recommended), inserting or deleting just one character will throw that map off. The functions which use file maps contain various integrity checks to enable them to detect that something is wrong, and to generate the error FILEMAP DOES NOT AGREE WITH CONTENTS OF FILE. In such cases, you can set USEMAPFLG to NIL, causing the map contained in the file to be ignored, and then reexecute the operation.
The compiler is contained in the standard Medley system. It may be used to compile functions
defined in Medley, or to compile definitions stored in a file. The resulting compiled code may be
stored as it is compiled, so as to be available for immediate use, or it may be written onto a file for
subsequent loading.

The most common way to use the compiler is to use one of the file package functions, such as
MAKEFILE (Chapter 17), which automatically updates source files, and produces compiled versions.
However, it is also possible to compile individual functions defined in Medley, by directly calling the
compiler using functions such as COMPILE. No matter how the compiler is called, the function
COMPSET is called which asks you certain questions concerning the compilation. (COMPSET sets the
free variables LAPFLG, STRF, SVFLG, LCFIL and LSTFIL which determine various modes of
operation.) Those that can be answered "yes" or "no" can be answered with YES, Y, or T for "yes"; and
NO, N, or NIL for "no". The questions are:

**LISTING?** This asks whether to generate a listing of the compiled code.
The LAP and machine code are usually not of interest but can 
be helpful in debugging macros. Possible answers are:

1. Prints output of pass 1, the LAP macro code
2. Prints output of pass 2, the machine code

**YES** Prints output of both passes

**NO** Prints no listings

The variable LAPFLG is set to the answer.

**FILE:** This question (which only appears if the answer to LISTING?
is affirmative) ask where the compiled code listing(s) should 
be written. Answering T will print the listings at the terminal.
The variable LSTFIL is set to the answer.

**REDEFINE?** This question asks whether the functions compiled should be 
redefined to their compiled definitions. If this is answered 
YES, the compiled code is stored and the function definition 
changed, otherwise the function definition remains 
unchanged.

The compiler does not respect the value of DFNFLG (Chapter 
10) when it redefines functions to their compiled definitions. 
Therefore, if you set DFNFLG to PROP to completely avoid inadvertently redefining something in your running system, 
you must not answer YES to this question.

The variable STRF is set to T (if this is answered YES) or NIL.
SAVE EXPRS?  This question asks whether the original defining EXPRs of functions should be saved. If answered YES, then before redefining a function to its compiled definition, the EXPR definition is saved on the property list of the function name. Otherwise they are discarded.

It is very useful to save the EXPR definitions, just in case the compiled function needs to be changed. The editing functions will retrieve this saved definition if it exists, rather than reading from a source file.

The variable SVFLG is set to T (if this is answered YES) or NIL.

OUTPUT FILE?  This question asks whether (and where) the compiled definitions should be written into a file for later loading. If you answer with the name of a file, that file will be used. If you answer Y or YES, you will be asked the name of the file. If the file named is already open, it will continue to be used. If you answer T or TTY:, the output will be typed on the teletype (not particularly useful). If you answer N, NO, or NIL, output will not be done.

The variable LCFIL is set to the name of the file.

To make answering these questions easier, there are four other possible answers to the LISTING? question, which specify common compiling modes:

S  Same as last setting. Uses the same answers to compiler questions as given for the last compilation.

F  Compile to File, without redefining functions.

ST  STore new definitions, saving EXPR definitions.

STF  STore new definitions; Forget EXPR definitions.

Implicit in these answers are the answers to the questions on disposition of compiled code and EXPR definitions, so the questions REDEFINE? and SAVE EXPRS? would not be asked if these answers were given. OUTPUT FILE? would still be asked, however. For example:

$\leftarrow$ COMPILE((FACT FACT1 FACT2))
LISTING? ST
OUTPUT FILE? FACT.DCOM
(FACT COMPILING)
.
.
(FACT REDefined)
.
.
(FACT2 REDefined)
(FACT FACT1 FACT2)
$\leftarrow$
This process caused the functions FACT, FACT1, and FACT2 to be compiled, redefined, and the compiled definitions also written on the file FACT.DCOM for subsequent loading.

**Compiler Printout**

In Medley, for each function $FN$ compiled, whether by TCOMPL, RECOMPILE, or COMPILE, the compiler prints:

\[
(FN (ARG_1 \ldots ARG_N) \text{(uses: } VAR_1 \ldots VAR_N) \text{(calls: } FN_1 \ldots FN_N))
\]

The message is printed at the beginning of the second pass of the compilation of $FN$. $(ARG_1 \ldots ARG_N)$ is the list of arguments to $FN$; following uses: are the free variables referenced or set in $FN$ (not including global variables); following calls: are the undefined functions called within $FN$.

If the compilation of $FN$ causes the generation of one or more auxiliary functions, a compiler message will be printed for these functions before the message for $FN$, e.g.,

\[
(FOO\_A0027 (X) \text{(uses: } XX))
\]

\[
(FOO (A B))
\]

When compiling a block, the compiler first prints $(BLKNAME BLKFN_1 BLKFN_2 \ldots)$. Then the normal message is printed for the entire block. The names of the arguments to the block are generated by suffixing # and a number to the block name, e.g., $(FOOBLOCK (FOOBLOCK#0 FOOBLOCK#1) FREE-VARIABLES)$. Then a message is printed for each entry to the block.

In addition to the above output, both RECOMPILE and BRECOMPILE print the name of each function that is being copied from the old compiled file to the new compiled file. The normal compiler message is printed for each function that is actually compiled.

The compiler prints out error messages when it encounters problems compiling a function. For example:

\[
----- In BAZ:
***** (BAZ - illegal RETURN)
-----
\]

The above error message indicates that an illegal RETURN compiler error occurred while trying to compile the function BAZ. Some compiler errors cause the compilation to terminate, producing nothing; however, there are other compiler errors which do not stop compilation. The compiler error messages are described in the last section of this chapter.

Compiler printout and error messages go to the file COUTFILE, initially T. COUTFILE can also be set to the name of a file opened for output, in which case all compiler printout will go to COUTFILE, i.e.
the compiler will compile “silently.” However, any error messages will be printed to both COUTFILE as well as T.

Global Variables

Variables that appear on the list GLOBALVARS, or have the property GLOBALVAR with value T, or are declared with the GLOBALVARS file package command, are called global variables. Such variables are always accessed through their top level value when they are used freely in a compiled function. In other words, a reference to the value of a global variable is equivalent to calling GETTOPVAL on the variable, regardless of whether or not it is bound in the current access chain. Similarly, (SETQ VARIABLE VALUE) will compile as (SETTOPVAL (QUOTE VARIABLE) VALUE).

All system parameters, unless otherwise specified, are declared as global variables. Thus, re-binding these variables in a deep bound system like Medley will not affect the behavior of the system: instead, the variables must be reset to their new values, and if they are to be restored to their original values, reset again. For example, you might write

```
(SETQ GLOBALVARIABLE NEWVALUE)
FORM
(SETQ GLOBALVARIABLE OLDVALUE)
```

In this case, if an error occurred during the evaluation of FORM, or a Control-D was typed, the global variable would not be restored to its original value. The function RESETVAR provides a convenient way of resetting global variables in such a way that their values are restored even if an error occurred or Control-D is typed.

Note: The variables that a given function accesses as global variables can be determined by using the function CALLS.

Local Variables and Special Variables

In normal compiled and interpreted code, all variable bindings are accessible by lower level functions because the variable’s name is associated with its value. We call such variables special variables, or specvars. As mentioned earlier, the block compiler normally does not associate names with variable values. Such unnamed variables are not accessible from outside the function which binds them and are therefore local to that function. We call such unnamed variables local variables, or localvars.

The time economies of local variables can be achieved without block compiling by use of declarations. Using local variables will increase the speed of compiled code; the price is the work of writing the necessary specvar declarations for those variables which need to be accessed from outside the block.

LOCALVARS and SPECVARS are variables that affect compilation. During regular compilation, SPECVARS is normally T, and LOCALVARS is NIL or a list. This configuration causes all variables
bound in the functions being compiled to be treated as special except those that appear on LOCALVARS. During block compilation, LOCALVARS is normally T and SPECVARS is NIL or a list. All variables are then treated as local except those that appear on SPECVARS.

Declarations to set LOCALVARS and SPECVARS to other values, and therefore affect how variables are treated, may be used at several levels in the compilation process with varying scope.

1. The declarations may be included in the filecoms of a file, by using the LOCALVARS and SPECVARS file package commands. The scope of the declaration is then the entire file:

   ... (LOCALVARS . T) (SPECVARS X Y) ...

2. The declarations may be included in block declarations; the scope is then the block, e.g.,

   (BLOCKS ((FOOBLOCK FOO FIE (SPECVARS . T) (LOCALVARS X)))

3. The declarations may also appear in individual functions, or in PROG’s or LAMBDA’s within a function, using the DECLARE function. In this case, the scope of the declaration is the function or the PROG or LAMBDA in which it appears. LOCALVARS and SPECVARS declarations must appear immediately after the variable list in the function, PROG, or LAMBDA, but intervening comments are permitted. For example:

   (DEFINEQ ((FOO
   (LAMBDA (X Y)
     (DECLARE (LOCALVARS Y))
     (PROG (X Y Z)
       (DECLARE (LOCALVARS X))
     ... ]

If the above function is compiled (non-block), the outer X will be special, the X bound in the PROG will be local, and both bindings of Y will be local.

Declarations for LOCALVARS and SPECVARS can be used in two ways: either to cause variables to be treated the same whether the function(s) are block compiled or compiled normally, or to affect one compilation mode while not affecting the default in the other mode. For example:

   (LAMBDA (X Y)
     (DECLARE (SPECVARS . T))
     (PROG (Z) ... ]

will cause X, Y, and Z to be specvars for both block and normal compilation while

   (LAMBDA (X Y)
     (DECLARE (SPECVARS X))
     ... ]
will make \( X \) a specvar when block compiling, but when regular compiling the declaration will have no effect, because the default value of specvars would be \( T \), and therefore both \( X \) and \( Y \) will be specvars by default.

Although \texttt{LOCALVARS} and \texttt{SPECVARS} declarations have the same form as other components of block declarations such as \( \text{(LINKFNS . T)} \), their operation is somewhat different because the two variables are not independent. \( \text{(SPECVARS . T)} \) will cause \texttt{SPECVARS} to be set to \( T \), and \texttt{LOCALVARS} to be set to \( \text{NIL} \). \( \text{(SPECVARS V1 V2 \ldots)} \) will have no effect if the value of \texttt{SPECVARS} is \( T \), but if it is a list (or \( \text{NIL} \)), \texttt{SPECVARS} will be set to the union of its prior value and \( \text{(V1 V2 \ldots)} \). The operation of \texttt{LOCALVARS} is analogous. Thus, to affect both modes of compilation one of the two \( \text{(LOCALVARS or SPECVARS)} \) must be declared \( T \) before specifying a list for the other.

Note: The variables that a given function binds as local variables or accesses as special variables can be determined by using the function \texttt{CALLS}.

Note: \texttt{LOCALVARS} and \texttt{SPECVARS} declarations affect the compilation of local variables within a function, but the arguments to functions are always accessible as specvars. This can be changed by redefining the following function:

\[
\text{(DASSEM.SAVELOCALVARS FN)} \quad \text{[Function]}
\]

This function is called by the compiler to determine whether argument information for \( FN \) should be written on the compiled file for \( FN \). If it returns \( \text{NIL} \), the argument information is not saved, and the function is stored with arguments \( U, V, W, \text{etc} \) instead of the originals.

Initially, \texttt{DASSEM.SAVELOCALVARS} is defined to return \( T \). \( \text{(MOVD 'NILL 'DASSEM.SAVELOCALVARS)} \) causes the compiler to retain no local variable or argument names. Alternatively, \texttt{DASSEM.SAVELOCALVARS} could be redefined as a more complex predicate, to allow finer discrimination.

### Constants

Interlisp allows the expression of constructions which are intended to be description of their constant values. The following functions are used to define constant values. The function \texttt{SELECTC} provides a mechanism for comparing a value to a number of constants.

\[
\text{(CONSTANT X)} \quad \text{[Function]}
\]

This function enables you to define that the expression \( X \) should be treated as a "constant" value. When \texttt{CONSTANT} is interpreted, \( X \) is evaluated each time it is encountered. If the \texttt{CONSTANT} form is compiled, however, the expression will be evaluated only once.

If the value of \( X \) has a readable print name, then it will be evaluated at compile-time, and the value will be saved as a literal in the compiled function’s definition, as if \( \text{(QUOTE VALUE-OF-EXPRESSION)} \) had appeared instead of \( \text{(CONSTANT EXPRESSION)} \).

If the value of \( X \) does not have a readable print name, then the expression \( X \) itself will be saved with the function, and it will be evaluated when the function is first loaded. The
value will then be stored in the function’s literals, and will be retrieved on future references.

If a program needed a list of 30 NILs, you could specify `(CONSTANT (to 30 collect NIL))` instead of `(QUOTE (NIL NIL ...))`. The former is more concise and displays the important parameter much more directly than the latter.

CONSTANT can also be used to denote values that cannot be quoted directly, such as `(CONSTANT (PACK NIL))`, `(CONSTANT (ARRAY 10))`. It is also useful to parameterize quantities that are constant at run time but may differ at compile time, e.g., `(CONSTANT BITSPERWORD)` in a program is exactly equivalent to 36, if the variable BITSPERWORD is bound to 36 when the CONSTANT expression is evaluated at compile time.

Whereas the function CONSTANT attempts to evaluate the expression as soon as possible (compile-time, load-time, or first-run-time), other options are available, using the following two function:

(LOADTIMECONSTANT X) [Function]

Similar to CONSTANT, except that the evaluation of X is deferred until the compiled code for the containing function is loaded in. For example, `(LOADTIMECONSTANT (DATE))` will return the date the code was loaded. If LOADTIMECONSTANT is interpreted, it merely returns the value of X.

(DEFERREDCONSTANT X) [Function]

Similar to CONSTANT, except that the evaluation of X is always deferred until the compiled function is first run. This is useful when the storage for the constant is excessive so that it shouldn’t be allocated until (unless) the function is actually invoked. If DEFERREDCONSTANT is interpreted, it merely returns the value of X.

(CONSTANTS VAR1 VAR2 ... VARN) [NLambda NoSpread Function]

Defines VAR1, ..., VARN (unevaluated) to be compile-time constants. Whenever the compiler encounters a (free) reference to one of these constants, it will compile the form `(CONSTANT VAR)` instead.

If VAR is a list of the form `(VAR FORM)`, a free reference to the variable will compile as `(CONSTANT FORM)`.

The compiler prints a warning if user code attempts to bind a variable previously declared as a constant.

Constants can be saved using the CONSTANTS file package command.
Compiling Function Calls

When compiling the call to a function, the compiler must know the type of the function, to determine how the arguments should be prepared (evaluated/unevaluated, spread/nospread). There are three separate cases: lambda, nlambda spread, and nlambda nospread functions.

To determine which of these three cases is appropriate, the compiler will first look for a definition among the functions in the file that is being compiled. The function can be defined anywhere in any of the files given as arguments to BCOMPL, TCOMPL, BCRECOMPILE or RECOMPILE. If the function is not contained in the file, the compiler will look for other information in the variables NLAMA, NLAML, and LAMS, which can be set by you:

**NLAMA**

(For NLMbda Atoms) A list of functions to be treated as nlambda nospread functions by the compiler.

**NLAML**

(For NLMbda List) A list of functions to be treated as nlambda spread functions by the compiler.

**LAMS**

A list of functions to be treated as lambda functions by the compiler. Note that including functions on LAMS is only necessary to override in-core nlambda definitions, since in the absence of other information, the compiler assumes the function is a lambda.

If the function is not contained in a file, or on the lists NLAMA, NLAML, or LAMS, the compiler will look for a current definition in the Interlisp system, and use its type. If there is no current definition, next COMPILEUSERFN is called:

**COMPILEUSERFN**

When compiling a function call, if the function type cannot be found by looking in files, the variables NLAMA, NLAML, or LAMS, or at a current definition, then if the value of COMPILEUSERFN is not NIL, the compiler calls (the value of) COMPILEUSERFN giving it as arguments CDR of the form and the form itself, i.e., the compiler does \texttt{(APPLY\^{*}\ COMPILEUSERFN \ (CDR \ FORM) \ FORM)}. If a non-NIL value is returned, it is compiled instead of FORM. If NIL is returned, the compiler compiles the original expression as a call to a lambda spread that is not yet defined.

COMPILEUSERFN is only called when the compiler encounters a list CAR of which is not the name of a defined function. You can instruct the compiler about how to compile other data types via COMPILETYPELST.

CLISP uses COMPILEUSERFN to tell the compiler how to compile iterative statements, IF-THEN-ELSE statements, and pattern match constructs.
If the compiler cannot determine the function type by any of the means above, it assumes that the function is a lambda function, and its arguments are to be evaluated.

If there are nlambda functions called from the functions being compiled, and they are only defined in a separate file, they must be included on NLAMA or NLAML, or the compiler will incorrectly assume that their arguments are to be evaluated, and compile the calling function correspondingly. This is only necessary if the compiler does not "know" about the function. If the function is defined at compile time, or is handled via a macro, or is contained in the same group of files as the functions that call it, the compiler will automatically handle calls to that function correctly.

FUNCTION and Functional Arguments

Compiling the function FUNCTION may involve creating and compiling a separate "auxiliary function", which will be called at run time. An auxiliary function is named by attaching a GENSYM to the end of the name of the function in which they appear, e.g., FOOA0003. For example, suppose FOO is defined as (LAMBDA (X) ... (FOO1 X (FUNCTION ...)) ...) and compiled. When FOO is run, FOO1 will be called with two arguments, X, and FOOA000N and FOO1 will call FOOA000N each time it uses its functional argument.

Compiling FUNCTION will not create an auxiliary function if it is a functional argument to a function that compiles open, such as most of the mapping functions (MAPCAR, MAPLIST, etc.). A considerable savings in time could be achieved by making FOO1 compile open via a computed macro, e.g.

```lisp
(PUTPROP 'FOO1 'MACRO
 ' (Z (LIST (SUBST (CADADR Z) (QUOTE FN) DEF) (CAR Z)))
```

DEF is the definition of FOO1 as a function of just its first argument, and FN is the name used for its functional argument in its definition. In this case, (FOO1 X (FUNCTION ...)) would compile as an expression, containing the argument to FUNCTION as an open LAMBDA expression. Thus you save not only the function call to FOO1, but also each of the function calls to its functional argument. For example, if FOO1 operates on a list of length ten, eleven function calls will be saved. Of course, this savings in time costs space, and you must decide which is more important.

Open Functions

When a function is called from a compiled function, a system routine is invoked that sets up the parameter and control push lists as necessary for variable bindings and return information. If the amount of time spent inside the function is small, this function calling time will be a significant percentage of the total time required to use the function. Therefore, many "small" functions, e.g., CAR, CDR, EQ, NOT, CONS are always compiled "open", i.e., they do not result in a function call. Other larger
functions such as PROG, SELECTQ, MAPC, etc. are compiled open because they are frequently used. You can make other functions compile open via MACRO definitions. You can also affect the compiled code via COMPILEUSERFN and COMPILETYPELST.

**COMPILETYPELST**

Most of the compiler's mechanism deals with how to handle forms (lists) and variables (symbols). You can affect the compiler's behaviour with respect to lists and literal atoms in a number of ways, e.g. macros, declarations, COMPILEUSERFN, etc. COMPILETYPELST allows you to tell the compiler what to do when it encounters a data type other than a list or an atom. It is the facility in the compiler that corresponds to DEFEVAL for the interpreter.

**COMPILETYPELST**

A list of elements of the form (TYPE_NAME . FUNCTION). Whenever the compiler encounters a datum that is not a list and not an atom (or a number) in a context where the datum is being evaluated, the type name of the datum is looked up on COMPILETYPELST. If an entry appears CAR of which is equal to the type name, CDR of that entry is applied to the datum. If the value returned by this application is not EQ to the datum, then that value is compiled instead. If the value is EQ to the datum, or if there is no entry on COMPILETYPELST for this type name, the compiler simply compiles the datum as (QUOTE DATUM).

**Compiling CLISP**

Since the compiler does not know about CLISP, in order to compile functions containing CLISP constructs, the definitions must first be DWIMIFYed. You can automate this process in several ways:

1. If the variable DWIMIFYCOMPFLG is T, the compiler will always DWIMIFY expressions before compiling them. DWIMIFYCOMPFLG is initially NIL.

2. If a file has the property FILETYPE with value CLISP on its property list, TCOMPL, BCOMPL, RECOMPILE, and BRECOMPILE will operate as though DWIMIFYCOMPFLG is T and DWIMIFY all expressions before compiling.

3. If the function definition has a local CLISP declaration, including a null declaration, i.e., just (CLISP:), the definition will be automatically DWIMIFYed before compiling.

Note: COMPILEUSERFN is defined to call DWIMIFY on iterative statements, IF-THEN statements, and fetch, replace, and match expressions, i.e., any CLISP construct which can be recognized by its CAR of form. Thus, if the only CLISP constructs in a function appear inside of iterative statements, IF statements, etc., the function does not have to be dwimified before compiling.
If DWIMIFY is ever unsuccessful in processing a CLISP expression, it will print the error message UNABLE TO DWIMIFY followed by the expression, and go into a break unless DWIMESSGAG = T. In this case, the expression is just compiled as is, i.e. as though CLISP had not been enabled. You can exit the break in one of these ways:

1. Type OK to the break, which will cause the compiler to try again, e.g. you could define some missing records while in the break, and then continue

2. Type ↑, which will cause the compiler to simply compile the expression as is, i.e. as though CLISP had not been enabled in the first place

3. Return an expression to be compiled in its place by using the RETURN break command.

Note: TCOMPL, BCOMPL, RECOMPILE, and BRECOMPILE all scan the entire file before doing any compiling, and take note of the names of all functions that are defined in the file as well as the names of all variables that are set by adding them to NOFIXFNSLST and NOFIXVARSLSLST, respectively. Thus, if a function is not currently defined, but is defined in the file being compiled, when DWIMIFY is called before compiling, it will not attempt to interpret the function name as CLISP when it appears as CAR of a form. DWIMIFY also takes into account variables that have been declared to be LOCALVARS, or SPECVARS, either via block declarations or DECLARE expressions in the function being compiled, and does not attempt spelling correction on these variables. The declaration USEDFREE may also be used to declare variables simply used freely in a function. These variables will also be left alone by DWIMIFY. Finally, NOSPELLFLG is reset to T when compiling functions from a file (as opposed to from their in-core definition) so as to suppress spelling correction.

Compiler Functions

Normally, the compiler is envoked through file package commands that keep track of the state of functions, and manage a set of files, such as MAKEFILE. However, it is also possible to explicitly call the compiler using one of a number of functions. Functions may be compiled from in-core definitions (via COMPILE), or from definitions in files (TCOMPL), or from a combination of in-core and file definitions (RECOMPILE).

TCOMPL and RECOMPILE produce "compiled" files. Compiled files usually have the same name as the symbolic file they were made from, suffixed with DCOM (the compiled file extension is stored as the value of the variable COMPILE.EXT). The file name is constructed from the name field only, e.g., (TCOMPL '<BOBROW>FOO.TEM;3) produces FOO.DCOM on the connected directory. The version number will be the standard default.

A "compiled file" contains the same expressions as the original symbolic file, except for the following:
1. A special FILECREATED expression appears at the front of the file which contains information used by the file package, and which causes the message COMPILED ON DATE to be printed when the file is loaded (the actual string printed is the value of COMPILEHEADER).

2. Every DEFINEQ in the symbolic file is replaced by the corresponding compiled definitions in the compiled file.

3. Expressions following a DONTCOPY tag inside of a DECLARE: that appears in the symbolic file are not copied to the compiled file.

The compiled definitions appear at the front of the compiled file, i.e., before the other expressions in the symbolic file, regardless of where they appear in the symbolic file. The only exceptions are expressions that follow a FIRST tag inside of a DECLARE: This "compiled" file can be loaded into any Interlisp system with LOAD.

Note: When a function is compiled from its in-core definition (as opposed to being compiled from a definition in a file), and the function has been modified by BREAK, TRACE, BREAKIN, or ADVISE, it is first restored to its original state, and a message is printed out, e.g., FOO UNBROKEN. If the function is not defined by an expr definition, the value of the function’s EXPR property is used for the compilation, if there is one. If there is no EXPR property, and the compilation is being performed by RECOMPILE, the definition of the function is obtained from the file (using LOADFNS). Otherwise, the compiler prints (FN NOT COMPILEABLE), and goes on to the next function.

**(COMPILE X FLG)**

X is a list of functions (if atomic, (LIST X) is used). COMPILE first asks the standard compiler questions, and then compiles each function on X, using its in-core definition. Returns X.

If compiled definitions are being written to a file, the file is closed unless FLG = T.

**(COMPILE1 FN DEF)**

Compiles DEF, redefining FN if STRF = T (STRF is one of the variables set by COMPSET). COMPILE1 is used by COMPILE, TCOMPL, and RECOMPILE.

If DWIMIFYCMPFLG is T, or DEF contains a CLISP declaration, DEF is dwimified before compiling.

**(TCOMPL FILES)**

TCOMPL is used to "compile files": given a symbolic LOAD file (e.g., one created by MAKEFILE), it produces a "compiled file". FILES is a list of symbolic files to be compiled (if atomic, (LIST FILES) is used). TCOMPL asks the standard compiler questions, except for "OUTPUT FILE:". The output from the compilation of each symbolic file is written on a file of the same name suffixed with DCOM, e.g., (TCOMPL ‘(SYM1 SYM2)) produces two files, SYM1.DCOM and SYM2.DCOM.
TCompl processes the files one at a time, reading in the entire file. For each file created expression, the list of functions that were marked as changed by the file package is noted, and the file created expression is written onto the output file. For each defineq expression, TCompl adds any lambda functions defined in the defineq to nlam or naml, and adds lambda functions to lams, so that calls to these functions will be compiled correctly. Nlama, naml, and lams are rebound to their top level values (using resetvar) by all of the compiling functions, so that any additions to these lists while inside of these functions will not propagate outside. Expressions beginning with declare: are processed specially. All other expressions are collected to be subsequently written onto the output file.

After processing the file in this fashion, TCompl compiles each function, except for those functions which appear on the list don'tcompilefns (initially nil), and writes the compiled definition onto the output file. TCompl then writes onto the output file the other expressions found in the symbolic file. Don'tcompilefns might be used for functions that compile open, since their definitions would be superfluous when operating with the compiled file. Note that don'tcompilefns can be set via block declarations.

Note: If the rootname of a file has the property filetype with value clisp, or value a list containing clisp, TCompl rebinds dwimifycomplfg to T while compiling the functions on file, so the compiler will dwimify all expressions before compiling them.

TCompl returns a list of the names of the output files. All files are properly terminated and closed. If the compilation of any file is aborted via an error or control-D, all files are properly closed, and the (partially complete) compiled file is deleted.

(recompile pfile cfile fns) [Function]

The purpose of recompile is to allow you to update a compiled file without recompiling every function in the file. Recompile does this by using the results of a previous compilation. It produces a compiled file similar to one that would have been produced by TCompl, but at a considerable savings in time by only compiling selected functions, and copying the compiled definitions for the remainder of the functions in the file from an earlier TCompl or recompile file.

Pfile is the name of the Pretty file (source file) to be compiled; Cfile is the name of the Compiled file containing compiled definitions that may be copied. Fns indicates which functions in Pfile are to be recompiled, e.g., have been changed or defined for the first time since Cfile was made. Note that Pfile, not FNS, drives recompile.

Recompile asks the standard compiler questions, except for "output file:". As with TCompl, the output automatically goes to Pfile.dcom. Recompile processes Pfile the same as does TCompl except that defineq expressions are not actually read into core. Instead, recompile uses the filemap to obtain a list of the functions contained in Pfile. The filemap enables recompile to skip over the defineqs in the file by simply resetting the file pointer, so that in most cases the scan of the symbolic file is very fast (the only processing required is the reading of the non-defineqs and the processing of the declare: expressions as with TCompl). A map is built if the symbolic file does not
already contain one, for example if it was written in an earlier system, or with
BUILDMAPFLG = NIL.

After this initial scan of *PFILE*, RECOMPILE then processes the functions defined in the
file. For each function in *PFILE*, RECOMPILE determines whether or not the function is to
be (re)compiled. Functions that are members of `DONTCOMPILEFNS` are simply ignored.
Otherwise, a function is recompiled if:

1. *FNS* is a list and the function is a member of that list
2. *FNS* = T or `EXPRS` and the function is defined by an expr definition
3. *FNS* = `CHANGES` and the function is marked as having been changed in the
   `FILECREATED` expression in *PFILE*
4. *FNS* = ALL

If a function is not to be recompiled, RECOMPILE obtains its compiled definition from
*CFILE*, and copies it (and all generated subfunctions) to the output file, *PFILE*.DCOM. If
the function does not appear on *CFILE*, RECOMPILE simply recompiles it. Finally, after
processing all functions, RECOMPILE writes out all other expressions that were collected
in the prescan of *PFILE*.

Note: If *FNS* = ALL, *CFILE* is superfluous, and does not have to be
specified. This option may be used to compile a symbolic file that has
never been compiled before, but which has already been loaded (since
using TCOMPL would require reading the file in a second time).

If *CFILE* = NIL, *PFILE*.DCOM (the old version of the output file) is used for copying
from. If both *FNS* and *CFILE* are NIL, *FNS* is set to the value of `RECOMPILEDEFAULT`,
which is initially `CHANGES`. Thus you can perform his edits, dump the file, and then
simply `(RECOMPILE 'FILE)` to update the compiled file.

The value of RECOMPILE is the file name of the new compiled file, *PFILE*.DCOM. If
RECOMPILE is aborted due to an error or Control-D, the new (partially complete)
compiled file will be closed and deleted.

RECOMPILE is designed to allow you to conveniently and efficiently update a compiled
file, even when the corresponding symbolic file has not been (completely) loaded. For
example, you can perform a LOADFROM to "notice" a symbolic file, edit the functions he
wants to change (the editor will automatically load those functions not already loaded),
call MAKEFILE to update the symbolic file (MAKEFILE will copy the unchanged functions
from the old symbolic file), and then perform `(RECOMPILE *PFILE*)`.

Note: Since PRETTYDEF automatically outputs a suitable DECLARE:
expression to indicate which functions in the file (if any) are defined as
NLAMBDA's, calls to these functions will be handled correctly, even
though the NLAMBE function themselves may never be loaded, or
even looked at, by RECOMPILE.
Block Compiling

In Interlisp-10, block compiling provides a way of compiling several functions into a single block. Function calls between the component functions of the block are very fast. Thus, compiling a block consisting of just a single recursive function may be yield great savings if the function calls itself many times. The output of a block compilation is a single, usually large, function. Calls from within the block to functions outside of the block look like regular function calls. A block can be entered via several different functions, called entries. These must be specified when the block is compiled.

In Medley, block compiling is handled somewhat differently; block compiling provides a mechanism for hiding function names internal to a block, but it does not provide a performance improvement. Block compiling in Medley works by automatically renaming the block functions with special names, and calling these functions with the normal function-calling mechanisms. Specifically, a function \( FN \) is renamed to \( \text{\textbackslash BLOCK-NAME}/FN \). For example, function \( \text{FOO} \) in block \( \text{BAR} \) is renamed to \( \text{\textbackslash BAR}/\text{FOO} \). Note that it is possible with this scheme to break functions internal to a block.

Block Declarations

Block compiling a file frequently involves giving the compiler a lot of information about the nature and structure of the compilation, e.g., block functions, entries, specvars, etc. To help with this, there is the \( \text{BLOCKS} \) file package command, which has the form:

\[
\text{(BLOCKS BLOCK1 \ldots BLOCKN)}
\]

where each \( BLOCK_i \) is a block declaration. The \( \text{BLOCKS} \) command outputs a \( \text{DECLARE:} \) expression, which is noticed by \( \text{BCOMPL} \) and \( \text{BRECOMPILE} \). \( \text{BCOMPL} \) and \( \text{BRECOMPILE} \) are sensitive to these declarations and take the appropriate action.

Note: Masterscope includes a facility for checking the block declarations of a file or files for various anomalous conditions, e.g., functions in block declarations which aren’t on the file(s), functions in \( \text{ENTRIES} \) not in the block, variables that may not need to be \( \text{SPECVARS} \) because they are not used freely below the places they are bound, etc.

A block declaration is a list of the form:

\[
(\text{BLKNAME BLKFN}_1 \ldots BLKFN_M \\
(\text{VAR}_1 \ . \ \text{VALUE}_1) \ldots (\text{VAR}_N \ . \ \text{VALUE}_N))
\]

\( \text{BLKNAME} \) is the name of a block. \( \text{BLKFN}_1 \ldots \text{BLKFN}_M \) are the functions in the block and correspond to \( \text{BLKFUNS} \) in the call to \( \text{BLOCKCOMPILE} \). The \( (\text{VAR}_i \ . \ \text{VALUE}_i) \) expressions indicate the settings for variables affecting the compilation of that block. If \( \text{VALUE}_i \) is atomic, then \( \text{VAR}_i \) is set to \( \text{VALUE}_i \), otherwise \( \text{VAR}_i \) is set to the \( \text{UNION} \) of \( \text{VALUE}_i \) and the current value of the variable \( \text{VAR}_i \). Also, expressions of the form \( (\text{VAR} * \ \text{FORM}) \) will cause \( \text{FORM} \) to be evaluated and the resulting list used as described above (e.g., \( \text{GLOBALVARS} * \ \text{MYGLOBALVARS} \)).
For example, consider the block declaration below. The block name is EDITBLOCK, it includes a
number of functions (EDITL0, EDITL1, ... EDITH), and it sets the variables ENTRIES,
SPECVARS, RETFNS, and GLOBALVARS.

```
(EDITBLOCK
  EDITL0 EDITL1 UNDOEDITL EDITCOM EDITCOMA
  EDITMAC EDITCOMS EDIT)UNDO UNDOEDITCOM EDITH
(ENTRIES EDITL0 ## UNDOEDITL)
(SPECVARS L COM LCFLG #1 #2 #3 LISPXBDFS)
(RETFNS EDITL0)
(GLOBALVARS EDITCOMSA EDITCOMSL EDITOPS))
```

Whenever BCOMPL or BRECOMPILE encounter a block declaration, they rebind RETFNS, SPECVARS,
GLOBALVARS, BLKLIBRARY, and DONTCOMPILEFNS to their top level values, bind BLKAPPLYFNS and
ENTRIES to NIL, and bind BLKNAME to the first element of the declaration. They then scan the rest of
the declaration, setting these variables as described above. When the declaration is exhausted, the
block compiler is called and given BLKNAME, the list of block functions, and ENTRIES.

If a function appears in a block declaration, but is not defined in one of the files, then if it has an in-
core definition, this definition is used and a message printed NOT ON FILE, COMPILING IN CORE
DEFINITION. Otherwise, the message NOT COMPILEABLE, is printed and the block declaration
processed as though the function were not on it, i.e. calls to the function will be compiled as external
function calls.

Since all compiler variables are rebound for each block declaration, the declaration only has to set
those variables it wants changed. Furthermore, setting a variable in one declaration has no effect on
the variable's value for another declaration.

After finishing all blocks, BCOMPL and BRECOMPILE treat any functions in the file that did not appear
in a block declaration in the same way as do TCOMPL and RECOMPILE. If you wish a function
compiled separately as well as in a block, or if you wish to compile some functions (not blockcompile),
with some compiler variables changed, you can use a special pseudo-block declaration of the form

```
(NIL BLKFN1 ... BLKFN_M (VAR1 . VALUE1) ... (VARN . VALUE_N) )
```

which means that BLKFN1 ... BLKFN_M should be compiled after first setting VAR1 ... VAR_N as
described above.

The following variables control other aspects of compiling a block:

```
RETFNS
[Variable]
```

Value is a list of internal block functions whose names must appear on the stack, e.g., if
the function is to be returned from RETFROM, RETTO, RETEVAL, etc. Usually, internal calls
between functions in a block are not put on the stack.
BLKAPPLYFNS  [Variable]

Value is a list of internal block functions called by other functions in the same block using BLKAPPLY or BLKAPPLY* for efficiency reasons.

Normally, a call to APPLY from inside a block would be the same as a call to any other function outside of the block. If the first argument to APPLY turned out to be one of the entries to the block, the block would have to be reentered. BLKAPPLYFNS enables a program to compute the name of a function in the block to be called next, without the overhead of leaving the block and reentering it. This is done by including on the list BLKAPPLYFNS those functions which will be called in this fashion, and by using BLKAPPLY in place of APPLY, and BLKAPPLY* in place of APPLY*. If BLKAPPLY or BLKAPPLY* is given a function not on BLKAPPLYFNS, the effect is the same as a call to APPLY or APPLY* and no error is generated. Note however, that BLKAPPLYFNS must be set at compile time, not run time, and furthermore, that all functions on BLKAPPLYFNS must be in the block, or an error is generated (at compile time), NOT ON BLKFNS.

BLKAPPLYFNS  [Variable]

Value is a list of functions that are considered to be in the "block library" of functions that should automatically be included in the block if they are called within the block.

Compiling a function open via a macro provides a way of eliminating a function call. For block compiling, the same effect can be achieved by including the function in the block. A further advantage is that the code for this function will appear only once in the block, whereas when a function is compiled open, its code appears at each place where it is called.

The block library feature provides a convenient way of including functions in a block. It is just a convenience since you can always achieve the same effect by specifying the function(s) in question as one of the block functions, provided it has an expr definition at compile time. The block library feature simply eliminates the burden of supplying this definition.

To use the block library feature, place the names of the functions of interest on the list BLKLIBRARY, and their expr definitions on the property list of the functions under the property BLKLIBRARYDEF. When the block compiler compiles a form, it first checks to see if the function being called is one of the block functions. If not, and the function is on BLKLIBRARY, its definition is obtained from the property value of BLKLIBRARYDEF, and it is automatically included as part of the block.

Block Compiling Functions

There are three user level functions for block compiling, BLOCKCOMPILE, BCOMPL, and BRECOMPILE, corresponding to COMPILE, TCOMPL, and RECOMPILE. Note that all of the remarks on macros, globalvars, compiler messages, etc., all apply equally for block compiling. Using block declarations, you can intermix in a single file functions compiled normally and block compiled functions.
(BLOCKCOMPILE  BLKNAME  BLKFNS  ENTRIES  FLG)

[Function]

BLKNAME is the name of a block, BLKFNS is a list of the functions comprising the block, and ENTRIES a list of entries to the block.

Each of the entries must also be on BLKFNS or an error is generated, NOT ON BLKFNS. If only one entry is specified, the block name can also be one of the BLKFNS, e.g., (BLOCKCOMPILE  'FOO  '(FOO  FIE  FUM)  '(FOO)). However, if more than one entry is specified, an error will be generated, CAN'T BE BOTH AN ENTRY AND THE BLOCK NAME.

If ENTRIES is NIL, (LIST BLKNAME) is used, e.g., (BLOCKCOMPILE  'COUNT  '(COUNT  COUNT1))

If BLKFNS is NIL, (LIST BLKNAME) is used, e.g., (BLOCKCOMPILE  'EQUAL)

BLOCKCOMPILE asks the standard compiler questions, and then begins compiling. As with COMPILE, if the compiled code is being written to a file, the file is closed unless FLG = T. The value of BLOCKCOMPILE is a list of the entries, or if ENTRIES = NIL, the value is BLKNAME.

The output of a call to BLOCKCOMPILE is one function definition for BLKNAME, plus definitions for each of the functions on ENTRIES if any. These entry functions are very short functions which immediately call BLKNAME.

(BCOMPL  FILES  CFILE)

[Function]

FILES is a list of symbolic files (if atomic, (LIST FILES) is used). BCOMPL differs from TCOMPL in that it compiles all of the files at once, instead of one at a time, in order to permit one block to contain functions in several files. (If you have several files to be BCOMPLed separately, you must make several calls to BCOMPL.) Output is to CFILE if given, otherwise to a file whose name is (CAR FILES) suffixed with DCOM. For example, (BCOMPL  '(EDIT  WEDIT)) produces one file, EDIT.DCOM.

BCOMPL asks the standard compiler questions, except for "OUTPUT FILE:", then processes each file exactly the same as TCOMPL. BCOMPL next processes the block declarations as described above. Finally, it compiles those functions not mentioned in one of the block declarations, and then writes out all other expressions.

If any of the files have property FILETYPE with value CLISP, or a list containing CLISP, then DWIMIFYCOMPFLG is rebound to T for all of the files.

The value of BCOMPL is the output file (the new compiled file). If the compilation is aborted due to an error or Control-D, all files are closed and the (partially complete) output file is deleted.

It is permissible to TCOMPL files set up for BCOMPL; the block declarations will simply have no effect. Similarly, you can BCOMPL a file that does not contain any block declarations and the result will be the same as having TCOMPLed it.
(BRECOMPILE FILES CFILE FNS —) [Function]

BRECOMPILE plays the same role for BCOMPL that RECOMPILE plays for TCOMPL. Its purpose is to allow you to update a compiled file without requiring an entire BCOMPL.

FILES is a list of symbolic files (if atomic, (LIST FILES) is used). CFILE is the compiled file produced by BCOMPL or a previous BRECOMPILE that contains compiled definitions that may be copied. The interpretation of FNS is the same as with RECOMPILE.

BRECOMPILE asks the standard compiler questions, except for "OUTPUT FILE:". As with BCOMPL, output automatically goes to FILE.DCOM, where FILE is the first file in FILES.

BRECOMPILE processes each file the same as RECOMPILE, then processes each block declaration. If any of the functions in the block are to be recompiled, the entire block must be (is) recompiled. Otherwise, the block is copied from CFILE as with RECOMPILE. For pseudo-block declarations of the form (NIL FN1 ...), all variable assignments are made, but only those functions indicated by FNS are recompiled.

After completing the block declarations, BRECOMPILE processes all functions that do not appear in a block declaration, recompiling those dictated by FNS, and copying the compiled definitions of the remaining from CFILE.

Finally, BRECOMPILE writes onto the output file the "other expressions" collected in the initial scan of FILES.

The value of BRECOMPILE is the output file (the new compiled file). If the compilation is aborted due to an error or Control-D, all files are closed and the (partially complete) output file is deleted.

If CFILE = NIL, the old version of FILE.DCOM is used, as with RECOMPILE. In addition, if FNS and CFILE are both NIL, FNS is set to the value of RECOMPILEDEFAULT, initially CHANGES.

Compiler Error Messages

Messages describing errors in the function being compiled are also printed on the terminal. These messages are always preceded by *****. Unless otherwise indicated below, the compilation will continue.

(FN NOT ON FILE, COMPILING IN CORE DEFINITION)

From calls to BCOMPL and BRECOMPILE.

(FN NOT COMPILABLE)

An EXPR definition for FN could not be found. In this case, no code is produced for FN, and the compiler proceeds to the next function to be compiled, if any.
(FN NOT FOUND)

Occurs when RECOMPILE or BRECOMPILE try to copy the compiled definition of \textit{FN} from \textit{CFILE}, and cannot find it. In this case, no code is copied and the compiler proceeds to the next function to be compiled, if any.

(FN NOT ON BLKFNS)

\textit{FN} was specified as an entry to a block, or else was on BLKAPPLYFNS, but did not appear on the BLKFNS. In this case, no code is produced for the entire block and the compiler proceeds to the next function to be compiled, if any.

(FN CAN'T BE BOTH AN ENTRY AND THE BLOCK NAME)

In this case, no code is produced for the entire block and the compiler proceeds to the next function to be compiled, if any.

(BLKNNAME - USED BLKAPPLY WHEN NOT APPLICABLE)

BLKAPPLY is used in the block \textit{BLKNNAME}, but there are no BLKAPPLYFNS or ENTRIES declared for the block.

(VAR SHOULD BE A SPECVAR - USED FREELY BY FN)

While compiling a block, the compiler has already generated code to bind \textit{VAR} as a \texttt{LOCALVAR}, but now discovers that \textit{FN} uses \textit{VAR} freely. \textit{VAR} should be declared a \texttt{SPECVAR} and the block recompiled.

((* - -) COMMENT USED FOR VALUE)

A comment appears in a context where its value is being used, e.g. \texttt{(LIST X (* - -) Y)}. The compiled function will run, but the value at the point where the comment was used is undefined.

((FORM) - NON-ATOMIC CAR OF FORM)

If you intended to treat the value of \textit{FORM} as a function, you should use APPLY* (Chapter 10). \textit{FORM} is compiled as if APPLY* had been used.

((SETQ VAR EXPR - -) BAD SETQ)

SETQ of more than two arguments.

(FN - USED AS ARG TO NUMBER FN?)

The value of a predicate, such as GREATERP or EQ, is used as an argument to a function that expects numbers, such as IPLUS.

(FN - NO LONGER INTERPRETED AS FUNCTIONAL ARGUMENT)

The compiler has assumed \textit{FN} is the name of a function. If you intended to treat the value of \textit{FN} as a function, APPLY* (Chapter 10) should be used. This message is printed when \textit{FN} is not defined, and is also a local variable of the function being compiled.
(FN - ILLEGAL RETURN)
RETURN encountered when not in PROG.

(TG - ILLEGAL GO)
GO encountered when not in a PROG.

(TG - MULTIPLY DEFINED TAG)
TG is a PROG label that is defined more than once in a single PROG. The second definition is ignored.

(TG - UNDEFINED TAG)
TG is a PROG label that is referenced but not defined in a PROG.

(VAR - NOT A BINDABLE VARIABLE)
VAR is NIL, T, or else not a literal atom.

(VAR VAL -- BAD PROG BINDING)
Occurs when there is a prog binding of the form (VAR VAL₁ ... VALₙ).

(TG - MULTIPLY DEFINED TAG, LAP)
TG is a label that was encountered twice during the second pass of the compilation. If this error occurs with no indication of a multiply defined tag during pass one, the tag is in a LAP macro.

(TG - UNDEFINED TAG, LAP)
TG is a label that is referenced during the second pass of compilation and is not defined. LAP treats TG as though it were a COREVAL, and continues the compilation.

(TG - MULTIPLY DEFINED TAG, ASSEMBLE)
TG is a label that is defined more than once in an assemble form.

(TG - UNDEFINED TAG, ASSEMBLE)
TG is a label that is referenced but not defined in an assemble form.

(OP - OPCODE? - ASSEMBLE)
OP appears as CAR of an assemble statement, and is illegal.

(NO BINARY CODE GENERATED OR LOADED FOR FN)
A previous error condition was sufficiently serious that binary code for FN cannot be loaded without causing an error.
A surprisingly large percentage of the errors made by Interlisp users are of the type that could be corrected by another Lisp programmer without any information about the purpose of the program or expression in question, e.g., misspellings, certain kinds of parentheses errors, etc. To correct these types of errors we have implemented in Medley a **DWIM** facility, short for Do-What-I-Mean. **DWIM** is called automatically whenever an error occurs in the evaluation of an Interlisp expression. (Currently, **DWIM** only operates on unbound atoms and undefined function errors.) **DWIM** then proceeds to try to correct the mistake using the current context of computation plus information about what you had previously been doing (and what mistakes you had been making) as guides to the remedy of the error. If **DWIM** is able to make the correction, the computation continues as though no error had occurred. Otherwise, the procedure is the same as though **DWIM** had not intervened: a break occurs, or an unwind to the last **ERRORSET** (see Chapter 14). The following protocol illustrates the operation of **DWIM**.

For example, suppose you define the factorial function \( (\text{FACT } N) \) as follows:

\[
\text{←DEFINEQ}((\text{FACT} \ (\text{LAMBDA} \ (N) \ (\text{COND} \\
\quad ((\text{ZEROP} \ N) \ 1) \ ((\text{T} \ \text{ITIMS} \ N \ (\text{FACT} \ 9\text{SUB1} \ N) \ \\
\quad \text{FACT}))) \\
\text{←}
\]

Note that the definition of **FACT** contains several mistakes: **ITIMES** and **FACT** have been misspelled; the 0 in **N0** was intended to be a right parenthesis, but the Shift key was not pressed; similarly, the 9 in **9SUB1** was intended to be a left parenthesis; and finally, there is an extra left parenthesis in front of the **T** that begins the final clause in the conditional.

\[
\text{←PRETTYPRNT}((\text{FACT}) \\
\quad =\text{PRETTYPRINT} \\
\quad =\text{FACT} \\
\quad (\text{FACT} \\
\quad \ (\text{LAMBDA} \ (N) \\
\quad \ (\text{COND} \\
\quad \quad ((\text{ZEROP} \ N) \ 1) \\
\quad \quad ((\text{T} \ \text{ITIMS} \ N \ (\text{FACT} \ 9\text{SUB1} \ N)) \\
\quad \text{FACT})) \\
\text{←}
\]

After defining **FACT**, you want to look at its definition using **PRETTYPRINT**, which you unfortunately misspell. Since there is no function **PRETTYPRINT** in the system, an undefined function error occurs, and **DWIM** is called. **DWIM** invokes its spelling corrector, which searches a list of functions frequently used (by this user) for the best possible match. Finding one that is extremely close, **DWIM** proceeds on the assumption that **PRETTYPRINT** meant **PRETTYPRINT**, notifies you of this, and calls **PRETTYPRINT**.
At this point, PRETTYPRINT would normally print \texttt{(FACCT NOT PRINTABLE)} and exit, since FACCT has no definition. Note that this is \textit{not} an Interlisp error condition, so that DWIM would not be called as described above. However, it is obviously not what you \textit{meant}.

This sort of mistake is corrected by having PRETTYPRINT itself explicitly invoke the spelling corrector portion of DWIM whenever given a function with no EXPR definition. Thus, with the aid of DWIM PRETTYPRINT is able to determine that you want to see the definition of the function FACT, and proceeds accordingly.

\texttt{←FACT(3)}\n\texttt{NO [IN FACT] -> N} ? \texttt{YES}\n\texttt{[IN FACT] (COND -- \{\texttt{(T \texttt{--\})} \} -->}\n\texttt{ (COND -- \{\texttt{T \texttt{--\})} \})}\n\texttt{ITIMS [IN FACT] -> ITIMES}\n\texttt{FACCT [IN FACT] -> FACT}\n\texttt{9SUB1 [IN FACT] -> \{ SUB1 ? YES 6}

\texttt{←PP FACT}\n\texttt{[LAMBDA (N)}\n\texttt{(COND}\n\texttt{\{\texttt{(ZEROP N)}\n\texttt{1}\n\texttt{\} (ITIMES N \text{FACT (SUB1 N])}}\n\texttt{FACT}\n
\texttt{←}

You now call FACT. During its execution, five errors occur, and DWIM is called five times. At each point, the error is corrected, a message is printed describing the action taken, and the computation is allowed to continue as if no error had occurred. Following the last correction, 6 is printed, the value of \texttt{(FACT 3)}. Finally, you prettyprint the new, now correct, definition of FACT.

In this particular example, you were operating in \texttt{TRUSTING} mode, which gives DWIM carte blanche for most corrections. You can also operate in \texttt{CAUTIOUS} mode, in which case DWIM will inform you of intended corrections before they are made, and allow you to approve or disapprove of them. If DWIM was operating in \texttt{CAUTIOUS} mode in the example above, it would proceed as follows:

\texttt{←FACT(3)}\n\texttt{NO [IN FACT] -> N} ? \texttt{YES}\n\texttt{U.D.F. T [IN FACT] FIX? YES}\n\texttt{[IN FACT] (COND -- \{\texttt{(T \texttt{--\})} \} -->}\n\texttt{ (COND -- \{\texttt{T \texttt{--\})} \})}\n\texttt{ITIMS [IN FACT] -> ITIMES ? ...YES}\n\texttt{FACCT [IN FACT] -> FACT ? ...YES}\n\texttt{9SUB1 [IN FACT] -> \{ SUB1 ? NO U.B.A.}\n\texttt{(9SUB1 BROKEN)}

;
For most corrections, if you do not respond in a specified interval of time, DWIM automatically proceeds with the correction, so that you need intervene only when you do not approve. In the example, you responded to the first, second, and fifth questions; DWIM responded for you on the third and fourth.

DWIM uses ASKUSER for its interactions with you (see Chapter 26). Whenever an interaction is about to take place and you have typed ahead, ASKUSER types several bells to warn you to stop typing, then clears and saves the input buffers, restoring them after the interaction is complete. Thus if you typed ahead before a DWIM interaction, DWIM will not confuse your type-ahead with the answer to its question, nor will your type-ahead be lost. The bells are printed by the function PRINTBELLS, which can be advised or redefined for specialized applications, e.g. to flash the screen for a display terminal.

A great deal of effort has gone into making DWIM "smart", and experience with a large number of users indicates that DWIM works very well; DWIM seldom fails to correct an error you feel it should have, and almost never mistakenly corrects an error. However, it is important to note that even when DWIM is wrong, no harm is done: since an error had occurred, you would have had to intervene anyway if DWIM took no action. Thus, if DWIM mistakenly corrects an error, you simply interrupt or abort the computation, reverse the DWIM change using UNDO (see Chapter 13), and make the correction you would have had to make without DWIM. An exception is if DWIM’s correction mistakenly caused a destructive computation to be initiated, and information was lost before you could interrupt. We have not yet had such an incident occur.

(DWIM X) [Function]

Used to enable/disable DWIM. If X is the symbol C, DWIM is enabled in CAUTIOUS mode, so that DWIM will ask you before making corrections. If X is T, DWIM is enabled in TRUSTING mode, so DWIM will make most corrections automatically. If X is NIL, DWIM is disabled. Medley initially has DWIM enabled in CAUTIOUS mode.

DWIM returns CAUTIOUS, TRUSTING or NIL, depending to what mode it has just been put into.

For corrections to expressions typed in for immediate execution (typed into LISPX, Chapter 13), DWIM always acts as though it were in TRUSTING mode, i.e., no approval necessary. For certain types of corrections, e.g., run-on spelling corrections, 9-0 errors, etc., DWIM always acts like it was in CAUTIOUS mode, and asks for approval. In either case, DWIM always informs you of its action as described below.

**Spelling Correction Protocol**

One type of error that DWIM can correct is the misspelling of a function or a variable name. When an unbound symbol or undefined function error occurs, DWIM tries to correct the spelling of the bad symbol. If a symbol is found whose spelling is "close" to the offender, DWIM proceeds as follows:
If the correction occurs in the typed-in expression, DWIM prints `CORRECT_SPELLING` and continues evaluating the expression. For example:

```
← (setq foo (ipluss 1 2))
=iplus
3
```

If the correction does not occur in type-in, DWIM prints

```
BAD_SPELLING [IN FUNCTION-NAME] → CORRECT_SPELLING
```

The appearance of `→` is to call attention to the fact that the user’s function will be or has been changed.

Then, if DWIM is in TRUSTING mode, it prints a carriage return, makes the correction, and continues the computation. If DWIM is in CAUTIOUS mode, it prints a few spaces and `?` and then waits for approval. The user then has six options:

1. Type `Y`. DWIM types `es`, and proceeds with the correction.
2. Type `N`. DWIM types `o`, and does not make the correction.
3. Type `↑`. DWIM does not make the correction, and furthermore guarantees that the error will not cause a break.
4. Type Control-E. For error correction, this has the same effect as typing `N`.
5. Do nothing. In this case DWIM waits for DWIMWAIT seconds, and if you have not responded, DWIM will type `...` followed by the default answer.

   The default on spelling corrections is determined by the value of the variable FIXSPELLDEFAULT, whose top level value is initially `Y`.

6. Type space or carriage-return. In this case DWIM will wait indefinitely. This option is intended for those cases where you want to think about your answer, and want to insure that DWIM does not get "impatient" and answer for you.

The procedure for spelling correction on other than Interlisp errors is analogous. If the correction is being handled as type-in, DWIM prints `es` followed by the correct spelling, and returns it to the function that called DWIM. Otherwise, DWIM prints the incorrect spelling, followed by the correct spelling. Then, if DWIM is in TRUSTING mode, DWIM prints a carriage-return and returns the correct spelling. Otherwise, DWIM prints a few spaces and a `?` and waits for approval. You can then respond with `Y, N`, Control-E, space, carriage return, or do nothing as described above.

The spelling corrector itself is not ERRORSET protected like the DWIM error correction routines. Therefore, typing `N` and typing Control-E may have different effects when the spelling corrector is called directly. The former simply instructs the spelling corrector to return `NIL`, and lets the calling
function decide what to do next; the latter causes an error which unwinds to the last ERRORSET, however far back that may be.

**Parentheses Errors Protocol**

When an unbound symbol or undefined error occurs, and the offending symbol contains 9 or 0, DWIM tries to correct errors caused by typing 9 for left parenthesis and 0 for right parenthesis. In these cases, the interaction with you is similar to that for spelling correction. If the error occurs in type-in, DWIM types =CORRECTION, and continues evaluating the expression. For example:

\[
\begin{align*}
\leftarrow & \text{(SETQ FOO 9IPLUS 1 2)} \cr &= ( \text{IPLUS} \cr & 3
\end{align*}
\]

If the correction does not occur in type-in, DWIM prints

```
BAD-ATOM [IN FUNCTION-NAME] -> CORRECTION ?
```

and then waits for approval. You then have the same six options as for spelling correction, except the waiting time is 3*DWIMWAIT seconds. If you type Y, DWIM operates as if it were in TRUSTING mode, i.e., it makes the correction and prints its message.

Actually, DWIM uses the value of the variables LPARKEY and RPARKEY to determine the corresponding lower case character for left and right parentheses. LPARKEY and RPARKEY are initially 9 and 0 respectively, but they can be reset for other keyboard layouts, e.g., on some terminals left parenthesis is over 8, and right parenthesis is over 9.

**Undefined Function T Errors**

When an undefined function error occurs, and the offending function is T, DWIM tries to correct certain types of parentheses errors involving a T clause in a conditional. DWIM recognizes errors of the following forms:

-\((\text{COND }--)\)\(\text{ (T }--\)\) The T clause appears outside and immediately following the COND.
-\((\text{COND }-- \text{ (}--\text{ & (T }--))\)\) The T clause appears inside a previous clause.
-\((\text{COND }-- \text{ ((T }--))\)\) The T clause has an extra pair of parentheses around it.

For undefined function errors that are not one of these three types, DWIM takes no corrective action at all, and the error will occur.
If the error occurs in type-in, DWIM simply types T FIXED and makes the correction. Otherwise if DWIM is in TRUSTING mode, DWIM makes the correction and prints the message:

\[ \text{[IN FUNCTION-NAME] (BAD-COND) -> (CORRECTED-COND)} \]

If DWIM is in CAUTIOUS mode, DWIM prints

\[ \text{UNDEFINED FUNCTION T [IN FUNCTION-NAME] FIX?} \]

and waits for approval. You then have the same options as for spelling corrections and parenthesis errors. If you type Y or default, DWIM makes the correction and prints its message.

Having made the correction, DWIM must then decide how to proceed with the computation. In the first case, (COND -- (T --)), DWIM cannot know whether the T clause would have been executed if it had been inside of the COND. Therefore DWIM asks you CONTINUE WITH T CLAUSE (with a default of YES). If you type N, DWIM continues with the form after the COND, i.e., the form that originally followed the T clause.

In the second case, (COND -- (-- & (T --))), DWIM has a different problem. After moving the T clause to its proper place, DWIM must return as the value of & as the value of the COND. Since this value is no longer around, DWIM asks you OK TO REEVALUATE and then prints the expression corresponding to &. If you type Y, or default, DWIM continues by reevaluating &, otherwise DWIM aborts, and a U.D.F. T error will then occur (even though the COND has in fact been fixed). If DWIM can determine for itself that the form can safely be reevaluated, it does not consult you before reevaluating. DWIM can do this if the form is atomic, or CAR of the form is a member of the list OKREEVALST, and each of the arguments can safely be reevaluated. For example, (SETQ X (CONS (IPLUS Y Z) W)) is safe to reevaluate because SETQ, CONS, and IPLUS are all on OKREEVALST.

In the third case, (COND -- ((T --))), there is no problem with continuation, so no further interaction is necessary.

**DWIM Operation**

Whenever the interpreter encounters an atomic form with no binding, or a non-atomic form CAR of which is not a function or function object, it calls the function FAULTEVAL. Similarly, when APPLY is given an undefined function, FAULTAPPLY is called. When DWIM is enabled, FAULTEVAL and FAULTAPPLY are redefined to first call the DWIM package, which tries to correct the error. If DWIM cannot decide how to fix the error, or you disapprove of DWIM's correction (by typing N), or you type Control-E, then FAULTEVAL and FAULTAPPLY cause an error or break. If you type ↑ to DWIM, DWIM exits by performing \( \text{(RETEVAL ‘FAULTEVAL ‘(ERROR!))} \), so that an error will be generated at the position of the call to FAULTEVAL.
If DWIM can (and is allowed to) correct the error, it exits by performing RETEVAL of the corrected form, as of the position of the call to FAULTEVAL or FAULTAPPLY. Thus in the example at the beginning of the chapter, when DWIM determined that ITIMS was ITIMES misspelled, DWIM called RETEVAL with (ITIMES N (FACCT 9SUB1 N)). Since the interpreter uses the value returned by FAULTEVAL exactly as though it were the value of the erroneous form, the computation will thus proceed exactly as though no error had occurred.

In addition to continuing the computation, DWIM also repairs the cause of the error whenever possible; in the above example, DWIM also changed (with RPLACA) the expression (ITIMES N (FACCT 9SUB1 N)) that caused the error. Note that if your program had computed the form and called EVAL, it would not be possible to repair the cause of the error, although DWIM could correct the misspelling each time it occurred.

Error correction in DWIM is divided into three categories: unbound atoms, undefined CAR of form, and undefined function in APPLY. Assuming that the user approves DWIM’s corrections, the action taken by DWIM for the various types of errors in each of these categories is summarized below.

**DWIM Correction: Unbound Atoms**

If DWIM is called as the result of an unbound atom error, it proceeds as follows:

1. If the first character of the unbound atom is ‘, DWIM assumes that you (intentionally) typed ‘ATOM for (QUOTE ATOM) and makes the appropriate change. No message is typed, and no approval is requested.

   If the unbound atom is just ‘ itself, DWIM assumes you want the next expression quoted, e.g., (CONS X ‘(A B C)) will be changed to (CONS X (QUOTE (A B C))). Again no message will be printed or approval asked. If no expression follows the ‘, DWIM gives up.

   Note: ‘ is normally defined as a read-macro character which converts ‘FOO to (QUOTE FOO) on input, so DWIM will not see the ‘ in the case of expressions that are typed-in.

2. If CLISP (see Chapter 21) is enabled, and the atom is part of a CLISP construct, the CLISP transformation is performed and the result returned. For example, N-1 is transformed to (SUB1 N), and (... FOO_3 ...) is transformed into (... (SETQ FOO 3) ...).

3. If the atom contains an 9 (actually LPARKEY (see the DWIM Functions and Variables section below), DWIM assumes the 9 was intended to be a left parenthesis, and calls the editor to make appropriate repairs on the expression containing the atom. DWIM assumes that you did not notice the mistake, i.e., that the entire expression was affected by the missing left parenthesis. For example, if you type (SETQ X (LIST (CONS 9CAR Y) (CDR Z)) Y), the expression will be changed to (SETQ X (LIST (CONS (CAR Y) (CDR Z)) Y)). The 9 does not have to be the first character of the atom: DWIM will handle (CONS X9CAR Y) correctly.
4. If the atom contains a 0 (actually RPARKEY, see the DWIM Functions and Variables section below), DWIM assumes the 0 was intended to be a right parenthesis and operates as in the case above.

5. If the atom begins with a 7, the 7 is treated as a ’. For example, 7FOO becomes ‘FOO, and then (QUOTE FOO).

6. The expressions on DWIMUSERFORMS (see the DWIMUSERFORMS section below) are evaluated in the order that they appear. If any of these expressions returns a non-NIL value, this value is treated as the form to be used to continue the computation, it is evaluated and its value is returned by DWIM.

7. If the unbound atom occurs in a function, DWIM attempts spelling correction using the LAMBDA and PROG variables of the function as the spelling list.

8. If the unbound atom occurred in a type-in to a break, DWIM attempts spelling correction using the LAMBDA and PROG variables of the broken function as the spelling list.

9. Otherwise, DWIM attempts spelling correction using SPELLINGS3 (see the Spelling Lists section below).

10. If all of the above fail, DWIM gives up.

Undefined CAR of Form

If DWIM is called as the result of an undefined CAR of form error, it proceeds as follows:

1. If CAR of the form is T, DWIM assumes a misplaced T clause and operates as described in the Undefined Function T Errors section above.

2. If CAR of the form is F/L, DWIM changes the "F/L" to "FUNCTION (LAMBDA". For example, (F/L (Y) (PRINT (CAR Y))) is changed to (FUNCTION (LAMBDA (Y) (PRINT (CAR Y))) . No message is printed and no approval requested. If you omit the variable list, DWIM supplies (X), e.g., (F/L (PRINT (CAR X))) is changed to (FUNCTION (LAMBDA (X) (PRINT (CAR X)))) . DWIM determines that you have supplied the variable list when more than one expression follows F/L, CAR of the first expression is not the name of a function, and every element in the first expression is atomic. For example, DWIM will supply (X) when correcting (F/L (PRINT (CDR X)) (PRINT (CAR X))).

3. If CAR of the form is a CLISP word (IF, FOR, DO, FETCH, etc.), the indicated CLISP transformation is performed, and the result is returned as the corrected form. See Chapter 21.

4. If CAR of the form has a function definition, DWIM attempts spelling correction on CAR of the definition using as spelling list the value of LAMBDAFLST, initially (LAMBDA NLAMBDAX).

5. If CAR of the form has an EXPR or CODE property, DWIM prints CAR-OF-FORM UNSAVED, performs an UNSAVEDEF, and continues. No approval is requested.
6. If CAR of the form has a FILEDEF property, the definition is loaded from a file (except when DWIMIFYing). If the value of the property is atomic, the entire file is to be loaded. If the value is a list, CAR is the name of the file and CDR the relevant functions, and LOADFNS will be used. For both cases, LDFLG will be SYSLOAD (see Chapter 17). DWIM uses FINDFILE (Chapter 24), so that the file can be on any of the directories on DIRECTORIES, initially (NIL NEWLISP LISP LISPUSERS). If the file is found, DWIM types SHALL I LOAD followed by the file name or list of functions. If you approve, DWIM loads the function(s) or file, and continues the computation.

7. If CLISP is enabled, and CAR of the form is part of a CLISP construct, the indicated transformation is performed, e.g., (N←N-1) becomes (SETQ N (SUB1 N)).

8. If CAR of the form contains an 9, DWIM assumes a left parenthesis was intended e.g., (CONS9CAR X).

9. If CAR of the form contains a 0, DWIM assumes a right parenthesis was intended.

10. If CAR of the form is a list, DWIM attempts spelling correction on CAAR of the form using LAMBDASPLST as spelling list. If successful, DWIM returns the corrected expression itself.

11. The expressions on DWIMUSERFORMS are evaluated in the order they appear. If any returns a non-NIL value, this value is treated as the corrected form, it is evaluated, and DWIM returns its value.

12. Otherwise, DWIM attempts spelling correction using SPELLINGS2 as the spelling list (see the Spelling Lists section below). When DWIMIFYing, DWIM also attempts spelling correction on function names not defined but previously encountered, using NOFIXFNSLST as a spelling list (see Chapter 21).

13. If all of the above fail, DWIM gives up.

**Undefined Function in APPLY**

If DWIM is called as the result of an undefined function in APPLY error, it proceeds as follows:

1. If the function has a definition, DWIM attempts spelling correction on CAR of the definition using LAMBDASPLST as spelling list.

2. If the function has an EXPR or CODE property, DWIM prints FN UNSAVED, performs an UNSAVEDEF and continues. No approval is requested.

3. If the function has a property FILEDEF, DWIM proceeds as in case 6 of undefined CAR of form.

4. If the error resulted from type-in, and CLISP is enabled, and the function name contains a CLISP operator, DWIM performs the indicated transformation, e.g., type FOO←(APPEND FIE FUM).

5. If the function name contains an 9, DWIM assumes a left parenthesis was intended, e.g., EDIT9FOO).
6. If the "function" is a list, DWIM attempts spelling correction on CAR of the list using LAMBDASPLST as spelling list.

7. The expressions on DWIMUSERFORMS are evaluated in the order they appear, and if any returns a non-NIL value, this value is treated as the function used to continue the computation, i.e., it will be applied to its arguments.

8. DWIM attempts spelling correction using SPELLINGS1 as the spelling list.

9. DWIM attempts spelling correction using SPELLINGS2 as the spelling list.

10. If all fail, DWIM gives up.

DWIMUSERFORMS

The variable DWIMUSERFORMS provides a convenient way of adding to the transformations that DWIM performs. For example, you might want to change atoms of the form $X$ to (QA4LOOKUP X). Before attempting spelling correction, but after performing other transformations (F/L, 9, 0, CLISP, etc.), DWIM evaluates the expressions on DWIMUSERFORMS in the order they appear. If any expression returns a non-NIL value, this value is treated as the transformed form to be used. If DWIM was called from FAULTEVAL, this form is evaluated and the resulting value is returned as the value of FAULTEVAL. If DWIM is called from FAULTAPPLY, this form is treated as a function to be applied to FAULTARGS, and the resulting value is returned as the value of FAULTAPPLY. If all of the expressions on DWIMUSERFORMS return NIL, DWIM proceeds as though DWIMUSERFORMS = NIL, and attempts spelling correction. Note that DWIM simply takes the value and returns it; the expressions on DWIMUSERFORMS are responsible for making any modifications to the original expression. The expressions on DWIMUSERFORMS should make the transformation permanent, either by associating it with FAULTX via CLISPTRAN, or by destructively changing FAULTX.

In order for an expression on DWIMUSERFORMS to be able to be effective, it needs to know various things about the context of the error. Therefore, several of DWIM’s internal variables have been made SPECVARS (see Chapter 18) and are therefore "visible" to DWIMUSERFORMS. Below are a list of those variables that may be useful.

**FAULTX**

[Variable]

For unbound atom and undefined car of form errors, FAULTX is the atom or form. For undefined function in APPLY errors, FAULTX is the name of the function.

**FAULTARGS**

[Variable]

For undefined function in APPLY errors, FAULTARGS is the list of arguments. FAULTARGS may be modified or reset by expressions on DWIMUSERFORMS.
FAULTAPPLYFLG  [Variable]
Value is T for undefined function in APPLY errors; NIL otherwise. The value of
FAULTAPPLYFLG after an expression on DWIMUSERFORMS returns a non-NIL value
determines how the latter value is to be treated. Following an undefined function in
APPLY error, if an expression on DWIMUSERFORMS sets FAULTAPPLYFLG to NIL, the
value returned is treated as a form to be evaluated, rather than a function to be applied.

FAULTAPPLYFLG is necessary to distinguish between unbound atom and undefined
function in APPLY errors, since FAULTARGS may be NIL and FAULTX atomic in both
cases.

TAIL  [Variable]
For unbound atom errors, TAIL is the tail of the expression CAR of which is the unbound
atom. DWIMUSERFORMS expression can replace the atom by another expression by
performing (/RPLACA TAIL EXPR)

PARENT  [Variable]
For unbound atom errors, PARENT is the form in which the unbound atom appears. TAIL
is a tail of PARENT.

TYPE-IN?  [Variable]
True if the error occurred in type-in.

FAULTFN  [Variable]
Name of the function in which error occurred. FAULTFN is TYPE-IN when the error
occurred in type-in, and EVAL or APPLY when the error occurred under an explicit call to
EVAL or APPLY.

DWIMIFYFLG  [Variable]
True if the error was encountered while DWIMIFYing (as opposed to happening while
running a program).

EXPR  [Variable]
Definition of FAULTFN, or argument to EVAL, i.e., the superform in which the error occurs.

The initial value of DWIMUSERFORMS is ((DWIMLOADFNS?)). DWIMLOADFNS? is a function for
automatically loading functions from files. If DWIMLOADFNSFLG is T (its initial value), and CAR of
the form is the name of a function, and the function is contained on a file that has been noticed by the file
package, the function is loaded, and the computation continues.
DWIM Functions and Variables

**DWIMWAIT**

[Variable]

Value is the number of seconds that DWIM will wait before it assumes that you are not going to respond to a question and uses the default response FIXSPELLDEFAULT.

DWIM operates by dismissing for 250 milliseconds, then checking to see if anything has been typed. If not, it dismisses again, etc. until DWIMWAIT seconds have elapsed. Thus, there will be a delay of at most 1/4 second before DWIM responds to your answer.

**FIXSPELLDEFAULT**

[Variable]

If approval is requested for a spelling correction, and you do not respond, defaults to value of FIXSPELLDEFAULT, initially Y. FIXSPELLDEFAULT is rebound to N when DWIMIFYing.

**ADDSPELLFLG**

[Variable]

If NIL, suppresses calls to ADDSPELL. Initially T.

**NOSPPELLFLG**

[Variable]

If T, suppresses all spelling correction. If some other non-NIL value, suppresses spelling correction in programs but not type-in. NOSPPELLFLG is initially NIL. It is rebound to T when compiling from a file.

**RUNONFLG**

[Variable]

If NIL, suppresses run-on spelling corrections. Initially NIL.

**DWIMLOADFNSFLG**

[Variable]

If T, tells DWIM that when it encounters a call to an undefined function contained on a file that has been noticed by the file package, to simply load the function. DWIMLOADFNSFLG is initially T (see above).

**LPARKEY**

**RPARKEY**

[Variable]

DWIM uses the value of the variables LPARKEY and RPARKEY (initially 9 and 0 respectively) to determine the corresponding lower case character for left and right parentheses. LPARKEY and RPARKEY can be reset for other keyboard layouts. For example, on some terminals left parenthesis is over 8, and right parenthesis is over 9.

**OKREEVALST**

[Variable]

The value of OKREEVALST is a list of functions that DWIM can safely reevaluate. If a form is atomic, or CAR of the form is a member of OKREEVALST, and each of the arguments can safely be reevaluated, then the form can be safely reevaluated. For example, (SETQ X (CONS (IPLUS Y Z) W)) is safe to reevaluate because SETQ, CONS, and IPLUS are all on OKREEVALST.
**DWIMFLG**

[Variable]

\[ \text{DWIMFLG} = \text{NIL}, \text{all DWIM operations are disabled.} \]
\( \text{(DWIM 'C)} \) and \( \text{(DWIM T)} \) set DWIMFLG to T; \( \text{(DWIM NIL)} \) sets DWIMFLG to NIL.

**APPROVEFLG**

[Variable]

\[ \text{APPROVEFLG} = \text{T} \text{ if DWIM should ask the user for approval before making a correction that will modify the definition of one of his functions; NIL otherwise.} \]

When DWIM is put into CAUTIOUS mode with \( \text{(DWIM 'C)} \), APPROVEFLG is set to T; for TRUSTING mode, APPROVEFLG is set to NIL.

**LAMBDASPLST**

[Variable]

DWIM uses the value of LAMBDASPLST as the spelling list when correcting "bad" function definitions. Initially \( \text{(LAMBDA NLAMBDA)} \). You may wish to add to LAMBDASPLST if you elect to define new "function types" via an appropriate DWIMUSERFORMS entry. For example, the QLAMBDA of SRI's QLISP are handled in this way.

**Spelling Correction**

The spelling corrector is given as arguments a misspelled word (word means symbol), a spelling list (a list of words), and a number: XWORD, SPLST, and REL respectively. Its task is to find that word on SPLST which is closest to XWORD, in the sense described below. This word is called a respelling of XWORD. REL specifies the minimum "closeness" between XWORD and a respelling. If the spelling corrector cannot find a word on SPLST closer to XWORD than REL, or if it finds two or more words equally close, its value is NIL, otherwise its value is the respelling. The spelling corrector can also be given an optional functional argument, FN, to be used for selecting out a subset of SPLST, i.e., only those members of SPLST that satisfy FN will be considered as possible respellings.

The exact algorithm for computing the spelling metric is described later, but briefly "closeness" is inversely proportional to the number of disagreements between the two words, and directly proportional to the length of the longer word. For example, PRTTYPRNT is "closer" to PRETTYPRINT than CS is to CONS even though both pairs of words have the same number of disagreements. The spelling corrector operates by proceeding down SPLST, and computing the closeness between each word and XWORD, and keeping a list of those that are closest. Certain differences between words are not counted as disagreements, for example a single transposition, e.g., CONS to CNOS, or a doubled letter, e.g., CONS to CONSS, etc. In the event that the spelling corrector finds a word on SPLST with no disagreements, it will stop searching and return this word as the respelling. Otherwise, the spelling corrector continues through the entire spelling list. Then if it has found one and only one "closest" word, it returns this word as the respelling. For example, if XWORD is VONS, the spelling corrector will probably return CONS as the respelling. However, if XWORD is CONZ, the spelling corrector will not be able to return a respelling, since CONZ is equally close to both CONS and COND. If the spelling corrector finds an acceptable respelling, it interacts with you as described earlier.
In the special case that the misspelled word contains one or more $s (escape), the spelling corrector searches for those words on SPLST that match XWORD, where a $ can match any number of characters (including 0), e.g., FOOS matches FO01 and FO0, but not NEWFOO. $FO0$ matches all three. Both completion and correction may be involved, e.g., RPETTE$ will match PRETTYPRINT, with one mistake. The entire spelling list is always searched, and if more than one respelling is found, the spelling corrector prints AMBIGUOUS, and returns NIL. For example, CONS would be ambiguous if both CONS and COND were on the spelling list. If the spelling corrector finds one and only one respelling, it interacts with you as described earlier.

For both spelling correction and spelling completion, regardless of whether or not you approve of the spelling corrector’s choice, the respelling is moved to the front of SPLST. Since many respellings are of the type with no disagreements, this procedure has the effect of considerably reducing the time required to correct the spelling of frequently misspelled words.

**Synonyms**

Spelling lists also provide a way of defining synonyms for a particular context. If a dotted pair appears on a spelling list (instead of just an atom), CAR is interpreted as the correct spelling of the misspelled word, and CDR as the antecedent for that word. If CAR is identical with the misspelled word, the antecedent is returned without any interaction or approval being necessary. If the misspelled word corrects to CAR of the dotted pair, the usual interaction and approval will take place, and then the antecedent, i.e., CDR of the dotted pair, is returned. For example, you could make IFLG synonymous with CLISPIFTRANFLG by adding (IFLG . CLISPIFTRANFLG) to SPELLINGS3, the spelling list for unbound atoms. Similarly, you could make OTHERWISE mean the same as ELSEIF by adding (OTHERWISE . ELSEIF) to CLISPIFWORDSPLST, or make L be synonymous with LAMBDA by adding (L . LAMBDA) to LAMBDASPLST. You can also use L as a variable without confusion, since the association of L with LAMBDA occurs only in the appropriate context.

**Spelling Lists**

Any list of atoms can be used as a spelling list, e.g., BROKENFNS, FILELST, etc. Various system packages have their own spellings lists, e.g., LISPXCOMS, CLISPFORWORDSPLST, EDITCOMSA, etc. These are documented under their corresponding sections, and are also indexed under “spelling lists.” In addition to these spelling lists, the system maintains, i.e., automatically adds to, and occasionally prunes, four lists used solely for spelling correction: SPELLINGS1, SPELLINGS2, SPELLINGS3, and USERWORDS. These spelling lists are maintained only when ADDSPELLFLG is non-NIL. ADDSPELLFLG is initially T.

**SPELLINGS1**

SPELLINGS1 is a list of functions used for spelling correction when an input is typed in apply format, and the function is undefined, e.g., EDITF(FOO). SPELLINGS1 is initialized to contain DEFINEQ, BREAK, MAKEFILE, EDITF, TCOMPL, LOAD, etc. Whenever LISPX is given an input in apply format, i.e., a function and arguments, the name of the function is added to SPELLINGS1 if the function has a definition.
For example, typing `CALLS (EDITF)` will cause `CALLS` to be added to `SPELLINGS1`. Thus if you typed `CALLS (EDITF)` and later typed `CALLLS (EDITV)`, since `SPELLINGS1` would then contain `CALLS`, DWIM would be successful in correcting `CALLLS` to `CALLS`.

**SPELLINGS2**

`SPELLINGS2` is a list of functions used for spelling correction for all other undefined functions. It is initialized to contain functions such as `ADD1`, `APPEND`, `COND`, `CONS`, `GO`, `LIST`, `NCONC`, `PRINT`, `PROG`, `RETURN`, `SETQ`, etc. Whenever `LISPX` is given a non-atomic form, the name of the function is added to `SPELLINGS2`. For example, typing `(RETFROM (STKPOS (QUOTE FOO) 2))` to a break would add `RETFROM` to `SPELLINGS2`. Function names are also added to `SPELLINGS2` by `DEFINE`, `DEFINEQ`, `LOAD` (when loading compiled code), `UNSAVEDEF`, `EDITF`, and `PRETTYPRINT`.

**SPELLINGS3**

`SPELLINGS3` is a list of words used for spelling correction on all unbound atoms. `SPELLINGS3` is initialized to `EDITMACROS`, `BREAKMACROS`, `BROKENFNS`, and `ADVISEDFNS`. Whenever `LISPX` is given an atom to evaluate, the name of the atom is added to `SPELLINGS3` if the atom has a value. Atoms are also added to `SPELLINGS3` whenever they are edited by `EDITV`, and whenever they are set via `RPAQ` or `RPAQQ`. For example, when a file is loaded, all of the variables set in the file are added to `SPELLINGS3`. Atoms are also added to `SPELLINGS3` when they are set by a `LISPX` input, e.g., typing `(SETQ FOO (REVERSE (SETQ FIE ...)))` will add both `FOO` and `FIE` to `SPELLINGS3`.

**USERWORDS**

`USERWORDS` is a list containing both functions and variables that you have referred to, e.g., by breaking or editing. `USERWORDS` is used for spelling correction by `ARGLIST`, `UNSAVEDEF`, `PRETTYPRINT`, `BREAK`, `EDITF`, `ADVISE`, etc. `USERWORDS` is initially `NIL`. Function names are added to it by `DEFINE`, `DEFINEQ`, `LOAD` (when loading compiled code, or loading exprs to property lists) `UNSAVEDEF`, `EDITF`, `EDITV`, `EDITP`, `PRETTYPRINT`, etc. Variable names are added to `USERWORDS` at the same time as they are added to `SPELLINGS3`. In addition, the variable `LASTWORD` is always set to the last word added to `USERWORDS`, i.e., the last function or variable referred to by the user, and the respelling of `NIL` is defined to be the value of `LASTWORD`. Thus, if you had just defined a function, you can then prettyprint it by typing `PP()`. Each of the above four spelling lists are divided into two sections separated by a special marker (the value of the variable `SPELLSTR1`). The first section contains the "permanent" words; the second section contains the temporary words. New words are added to the corresponding spelling list at the front of its temporary section (except that functions added to `SPELLINGS1` or `SPELLINGS2` by `LISPX` are always added to the end of the permanent section. If the word is already in the temporary section, it is moved to the front of that section; if the word is in the permanent section, no action is taken. If the length of the temporary section then exceeds a specified number, the last (oldest) word in the temporary section is forgotten, i.e., deleted. This procedure prevents the spelling lists from becoming cluttered with unimportant words that are no longer being used, and thereby slowing down spelling.
correction time. Since the spelling corrector usually moves each word selected as a respelling to the front of its spelling list, the word is thereby moved into the permanent section. Thus once a word is misspelled and corrected, it is considered important and will never be forgotten.

The spelling correction algorithm will not alter a spelling list unless it contains the special marker (the value of SPELLSTR1). This provides a way to ensure that a spelling list will not be altered.

Generators for Spelling Correction

For some applications, it is more convenient to generate candidates for a respelling one by one, rather than construct a complete list of all possible candidates, e.g., spelling correction involving a large directory of files, or a natural language data base. For these purposes, SPLST can be an array (of any size). The first element of this array is the generator function, which is called with the array itself as its argument. Thus the function can use the remainder of the array to store "state" information, e.g., the last position on a file, a pointer into a data structure, etc. The value returned by the function is the next candidate for respelling. If NIL is returned, the spelling "list" is considered to be exhausted, and the closest match is returned. If a candidate is found with no disagreements, it is returned immediately without waiting for the "list" to exhaust.

SPLST can also be a generator, i.e. the value of the function GENERATOR (Chapter 11). The generator SPLST will be started up whenever the spelling corrector needs the next candidate, and it should return candidates via the function PRODUCE. For example, the following could be used as a "spelling list" which effectively contains all functions in the system:

\[
\text{[GENERATOR MAPATOMS (FUNCTION (LAMBDA (X) (if (GETD X) then (PRODUCE X)))]}
\]

Spelling Corrector Algorithm

The basic philosophy of DWIM spelling correction is to count the number of disagreements between two words, and use this number divided by the length of the longer of the two words as a measure of their relative disagreement. One minus this number is then the relative agreement or closeness. For example, CONS and CONX differ only in their last character. Such substitution errors count as one disagreement, so that the two words are in 75% agreement. Most calls to the spelling corrector specify a relative agreement of 70, so that a single substitution error is permitted in words of four characters
or longer. However, spelling correction on shorter words is possible since certain types of differences such as single transpositions are not counted as disagreements. For example, AND and NAD have a relative agreement of 100. Calls to the spelling corrector from DWIM use the value of FIXSPELLREL, which is initially 70. Note that by setting FIXSPELLREL to 100, only spelling corrections with "zero" mistakes, will be considered, e.g., transpositions, double characters, etc.

The central function of the spelling corrector is CHOOZ. CHOOZ takes as arguments: a word, a minimum relative agreement, a spelling list, and an optional functional argument, XWORD, REL, SPLST, and FN respectively.

CHOOZ proceeds down SPLST examining each word. Words not satisfying FN (if FN is non-NIL), or those obviously too long or too short to be sufficiently close to XWORD are immediately rejected. For example, if REL = 70, and XWORD is 5 characters long, words longer than 7 characters will be rejected.

Special treatment is necessary for words shorter than XWORD, since doubled letters are not counted as disagreements. For example, CONNSSS and CONS have a relative agreement of 100. CHOOZ handles this by counting the number of doubled characters in XWORD before it begins scanning SPLST, and taking this into account when deciding whether to reject shorter words.

If TWORD, the current word on SPLST, is not rejected, CHOOZ computes the number of disagreements between it and XWORD by calling a subfunction, SKOR.

SKOR operates by scanning both words from left to right one character at a time. SKOR operates on the list of character codes for each word. This list is computed by CHOOZ before calling SKOR. Characters are considered to agree if they are the same characters or appear on the same key (i.e., a shift mistake). The variable SPELLCASEARRAY is a CASEARRAY which is used to determine equivalence classes for this purpose. It is initialized to equivalence lowercase and upper case letters, as well as the standard key transitions: for example, 1 with !, 3 with #, etc.

If the first character in XWORD and TWORD do not agree, SKOR checks to see if either character is the same as one previously encountered, and not accounted-for at that time. (In other words, transpositions are not handled by lookahead, but by lookback.) A displacement of two or fewer positions is counted as a tranposition; a displacement by more than two positions is counted as a disagreement. In either case, both characters are now considered as accounted for and are discarded, and SKORing continues.

If the first character in XWORD and TWORD do not agree, and neither agree with previously unaccounted-for characters, and TWORD has more characters remaining than XWORD, SKOR removes and saves the first character of TWORD, and continues by comparing the rest of TWORD with XWORD as described above. If TWORD has the same or fewer characters remaining than XWORD, the procedure is the same except that the character is removed from XWORD. In this case, a special check is first made to see if that character is equal to the previous character in XWORD, or to the next character in XWORD, i.e., a double character typo, and if so, the character is considered accounted-for, and not counted as a disagreement. In this case, the "length" of XWORD is also decremented. Otherwise making XWORD
sufficiently long by adding double characters would make it be arbitrarily close to `TWORD`, e.g., `XXXXXX` would correct to `PP`.

When `SKOR` has finished processing both `XWORD` and `TWORD` in this fashion, the value of `SKOR` is the number of unaccounted-for characters, plus the number of disagreements, plus the number of transpositions, with two qualifications:

1. If both `XWORD` and `TWORD` have a character unaccounted-for in the same position, the two characters are counted only once, i.e., substitution errors count as only one disagreement, not two
2. If there are no unaccounted-for characters and no disagreements, transpositions are not counted.

This permits spelling correction on very short words, such as edit commands, e.g., `XRT->XTR`. Transpositions are also not counted when `FASTYPEFLG = T`, for example, `IPULX` and `IPLUS` will be in 80% agreement with `FASTYPEFLG = T`, only 60% with `FASTYPEFLG = NIL`. The rationale behind this is that transpositions are much more common for fast typists, and should not be counted as disagreements, whereas more deliberate typists are not as likely to combine transpositions and other mistakes in a single word, and therefore can use more conservative metric. `FASTYPEFLG` is initially `NIL`.

### Spelling Corrector Functions and Variables

**ADDSPELL**

```
(ADDSPELL X SPLST N) [Function]
```

Adds `X` to one of the spelling lists as determined by the value of `SPLST`:

- `NIL`: Adds `X` to `USERWORDS` and to `SPELLINGS2`. Used by `DEFINEQ`.
- `0`: Adds `X` to `USERWORDS`. Used by `LOAD` when loading `EXPRs` to property lists.
- `1`: Adds `X` to `SPELLINGS1` (at end of permanent section). Used by `LISPX`.
- `2`: Adds `X` to `SPELLINGS2` (at end of permanent section). Used by `LISPX`.
- `3`: Adds `X` to `USERWORDS` and `SPELLINGS3`.

If `SPLST` is a spelling list, `X` is added to it. In this case, `N` is the (optional) length of the temporary section.

- ADDSPELL sets `LASTWORD` to `X` when `SPLST = NIL`, `0` or `3`.

If `X` is not a symbol, ADDSPELL takes no action.
Note that the various systems calls to ADDSPELL, e.g., from DEFINE, EDITF, LOAD, etc., can all be suppressed by setting or binding ADDSPELLFLG to NIL (see the DWIM Functions and Variables section above).

**MISSPELLED?**  
\[
\text{XWORD REL SPLST FLG TAIL FN}
\]

*Function*

If XWORD = NIL or $ (<esc>), MISSPELLED? prints = followed by the value of LASTWORD, and returns this as the respelling, without asking for approval. Otherwise, MISSPELLED? checks to see if XWORD is really misspelled, i.e., if FN applied to XWORD is true, or XWORD is already contained on SPLST. In this case, MISSPELLED? simply returns XWORD. Otherwise MISSPELLED? computes and returns (FIXSPELL XWORD REL SPLST FLG TAIL FN).

**FIXSPELL**  
\[
\text{XWORD REL SPLST FLG TAIL FN TIEFLG DONTMOVETOPFLG}
\]

*Function*

The value of FIXSPELL is either the respelling of XWORD or NIL. If for some reason XWORD itself is on, then FIXSPELL aborts and calls ERROR!. If there is a possibility that XWORD is spelled correctly, MISSPELLED? should be used instead of FIXSPELL. FIXSPELL performs all of the interactions described earlier, including requesting your approval if necessary.

If XWORD = NIL or $ (escape), the respelling is the value of LASTWORD, and no approval is requested.

If XWORD contains lowercase characters, and the corresponding uppercase word is correct, i.e. on SPLST or satisfies FN, the uppercase word is returned and no interaction is performed. If FIXSPELL.UPPERCASE.QUIET is NIL (the default), a warning "=XX" is printed when coercing from "xx" to "XX". If FIXSPELL.UPPERCASE.QUIET is non-NIL, no warning is given.

If REL = NIL, defaults to the value of FIXSPELLREL (initially 70).

If FLG = NIL, the correction is handled in type-in mode, i.e., approval is never requested, and XWORD is not typed. If FLG = T, XWORD is typed (before the =) and approval is requested if APPROVEFLG = T. If FLG = NO-MESSAGE, the correction is returned with no further processing. In this case, a run-on correction will be returned as a dotted pair of the two parts of the word, and a synonym correction as a list of the form (WORD1 WORD2), where WORD1 is (the corrected version of) XWORD, and WORD2 is the synonym. The effect of the function CHOOZ can be obtained by calling FIXSPELL with FLG = NO-MESSAGE.

If TAIL is not NIL, and the correction is successful, CAR of TAIL is replaced by the respelling (using /RPLACA).

FIXSPELL will attempt to correct misspellings caused by running two words together, if the global variable RUNONFLG is non-NIL (default is NIL). In this case, approval is always requested. When a run-on error is corrected, CAR of TAIL is replaced by the two words, and the value of FIXSPELL is the first one. For example, if FIXSPELL is called to correct the edit command (MOVE TO AFTERCOND 3 2) with TAIL = (AFTERCOND 3 2), TAIL would be changed to (AFTERCOND 2 3), and FIXSPELL would return AFTER (subject to your approval where necessary). If TAIL = T, FIXSPELL will also perform run-
on corrections, returning a dotted pair of the two words in the event the correction is of this type.

If \texttt{TIEFLG} = \texttt{NIL} and a tie occurs, i.e., more than one word on \texttt{SPLST} is found with the same degree of "closeness", \texttt{FIXSPELL} returns \texttt{NIL}, i.e., no correction. If \texttt{TIEFLG} = \texttt{PICKONE} and a tie occurs, the first word is taken as the correct spelling. If \texttt{TIEFLG} = \texttt{LIST}, the value of \texttt{FIXSPELL} is a list of the respellings (even if there is only one), and \texttt{FIXSPELL} will not perform any interaction with you, nor modify \texttt{TAIL}, the idea being that the calling program will handle those tasks. Similarly, if \texttt{TIEFLG} = \texttt{EVERYTHING}, a list of all candidates whose degree of closeness is above \texttt{REL} will be returned, regardless of whether some are better than others. No interaction will be performed.

If \texttt{DONTMOVETOPFLG} = \texttt{T} and a correction occurs, it will not be moved to the front of the spelling list. Also, the spelling list will not be altered unless it contains the special marker used to separate the temporary and permanent parts of the system spelling lists (the value of \texttt{SPELLSTR1}).

\textbf{(FNCHECK \texttt{FN NOERRORFLG SPELLFLG PROPFLG TAIL})} \quad \textit{[Function]}

The task of \texttt{FNCHECK} is to check whether \texttt{FN} is the name of a function and if not, to correct its spelling. If \texttt{FN} is the name of a function or spelling correction is successful, \texttt{FNCHECK} adds the (corrected) name of the function to \texttt{USERWORDS} using \texttt{ADDSPELL}, and returns it as its value.

Since \texttt{FNCHECK} is called by many low level functions such as \texttt{ARGLIST}, \texttt{UNSAVEDEF}, etc., spelling correction only takes place when \texttt{DWIMFLG} = \texttt{T}, so that these functions can operate in a small Interlisp system which does not contain \texttt{DWIM}.

\texttt{NOERRORFLG} informs \texttt{FNCHECK} whether or not the calling function wants to handle the unsuccessful case: if \texttt{NOERRORFLG} is \texttt{T}, \texttt{FNCHECK} simply returns \texttt{NIL}, otherwise it prints \texttt{fn NOT A FUNCTION} and generates a non-breaking error.

If \texttt{FN} does not have a definition, but does have an \texttt{EXPR} property, then spelling correction is not attempted. Instead, if \texttt{PROPFLG} = \texttt{T}, \texttt{FN} is considered to be the name of a function, and is returned. If \texttt{PROPFLG} = \texttt{NIL}, \texttt{FN} is not considered to be the name of a function, and \texttt{NIL} is returned or an error generated, depending on the value of \texttt{NOERRORFLG}.

\texttt{FNCHECK} calls \texttt{MISSPELLED?} to perform spelling correction, so that if \texttt{FN} = \texttt{NIL}, the value of \texttt{LASTWORD} will be returned. \texttt{SPELLFLG} corresponds to \texttt{MISSPELLED?}'s fourth argument, \texttt{FLG}. If \texttt{SPELLFLG} = \texttt{T}, approval will be asked if \texttt{DWIM} was enabled in \texttt{CAUTIOUS} mode, i.e., if \texttt{APPROVEFLG} = \texttt{T}. \texttt{TAIL} corresponds to the fifth argument to \texttt{MISSPELLED?}.

\texttt{FNCHECK} is currently used by \texttt{ARGLIST}, \texttt{UNSAVEDEF}, \texttt{PRETTYPRINT}, \texttt{BREAK0}, \texttt{BREAKIN}, \texttt{ADVISE}, and \texttt{CALLS}. For example, \texttt{BREAK0} calls \texttt{FNCHECK} with \texttt{NOERRORFLG} = \texttt{T} since if \texttt{FNCHECK} cannot produce a function, \texttt{BREAK0} wants to define a dummy one. \texttt{CALLS} however calls \texttt{FNCHECK} with \texttt{NOERRORFLG} = \texttt{NIL}, since it cannot operate without a function.
Many other system functions call \texttt{MISSPELLED\?} or \texttt{FIXSPELL} directly. For example, \texttt{BREAK1} calls \texttt{FIXSPELL} on unrecognized atomic inputs before attempting to evaluate them, using as a spelling list a list of all break commands. Similarly, \texttt{LISPX} calls \texttt{FIXSPELL} on atomic inputs using a list of all \texttt{LISPX} commands. When \texttt{UNBREAK} is given the name of a function that is not broken, it calls \texttt{FIXSPELL} with two different spelling lists, first with \texttt{BROKENFNS}, and if that fails, with \texttt{USERWORDS}. \texttt{MAKEFILE} calls \texttt{MISSPELLED\?} using \texttt{FILELST} as a spelling list. Finally, \texttt{LOAD}, \texttt{BCOMPL}, \texttt{BRECOMPILE}, \texttt{TCOMPL}, and \texttt{RECOMPILE} all call \texttt{MISSPELLED\?} if their input file(s) won’t open.
The syntax of Lisp is very simple. It can be described concisely, but it makes Lisp difficult to read and write without tools. Unlike many languages, there are no reserved words in Lisp such as IF, THEN, FOR, DO, etc., nor reserved characters like +, -, =, ←, etc. The only components of the language are atoms and delimiters. This eliminates the need for parsers and precedence rules, and makes Lisp programs easy to manipulate. For example, a Lisp interpreter can be written in one or two pages of Lisp code. This makes Lisp the most suitable programming language for writing programs that deal with other programs as data.

Human language is based on more complicated structures and relies more on special words to carry the meaning. The definition of the factorial function looks like this in Lisp:

```
(COND ((ZEROP N) 1) (T (TIMES N (FACTORIAL ((SUB1 N))))))
```

This definition is easy to read for a machine but difficult to read for a human. CLISP is designed to make Interlisp programs easier to read and write. CLISP does this by translating various operators, conditionals, and iterative statements to Interlisp. For example, factorial can be written in CLISP:

```
(IF N = 0 THEN 1 ELSE N* (FACTORIAL N-1))
```

CLISP will translate this expression to the form in the example above. The translation will take place when the form is read so there are no performance penalties.

You should view CLISP as a shorthand for producing Lisp programs. CLISP makes a program easy to read and sometimes more compact.

CLISP is implemented via the error correction machinery in Interlisp (see Chapter 20). Any expression that Interlisp thinks is well-formed will never be seen by CLISP. This means that interpreted programs that do not use CLISP constructs do not pay for its availability by slower execution time. In fact, the Interlisp interpreter does not know about CLISP at all. When the interpreter finds an error it calls an error routine which in turn invokes the Do-What-I-Mean (DWIM) analyzer. The DWIM analyzer knows how to deal with CLISP expressions. If the expression in question turns out to be a CLISP construct, the translated form is returned to the interpreter. In addition, the original CLISP expression is modified so that it becomes the correctly translated Interlisp form. In this way, the analysis and translation are done only once.

Integrating CLISP into Medley makes possible Do-What-I-Mean features for CLISP constructs as well as for pure Lisp expressions. For example, if you have defined a function named GET-PARENT, CLISP would know not to attempt to interpret the form (GET-PARENT) as an arithmetic infix operation. Actually, CLISP would never get to see this form, since it does not contain any errors. If you mistakenly write (GET-PRAENT), CLISP would know you meant (GET-PARENT), and not (DIFFERENCE GET PRAENT), by using the information that PARENT is not the name of a variable, and that GET-PARENT is the name of a user function whose spelling is "very close" to that of GET-
PRAENT. Similarly, by using information about the program’s environment not readily available to a preprocessor, CLISP can successfully resolve the following sorts of ambiguities:

1. \( (\text{LIST \ X*FACT \ N}) \), where FACT is the name of a variable, means \( (\text{LIST \ (X*FACT)} \ N) \).

2. \( (\text{LIST \ X*FACT \ N}) \), where FACT is not the name of a variable but instead is the name of a function, means \( (\text{LIST \ X*(FACT \ N)}) \), i.e., \( N \) is FACT’s argument.

3. \( (\text{LIST \ X*FACT(\(N)\)}) \), FACT the name of a function (and not the name of a variable), means \( (\text{LIST \ X*(FACT \ N)}) \).

4. Cases 1, 2 and 3 with FACT misspelled! The first expression is correct both from the standpoint of CLISP syntax and semantics so the change would be made notification. In the other cases, you would be informed or consulted about what was taking place. For example, suppose you write the expression \( (\text{LIST \ X*FCCT \ N}) \). Assume also that there was both a function named FACT and a variable named FCT.

1. You will first be asked if FCCT is a misspelling of FCT. If you say YES, the expression will be interpreted as \( (\text{LIST \ (X*FCT)} \ N) \). If you say NO, you will be asked if FCCT was a misspelling of FACT, i.e., if you intended \( X*FCCT \ N \) to mean \( X*(FACT \ N) \).

2. If you say YES to this question, the indicated transformation will be performed. If you say NO, the system will ask if \( X*FCCT \) should be treated as CLISP, since FCCT is not the name of a (bound) variable.

3. If you say YES, the expression will be transformed, if NO, it will be left alone, i.e., as \( (\text{LIST \ X*FCCT \ N}) \). Note that we have not even considered the case where \( X*FCCT \) is itself a misspelling of a variable name, e.g., a variable named XFCT (as with GET-PRAENT). This sort of transformation will be considered after you said NO to \( X*FCCT \) to mean \( X*(FACT \ N) \).

The question of whether \( X*FCCT \) should be treated as CLISP is important because Interlisp users may have programs that employ identifiers containing CLISP operators. Thus, if CLISP encounters the expression \( A/B \) in a context where either \( A \) or \( B \) are not the names of variables, it will ask you if \( A/B \) is intended to be CLISP, in case you really do have a free variable named \( A/B \).

Note: Through the discussion above, we speak of CLISP or DWIM asking you. Actually, if you typed in the expression in question for immediate execution, you are simply informed of the transformation, on the grounds that you would prefer an occasional misinterpretation rather than being continuously bothered, especially since you can always retype what you intended if a mistake occurs, and ask the programmer’s assistant to UNDO the effects of the mistaken operations if necessary. For transformations on expressions in your programs, you can tell CLISP whether you wish to operate in CAUTIOUS or TRUSTING mode. In the former case (most typical) you will be asked to approve transformations, in the latter, CLISP will operate as it does on type-in, i.e., perform the transformation after informing you.
CLISP

CLISP can also handle parentheses errors caused by typing 8 or 9 for ( or ). (On most terminals, 8 and 9 are the lowercase characters for ( and ), i.e., ( and 8 appear on the same key, as do ) and 9.) For example, if you write N*8FACTTORIAL N-1, the parentheses error can be detected and fixed before the infix operator * is converted to the Interlisp function TIMES. CLISP is able to distinguish this situation from cases like N*8*X meaning (TIMES N 8 X), or N*8X, where 8X is the name of a variable, again by using information about the programming environment. In fact, by integrating CLISP with DWIM, CLISP has been made sufficiently tolerant of errors that almost everything can be misspelled! For example, CLISP can successfully translate the definition of FACTORIAL:

\[(\text{IFF } N = 0 \text{ THEN } 1 \text{ ELSE } N*8\text{FACTTORIAL}N-1)\]

to the corresponding COND, while making five spelling corrections and fixing the parenthesis error. CLISP also contains a facility for converting from Interlisp back to CLISP, so that after running the above incorrect definition of FACTORIAL, you could “clispify” the now correct version to obtain \((\text{IF } N = 0 \text{ THEN 1 ELSE } N*(\text{FACTORIAL} N-1))\).

This sort of robustness prevails throughout CLISP. For example, the iterative statement permits you to say things like:

\[(\text{FOR OLD } X \text{ FROM } M \text{ TO } N \text{ DO (PRINT } X) \text{ WHILE (PRIMEP } X))\]

However, you can also write OLD (X←M), (OLD X←M), (OLD (X←M)), permute the order of the operators, e.g., (DO PRINT X TO N FOR OLD X←M WHILE PRIMEP X), omit either or both sets of parentheses, misspell any or all of the operators FOR, OLD, FROM, TO, DO, or WHILE, or leave out the word DO entirely! And, of course, you can also misspell PRINT, PRIMEP, M or N! In this example, the only thing you could not misspell is the first X, since it specifies the name of the variable of iteration. The other two instances of X could be misspelled.

CLISP is well integrated into Medley. For example, the above iterative statement translates into an equivalent Interlisp form using PROG, COND, GO, etc. When the interpreter subsequently encounters this CLISP expression, it automatically obtains and evaluates the translation. Similarly, the compiler “knows” to compile the translated form. However, if you PRETTYPRINT your program, PRETTYPRINT "knows" to print the original CLISP at the corresponding point in your function. Similarly, when you edit your program, the editor keeps the translation invisible to you. If you modify the CLISP, the translation is automatically discarded and recomputed the next time the expression is evaluated.

In short, CLISP is not a language at all, but rather a system. It plays a role analagous to that of the programmer’s assistant (Chapter 13). Whereas the programmer’s assistant is an invisible intermediary agent between your console requests and the Interlisp executive, CLISP sits between your programs and the Interlisp interpreter.

Only a small effort has been devoted to defining the core syntax of CLISP. Instead, most of the effort has been concentrated on providing a facility which “makes sense” out of the input expressions using context information as well as built-in and acquired information about user and system programs. It has been said that communication is based on the intention of the speaker to produce an effect in the
recipient. CLISP operates under the assumption that what you say is *intended* to represent a meaningful operation, and therefore tries very hard to make sense out of it. The motivation behind CLISP is not to provide you with many different ways of saying the same thing, but to enable you to worry less about the *syntactic* aspects of your communication with the system. In other words, it gives you a new degree of freedom by permitting you to concentrate more on the problem at hand, rather than on translation into a formal and unambiguous language.

DWIM and CLISP are invoked on iterative statements because `CAR` of the iterative statement is not the name of a function, and hence generates an error. If you define a function by the same name as an i.s. operator, e.g., `WHILE`, `TO`, etc., the operator will no longer have the CLISP interpretation when it appears as `CAR` of a form, although it will continue to be treated as an i.s. operator if it appears in the interior of an i.s. To alert you, a warning message is printed, e.g., `(WHILE DEFINED, THEREFORE DISABLED IN CLISP)`.

### CLISP Interaction with User

Syntactically and semantically well formed CLISP transformations are always performed without informing you. Other CLISP transformations described in the previous section, e.g., misspellings of operands, infix operators, parentheses errors, unary minus - binary minus errors, all follow the same protocol as other DWIM transformations (Chapter 19). That is, if DWIM has been enabled in TRUSTING mode, or the transformation is in an expression you typed in for immediate execution, your approval is not requested, but you are informed. However, if the transformation involves a user program, and DWIM was enabled in CAUTIOUS mode, you will be asked to approve. If you say *NO*, the transformation is not performed. Thus, in the previous section, phrases such as 'one of these (transformations) succeeds' and 'the transformation `LAST-ELL -> LAST-EL` would be found' etc., all mean if you are in CAUTIOUS mode and the error is in a program, the corresponding transformation will be performed only if you approve (or defaults by not responding). If you say *NO*, the procedure followed is the same as though the transformation had not been found. For example, if `A*B` appears in the function `FOO`, and `B` is not bound (and no other transformations are found) you would be asked `A*B [IN FOO] TREAT AS CLISP ?` (The waiting time on such interactions is three times as long as for simple corrections, i.e., `3*DWIMWAIT`).

In certain situations, DWIM asks for approval even if DWIM is enabled in TRUSTING mode. For example, you are always asked to approve a spelling correction that might also be interpreted as a CLISP transformation, as in `LAST-ELL -> LAST-EL`.

If you approved, `A*B` would be transformed to `(*TIMES A B)`, which would then cause a U.B.A.B. error in the event that the program was being run (remember the entire discussion also applies to DWIMifying). If you said *NO*, `A*B` would be left alone.

If the value of `CLISHELPFLG = NIL` (initially `T`), you will not be asked to approve any CLISP transformation. Instead, in those situations where approval would be required, the effect is the same as though you had been asked and said *NO*.
CLISP Character Operators

CLISP recognizes a number of special characters operators, both prefix and infix, which are translated into common expressions. For example, the character + is recognized to represent addition, so CLISP translates the symbol A+B to the form (PLUS A B). Note that CLISP is invoked, and this translation is made, only if an error occurs, such as an unbound atom error or an undefined function error for the perfectly legitimate symbol A+B. Therefore you may choose not to use these facilities with no penalty, similar to other CLISP facilities.

You have a lot of flexibility in using CLISP character operators. A list can always be substituted for a symbol, and vice versa, without changing the interpretation of a phrase. For example, if the value of (FOO X) is A, and the value of (FIE Y) is B, then (LIST (FOO X) + (FIE Y)) has the same value as (LIST A+B). Note that the first expression is a list of four elements: the atom "LIST", the list "(FOO X)", the atom "+", and the list "(FIE X)", whereas the second expression, (LIST A+B), is a list of only two elements: the symbol "LIST" and the symbol "A+B". Since (LIST (FOO X) + (FIE Y)) is indistinguishable from (LIST (FOO X) + (FIE Y)) because spaces before or after parentheses have no effect on the Interlisp READ program, to be consistent, extra spaces have no effect on atomic operands either. In other words, CLISP will treat (LIST A+ B), (LIST A +B), and (LIST A + B) the same as (LIST A+B).

Note: CLISP does not use its own special READ program because this would require you to explicitly identify CLISP expressions, instead of being able to intermix Interlisp and CLISP.

+ [CLISP Operator]
- [CLISP Operator]
* [CLISP Operator]
/ [CLISP Operator]
↑ [CLISP Operator]

CLISP recognizes +, -, *, /, and ↑ as the normal arithmetic infix operators. The - is also recognized as the prefix operator, unary minus. These are converted to PLISS, DIFFERENCE (or in the case of unary minus, MINUS), TIMES, QUOTIENT, and EXPT.

Normally, CLISP uses the "generic" arithmetic functions PLUS, TIMES, etc. CLISP contains a facility for declaring which type of arithmetic is to be used, either by making a global declaration, or by separate declarations about individual functions or variables.

The usual precedence rules apply (although you can easily change them), i.e., * has higher precedence than + so that A+B+C is the same as A+(B*C), and both * and / are lower than ↑ so that 2*X↑2 is the same as 2*(X↑2). Operators of the same precedence group from left to right, e.g., A/B/C is equivalent to (A/B)/C. Minus is binary whenever possible, i.e., except when it is the first operator in a list, as in (-A) or (-A), or when it immediately follows another operator, as in A*-B. Note that grouping with parentheses can always be used to override the normal precedence grouping, or when you are not sure how a particular expression will parse. The complete order of precedence for CLISP operators is given below.
Note that + in front of a number will disappear when the number is read, e.g., (FOO X +2) is indistinguishable from (FOO X 2). This means that (FOO X +2) will not be interpreted as CLISP, or be converted to (FOO (IPLUS X 2)). Similarly, (FOO X -2) will not be interpreted the same as (FOO X-2). To circumvent this, always type a space between the + or - and a number if an infix operator is intended, e.g., write (FOO X + 2).

\[\text{GT, LT, GE, LE}\]  
These are infix operators for "Equal", "Greater Than", "Less Than", "Greater Than or Equal", and "Less Than or Equal".

GT, LT, GE, and LE are all affected by the same declarations as + and *, with the initial default to use GREATERP and LESSP.

Note that only single character operators, e.g., +, ←, =, etc., can appear in the interior of an atom. All other operators must be set off from identifiers with spaces. For example, XLTY will not be recognized as CLISP. In some cases, DWIM will be able to diagnose this situation as a run-on spelling error, in which case after the atom is split apart, CLISP will be able to perform the indicated transformation.

A number of Lisp functions, such as \text{EQUAL}, \text{MEMBER}, \text{AND}, \text{OR}, etc., can also be treated as CLISP infix operators. New infix operators can be easily added (see the CLISP Internal Convetions section below). Spelling correction on misspelled infix operators is performed using CLISPINFIXSPLST as a spelling list.

\text{AND} is higher than \text{OR}, and both \text{AND} and \text{OR} are lower than the other infix operators, so (X OR Y AND Z) is the same as (X OR (Y AND Z)), and (X AND Y EQUAL Z) is the same as (X AND (Y EQUAL Z)). All of the infix predicates have lower precedence than Interlisp forms, since it is far more common to apply a predicate to two forms, than to use a Boolean as an argument to a function. Therefore, (FOO X GT FIE Y) is translated as ((FOO X) GT (FIE Y)), rather than as (FOO (X GT (FIE Y))). However, you can easily change this.

\text{CADR} extracts the \text{Nth} element of the list \text{X}. \text{FOO}:3 specifies the third element of \text{FOO}, or (CADDR FOO). If \text{N} is less than zero, this indicates elements counting from the end of the list; i.e. FOO: -1 is the last element of FOO. \text{operators} can be nested, so FOO:1:2 means the second element of the first element of FOO, or (CADAR FOO).

The : operator can also be used for extracting substructures of records (see Chapter 8). Record operations are implemented by replacing expressions of the form \text{X:FOO} by (fetch FOO of X). Both lower- and uppercase are acceptable.
CLISP

: is also used to indicate operations in the pattern match facility (see Chapter 12). X: (& 'A -- 'B) translates to (match X with (& 'A -- 'B))

[CLISP Operator]

In combination with ; a period can be used to specify the "data path" for record operations. For example, if FOO is a field of the BAR record, X:BAR.FOO is translated into (fetch (BAR FOO) of X). Subrecord fields can be specified with multiple periods: X:BAR.FOO.BAZ translates into (fetch (BAR FOO BAZ) of X).

Note: If a record contains fields with periods in them, CLISPIFY will not translate a record operation into a form using periods to specify the data path. For example, CLISPIFY will NOT translate (fetch A.B of X) into X:A.B.

::

[CLISP Operator]

X::N, returns the Nth tail of the list X. For example, FOO::3 is (CDDDR FOO), and FOO::-1 is (LAST FOO).

←

[CLISP Operator]

← is used to indicate assignment. For example, X←Y translates to (SETQ X Y). If X does not have a value, and is not the name of one of the bound variables of the function in which it appears, spelling correction is attempted. However, since this may simply be a case of assigning an initial value to a new free variable, DWIM will always ask for approval before making the correction.

In conjunction with : and ::, ← can also be used to perform a more general type of assignment, involving structure modification. For example, X:2←Y means "make the second element of X be Y", in Interlisp terms (RPLACA (CDR X) Y). Note that the value of this operation is the value of RPLACA, which is (CDR X), rather than Y. Negative numbers can also be used, e.g., X:-2←Y, which translates to (RPLACA (NLEFT X 2) Y).

You can indicate you want /RPLACA and /RPLACD used (undoable version of RPLACA and RPLACD, see Chapter 13), or FRPLACA and FRPLACD (fast versions of RPLACA and RPLACD, see Chapter 3), by means of CLISP declarations. The initial default is to use RPLACA and RPLACD.

← is also used to indicate assignment in record operations (X:FOO←Y translates to (replace FOO of X with Y)), and pattern match operations (Chapter 12).

← has different precedence on the left from on the right. On the left, ← is a "tight" operator, i.e., high precedence, so that A+B←C is the same as A+ (B←C). On the right, ← has broader scope so that A←B+C is the same as A← (B+C).

On type-in, $←FORM (where $ is the escape key) is equivalent to set the "last thing mentioned", i.e., is equivalent to (SET LASTWORD FORM) (see Chapter 20). For example,
immediately after examining the value of \texttt{LONGVARIABLENAME}, you could set it by typing \\
\texttt{$\leftarrow$} followed by a form.

Note that an atom of the form \texttt{X$\leftarrow$Y}, appearing at the top level of a \texttt{PROG}, will not be recognized as an assignment statement because it will be interpreted as a \texttt{PROG} label by the Interlisp interpreter, and therefore will not cause an error, so \texttt{DWIM} and \texttt{CLISP} will never get to see it. Instead, one must write \texttt{(X$\leftarrow$Y)}.

Angle brackets are used in \texttt{CLISP} to indicate list construction. The appearance of a '"<' corresponds to a '"(' and indicates that a list is to be constructed containing all the elements up to the corresponding '">'. For example, \texttt{<A B <C>} translates to \texttt{(LIST A B (LIST C))}. ! can be used to indicate that the next expression is to be inserted in the list as a segment, e.g., \texttt{<A B ! C>} translates to \texttt{(CONS A (CONS B C))} and \texttt{<! A ! B C>} to \texttt{(APPEND A B (LIST C))}. !! is used to indicate that the next expression is to be inserted as a segment, and furthermore, all list structure to its right in the angle brackets is to be physically attached to it, e.g., \texttt{<!! A B>} translates to \texttt{(NCONC A (APPEND B C))}, and \texttt{<! A ! B ! C>} to \texttt{(NCONC A (APPEND B C)).} Not (\texttt{NCONC (APPEND A B) C}), which would have the same value, but would attach C to B, and not attach either to A. Note that <, !, !, and > need not be separate atoms, for example, \texttt{<A B ! C>} may be written equally well as \texttt{< A B ! C >}. Also, arbitrary Interlisp or \texttt{CLISP} forms may be used within angle brackets. For example, one can write \texttt{<FOO$\leftarrow$($\texttt{FIE}$ X) ! Y>} which translates to \texttt{(CONS (SETQ FOO ($\texttt{FIE}$ X)) Y)}. \texttt{CLISPIFY} converts expressions in \texttt{CONS, LIST, APPEND, NCONC, NCONC1, /NCONC, and /NCONC1} into equivalent \texttt{CLISP} expressions using <, >, !, and !!.

Note: brackets differ from other \texttt{CLISP} operators. For example, \texttt{<A B 'C>} translates to \texttt{(LIST A B (QUOTE C))} even though following '"', all operators are ignored for the rest of the identifier. (This is true only if a previous unmatched < has been seen, e.g., \texttt{(PRINT 'A>B)} will print the atom \texttt{A>B}.) Note however that \texttt{<A B 'C> D>} is equivalent to \texttt{(LIST A B (QUOTE C)) D)}.

\texttt{CLISP} recognizes '"' as a prefix operator. '"' means \texttt{QUOTE} when it is the first character in an identifier, and is ignored when it is used in the interior of an identifier. Thus, \texttt{X = 'Y} means \texttt{(EQ X (QUOTE Y))}, but \texttt{X = CAN'T} means \texttt{(EQ X CAN'T)}, \texttt{not (EQ X CAN)} followed by \texttt{(QUOTE T)}. This enables users to have variable and function names with '"' in them (so long as the '"' is not the first character).

Following '"', all operators are ignored for the rest of the identifier, e.g., '"*A means \texttt{(QUOTE *A)}, and '"*X=Y means \texttt{(QUOTE X=Y)}, \texttt{not (EQ (QUOTE X) Y)}. To write \texttt{(EQ (QUOTE X) Y)}, one writes \texttt{Y='X}, or '"X =Y. This is one place where an extra space does make a difference.
CLISP

On type-in, ' $ (escape) is equivalent to (QUOTE VALUE-OF-LASTWORD) (see Chapter 19). For example, after calling PRETTYPRINT on LONGFUNCTION, you could move its definition to FOO by typing (MOVQ ' $ 'FOO).

Note that this is not (MOVQ $ 'FOO), which would be equivalent to (MOVQ LONGFUNCTION 'FOO), and would (probably) cause a U.B.A. LONGFUNCTION error, nor MOVQ($ FOO), which would actually move the definition of $ to FOO, since DWIM and the spelling corrector would never be invoked.

CLISP

CLISP recognizes - as a prefix operator meaning NOT. - can negate a form, as in -(ASSOC X Y), or -X, or negate an infix operator, e.g., (A -GT B) is the same as (A LEQ B). Note that -A = B means (EQ (NOT A) B).

When - negates an operator, e.g., -=, -LT, the two operators are treated as a single operator whose precedence is that of the second operator. When - negates a function, e.g., (-FOO X Y), it negates the whole form, i.e., (- (FOO X Y)).

Order of Precedence of CLISP Operators:

- (left precedence)
  <- (left precedence)
  - (unary), -
  ↑
  *, /
  +, - (binary)
  <- (right precedence)

Interlisp forms

LT, GT, EQUAL, MEMBER, etc.
AND
OR
IF, THEN, ELSEIF, ELSE
iterative statement operators

Declarations

CLISP declarations are used to affect the choice of Interlisp function used as the translation of a particular operator. For example, A+B can be translated as either (PLUS A B), (FPLUS A B), or (IPLUS A B), depending on the declaration in effect. Similarly X:14–Y can mean (RPLACA X Y), (FRPLACA X Y), or (/RPLACA X Y), and <!! A B> either (NCONC1 A B) or (/NCONC1 A B). Note that the choice of function on all CLISP transformations are affected by the CLISP declaration in
effect, i.e., iterative statements, pattern matches, record operations, as well as infix and prefix operators.

**(CLISPDEC DECLST)**  

[Function]  

Puts into effect the declarations in DECLST. CLISPDEC performs spelling corrections on words not recognized as declarations. CLISPDEC is undoable.

You can make (changes) a global declaration by calling CLISPDEC with DECLST a list of declarations, e.g., (CLISPDEC "((FLOATING UNDOABLE))"). Changing a global declaration does not affect the speed of subsequent CLISP transformations, since all CLISP transformation are table driven (i.e., property list), and global declarations are accomplished by making the appropriate internal changes to CLISP at the time of the declaration. If a function employs local declarations (described below), there will be a slight loss in efficiency owing to the fact that for each CLISP transformation, the declaration list must be searched for possibly relevant declarations.

Declarations are implemented in the order that they are given, so that later declarations override earlier ones. For example, the declaration FAST specifies that FRPLACA, FRPLACD, FMEMB, and FLAST be used in place of RPLACA, RPLACD, MEMB, and LAST; the declaration RPLACA specifies that RPLACA be used. Therefore, the declarations (FAST RPLACA RPLACD) will cause FMEMB, FLAST, RPLACA, and RPLACD to be used.

The initial global declaration is MIXED and STANDARD.

The table below gives the declarations available in CLISP, and the Interlisp functions they indicate:

<table>
<thead>
<tr>
<th>Declaration</th>
<th>Interlisp Functions to be used:</th>
</tr>
</thead>
<tbody>
<tr>
<td>MIXED</td>
<td>PLUS, MINUS, DIFFERENCE, TIMES, QUOTIENT, LESSP, GREATERP</td>
</tr>
<tr>
<td>INTEGER or FIXED</td>
<td>IPLUS, IMINUS, IDIFFERENCE, ITIMES, IQUOTIENT, ILESSP, IGREATERP</td>
</tr>
<tr>
<td>FLOATING</td>
<td>FPLUS, FMINUS, FDIFFERENCE, FTIMES, FQUOTIENT, LESSP, FGREATERP</td>
</tr>
<tr>
<td>FAST</td>
<td>FRPLACA, FRPLACD, FMEMB, FLAST, FASSOC</td>
</tr>
<tr>
<td>UNDOABLE</td>
<td>/RPLACA, /RPLACD, /NCONC, /NCONC1, /MAPCONC, /MAPCON</td>
</tr>
<tr>
<td>STANDARD</td>
<td>RPLACA, RPLACD, MEMB, LAST, ASSOC, NCONC, NCONC1, MAPCONC, MAPCON</td>
</tr>
<tr>
<td>RPLACA, RPLACD, /RPLACA, etc.</td>
<td>corresponding function</td>
</tr>
</tbody>
</table>

You can also make local declarations affecting a selected function or functions by inserting an expression of the form (CLISP: . DECLARATIONS) immediately following the
argument list, i.e., as CADDR of the definition. Such local declarations take precedence over global declarations. Declarations affecting selected variables can be indicated by lists, where the first element is the name of a variable, and the rest of the list the declarations for that variable. For example, (CLISP: FLOATING (X INTEGER)) specifies that in this function integer arithmetic be used for computations involving X, and floating arithmetic for all other computations, where "involving" means where the variable itself is an operand. For example, with the declaration (FLOATING (X INTEGER)) in effect, (FOO X)+(FIE X) would translate to FPLUS, i.e., use floating arithmetic, even though X appears somewhere inside of the operands, whereas X+(FIE X) would translate to IPLUS. If there are declarations involving both operands, e.g., X+Y, with (X FLOATING) (Y INTEGER), whichever appears first in the declaration list will be used.

You can also make local record declarations by inserting a record declaration, e.g., (RECORD --), (ARRAYRECORD --), etc., in the local declaration list. In addition, a local declaration of the form (RECORDS A B C) is equivalent to having copies of the global declarations A, B, and C in the local declaration. Local record declarations override global record declarations for the function in which they appear. Local declarations can also be used to override the global setting of certain DWIM/CLISP parameters effective only for transformations within that function, by including in the local declaration an expression of the form (VARIABLE = VALUE), e.g., (PATVARDEFAULT = QUOTE).

The CLISP: expression is converted to a comment of a special form recognized by CLISP. Whenever a CLISP transformation that is affected by declarations is about to be performed in a function, this comment will be searched for a relevant declaration, and if one is found, the corresponding function will be used. Otherwise, if none are found, the global declaration(s) currently in effect will be used.

Local declarations are effective in the order that they are given, so that later declarations can be used to override earlier ones, e.g., (CLISP: FAST RPLACA RPLACD) specifies that FMEMB, FLAST, RPLACA, and RPLACD be used. An exception to this is that declarations for specific variables take precedence of general, function-wide declarations, regardless of the order of appearance, as in (CLISP: (X INTEGER) FLOATING).

CLISPIFY also checks the declarations in effect before selecting an infix operator to ensure that the corresponding CLISP construct would in fact translate back to this form. For example, if a FLOATING declaration is in effect, CLISPIFY will convert (FPLUS X Y) to X+Y, but leave (IPLUS X Y) as is. If (FPLUS X Y) is CLISPIFYed while a FLOATING declaration is under effect, and then the declaration is changed to INTEGER, when X+Y is translated back to Interlisp, it will become (IPLUS X Y).

**CLISP Operation**

CLISP is a part of the basic Medley system. Without any special preparations, you can include CLISP constructs in programs, or type them in directly for evaluation (in EVAL or APPLY format), then, when the "error" occurs, and DWIM is called, it will destructively transform the CLISP to the equivalent Interlisp expression and evaluate the Interlisp expression. CLISP transformations, like all DWIM
corrections, are undoable. User approval is not requested, and no message is printed. This entire discussion also applies to CLISP transformation initiated by calls to DWIM from DWIMIFY.

However, if a CLISP construct contains an error, an appropriate diagnostic is generated, and the form is left unchanged. For example, if you write `(LIST X+Y*)`, the error diagnostic `MISSING OPERAND AT X+Y* IN (LIST X+Y*)` would be generated. Similarly, if you write `(LAST+EL X)`, CLISP knows that `((IPLUS LAST EL) X)` is not a valid Interlisp expression, so the error diagnostic `MISSING OPERATOR IN (LAST+EL X)` is generated. (For example, you might have meant to say `(LAST+EL*X)`.) If LAST+EL were the name of a defined function, CLISP would never see this form.

Since the bad CLISP transformation might not be CLISP at all, for example, it might be a misspelling of a user function or variable, DWIM holds all CLISP error messages until after trying other corrections. If one of these succeeds, the CLISP message is discarded. Otherwise, if all fail, the message is printed (but no change is made). For example, suppose you type `(R/PLACA X Y)`. CLISP generates a diagnostic, since `((IQUOTIENT R PLACA) X Y)` is obviously not right. However, since `R/PLACA` spelling corrects to `/RPLACA`, this diagnostic is never printed.

Note: CLISP error messages are not printed on type-in. For example, typing `X+*Y` will just produce a U.B.A. `X+*Y` message.

If a CLISP infix construct is well formed from a syntactic standpoint, but one or both of its operands are atomic and not bound, it is possible that either the operand is misspelled, e.g., you wrote `X+YY` for `X+Y`, or that a CLISP transformation operation was not intended at all, but that the entire expression is a misspelling. For the purpose of DWIMIFYing, "not bound" means no top level value, not on list of bound variables built up by DWIMIFY during its analysis of the expression, and not on NOFIXVARS, i.e., not previously seen.

For example, if you have a variable named `LAST-EL`, and write `(LIST LAST-ELL)`. Therefore, CLISP computes, but does not actually perform, the indicated infix transformation. DWIM then continues, and if it is able to make another correction, does so, and ignores the CLISP interpretation. For example, with `LAST-ELL`, the transformation `LAST-ELL` -> `LAST-EL` would be found.

If no other transformation is found, and DWIM is about to interpret a construct as CLISP for which one of the operands is not bound, DWIM will ask you whether CLISP was intended, in this case by printing `LAST-ELL TREAT AS CLISP ?`.

Note: If more than one infix operator was involved in the CLISP construct, e.g., `X+Y+Z`, or the operation was an assignment to a variable already noticed, or TREATASCLISPFLG is T (initially NIL), you will simply be informed of the correction, e.g., `X+Y+Z TREATED AS CLISP`. Otherwise, even if DWIM was enabled in TRUSTING mode, you will be asked to approve the correction.

The same sort of procedure is followed with 8 and 9 errors. For example, suppose you write `FOO8*X` where `FOO8` is not bound. The CLISP transformation is noted, and DWIM proceeds. It next asks you to approve `FOO8*X` -> `FOO ( *X`. For example, this would make sense if you have (or plan to define) a function named `*X`. If you refuses, you are asked whether `FOO8*X` is to be treated as CLISP.
Similarly, if \textit{FO08} were the name of a variable, and you write \texttt{FO08*X}, you will first be asked to approve \texttt{FO08*X} -> \texttt{FOO (XX}, and if you refuse, then be offered the \texttt{FO08} -> \texttt{FOO8} correction. The 8-9 transformation is tried before spelling correction since it is empirically more likely that an unbound atom or undefined function containing an 8 or a 9 is a parenthesis error, rather than a spelling error.

CLISP also contains provision for correcting misspellings of infix operators (other than single characters), \texttt{IF} words, and i.s. operators. This is implemented in such a way that the user who does not misspell them is not penalized. For example, if you write \texttt{IF N = 0 \textit{ELSE N*(FACT N-1)}} CLISP does not operate by checking each word to see if it is a misspelling of \texttt{IF, THEN, ELSE, or ELSEIF}, since this would seriously degrade CLISP’s performance on all \texttt{IF} statements. Instead, CLISP assumes that all of the \texttt{IF} words are spelled correctly, and transforms the expression to \texttt{COND ((ZEROP N) 1 \textit{ELSE N*(FACT N-1))}. Later, after DWIM cannot find any other interpretation for \texttt{ELSE}, and using the fact that this atom originally appeared in an \texttt{IF} statement, DWIM attempts spelling correction, using \texttt{(IF THEN ELSE ELSEIF)} for a spelling list. When this is successful, DWIM “fails” all the way back to the original \texttt{IF} statement, changes \texttt{ELSE} to \texttt{ELSE}, and starts over. Misspellings of \texttt{ANID, OR, LT, GT}, etc. are handled similarly.

CLISP also contains many Do-What-I-Mean features besides spelling corrections. For example, the form \texttt{(LIST +X Y)} would generate a \texttt{MISSING OPERATOR} error. However, \texttt{(LIST -X Y)} makes sense, if the minus is unary, so DWIM offers this interpretation to you. Another common error, especially for new users, is to write \texttt{(LIST X*FOO(Y))} or \texttt{(LIST X*FOO Y)}, where \texttt{FOO} is the name of a function, instead of \texttt{(LIST X*(FOO Y))}. Therefore, whenever an operand that is not bound is also the name of a function (or corrects to one), the above interpretations are offered.

\section*{CLISP Translations}

The translation of CLISP character operators and the CLISP word \texttt{IF} are handled by replacing the CLISP expression with the corresponding Interlisp expression, and discarding the original CLISP. This is done because (1) the CLISP expression is easily recomputable (by \texttt{CLISPIFY}) and (2) the Interlisp expressions are simple and straightforward. Another reason for discarding the original CLISP is that it may contain errors that were corrected in the course of translation (e.g., \texttt{FOO<->FOO:1, N*8FOO X}), etc.). If the original CLISP were retained, either you would have to go back and fix these errors by hand, thereby negating the advantage of having DWIM perform these corrections, or else DWIM would have to keep correcting these errors over and over.

Note that \texttt{CLISPIFY} is sufficiently fast that it is practical for you to configure your Interlisp system so that all expressions are automatically \texttt{CLISPIFYed} immediately before they are presented to you. For example, you can define an edit macro to use in place of \texttt{P} which calls \texttt{CLISPIFY} on the current expression before printing it. Similarly, you can inform \texttt{PRETTYPRINT} to call \texttt{CLISPIFY} on each expression before printing it, etc.

Where (1) or (2) are not the case, e.g., with iterative statements, pattern matches, record expressions, etc. the original CLISP is retained (or a slightly modified version thereof), and the translation is stored
elsewhere (by the function CLISPTRAN, in the Miscellaneous Functions and Variables), usually in the hash array CLISPARRAY. The interpreter automatically checks this array when given a form CAR of which is not a function. Similarly, the compiler performs a GETHASH when given a form it does not recognize to see if it has a translation, which is then compiled instead of the form. Whenever you change a CLISP expression by editing it, the editor automatically deletes its translation (if one exists), so that the next time it is evaluated or DWIMIFIED, the expression will be retranslated (if the value of CLISPRETRANFLG is T, DWIMIFY will also (re)translate any expressions which have translations stored remotely, see the CLISPIFY section). The function PFT and the edit commands PFT and CLISP: are available for examining translations (see the Miscellaneous Functions and Variables section).

You can also indicate that you want the original CLISP retained by embedding it in an expression of the form (CLISP . CLISP-EXPRESSION), e.g., (CLISP X:5:3) or (CLISP <A B C ! D>). In such cases, the translation will be stored remotely as described above. Furthermore, such expressions will be treated as CLISP even if infix and prefix transformations have been disabled by setting CLISPFCLG to NIL (see the Miscellaneous Functions and Variables section). In other words, you can instruct the system to interpret as CLISP infix or prefix constructs only those expressions that are specifically flagged as such. You can also include CLISP declarations by writing (CLISP DECLARATIONS . FORM), e.g., (CLISP (CLISP: FLOATING) ...). These declarations will be used in place of any CLISP declarations in the function definition. This feature provides a way of including CLISP declarations in macro definitions.

Note: CLISP translations can also be used to supply an interpretation for function objects, as well as forms, either for function objects that are used openly, i.e., appearing as CAR of form, function objects that are explicitly APPLYed, as with arguments to mapping functions, or function objects contained in function definition cells. In all cases, if CAR of the object is not LAMBDA or NLAMBDA, the interpreter and compiler will check CLISPARRAY.

**DWIMIFY**

DWIMIFY is effectively a preprocessor for CLISP. DWIMIFY operates by scanning an expression as though it were being interpreted, and for each form that would generate an error, calling DWIM to "fix" it. DWIMIFY performs all DWIM transformations, not just CLISP transformations, so it does spelling correction, fixes 8-9 errors, handles F/L, etc. Thus you will see the same messages, and be asked for approval in the same situations, as you would if the expression were actually run. If DWIM is unable to make a correction, no message is printed, the form is left as it was, and the analysis proceeds.

DWIMIFY knows exactly how the interpreter works. It knows the syntax of PROGS, SELECTQs, LAMBDA expressions, SETQs, et al. It knows how variables are bound, and that the argument of NLAMBDA are not evaluated (you can inform DWIMIFY of a function or macro's nonstandard binding or evaluation by giving it a suitable INFO property, see below). In the course of its analysis of a particular expression, DWIMIFY builds a list of the bound variables from the LAMBDA expressions and PROGs that it encounters. It uses this list for spelling corrections. DWIMIFY also knows not to try to
"correct" variables that are on this list since they would be bound if the expression were actually being run. However, note that DWIMIFY cannot, a priori, know about variables that are used freely but would be bound in a higher function if the expression were evaluated in its normal context. Therefore, DWIMIFY will try to "correct" these variables. Similarly, DWIMIFY will attempt to correct forms for which CAR is undefined, even when the form is not in error from your standpoint, but the corresponding function has simply not yet been defined.

Note: DWIMIFY rebinds FIXSPELLDEFAULT to N, so that if you are not at the terminal when DWIMIFYing (or compiling), spelling corrections will not be performed.

DWIMIFY will also inform you when it encounters an expression with too many arguments (unless DWIMCHECKARGSFLG = NIL), because such an occurrence, although does not cause an error in the Interlisp interpreter, nevertheless is frequently symptomatic of a parenthesis error. For example, if you wrote (CONS (QUOTE FOO X)) instead of (CONS (QUOTE FOO) X), DWIMIFY will print:

POSSIBLE PARENTHESIS ERROR IN
(QUOTE FOO X)
TOO MANY ARGUMENTS (MORE THAN 1)

DWIMIFY will also check to see if a PROG label contains a clisp character (unless DWIMCHECKPROGLABELSFLG = NIL, or the label is a member of NOFIXVARSLST), and if so, will alert you by printing the message SUSPICIOUS PROG LABEL, followed by the label. The PROG label will not be treated as CLISP.

Note that in most cases, an attempt to transform a form that is already as you intended will have no effect (because there will be nothing to which that form could reasonably be transformed). However, in order to avoid needless calls to DWIM or to avoid possible confusion, you can inform DWIMIFY not to attempt corrections or transformations on certain functions or variables by adding them to the list NOFIXFNSLST or NOFIXVARSLST respectively. Note that you could achieve the same effect by simply setting the corresponding variables, and giving the functions dummy definitions.

DWIMIFY will never attempt corrections on global variables, i.e., variables that are a member of the list GLOBALVARS, or have the property GLOBALVAR with value T, on their property list. Similarly, DWIMIFY will not attempt to correct variables declared to be SPECVARS in block declarations or via DECLARE expressions in the function body. You can also declare variables that are simply used freely in a function by using the USEDFREE declaration.

DWIMIFY and DWIMIFYFNS (used to DWIMIFY several functions) maintain two internal lists of those functions and variables for which corrections were unsuccessfully attempted. These lists are initialized to the values of NOFIXFNSLST and NOFIXVARSLST. Once an attempt is made to fix a particular function or variable, and the attempt fails, the function or variable is added to the corresponding list, so that on subsequent occurrences (within this call to DWIMIFY or DWIMIFYFNS), no attempt at correction is made. For example, if FOO calls FIE several times, and FIE is undefined at the time FOO is DWIMIFYed, DWIMIFY will not bother with FIE after the first occurrence. In other words, once DWIMIFY "notices" a function or variable, it no longer attempts to correct it. DWIMIFY and DWIMIFYFNS also "notice" free variables that are set in the expression being processed.
Moreover, once DWIMIFY "notices" such functions or variables, it subsequently treats them the same as though they were actually defined or set.

Note that these internal lists are local to each call to DWIMIFY and DWIMIFYFNS, so that if a function containing FOO, a misspelled call to FOO, is DWIMIFYed before FOO is defined or mentioned, if the function is DWIMIFYed again after FOO has been defined, the correction will be made.

You can undo selected transformations performed by DWIMIFY, as described in Chapter 13.

**(DWIMIFY X QUIETFLG L)**

Performs all DWIM and CLISP corrections and transformations on X that would be performed if X were run, and prints the result unless QUIETFLG = T.

If X is an atom and L is NIL, X is treated as the name of a function, and its entire definition is DWIMIFYed. If X is a list or L is not NIL, X is the expression to be DWIMIFYed. If L is not NIL, it is the edit push-down list leading to X, and is used for determining context, i.e., what bound variables would be in effect when X was evaluated, whether X is a form or sequence of forms, e.g., a COND clause, etc.

If X is an iterative statement and L is NIL, DWIMIFY will also print the translation, i.e., what is stored in the hash array.

**(DWIMIFYFNS FN₁ ... FNₙ)**

DWIMIFYs each of the functions given. If only one argument is given, it is evaluated. If its value is a list, the functions on this list are DWIMIFYed. If only one argument is given, it is atomic, its value is not a list, and it is the name of a known file, DWIMIFYFNS will operate on (FILEFNSLST FN₁), e.g. (DWIMIFYFNS FOO.LSP) will DWIMIFY every function in the file FOO.LSP.

Every 30 seconds, DWIMIFYFNS prints the name of the function it is processing, a la PRETTYPRINT.

Value is a list of the functions DWIMIFYed.

**DWIMINMACROSFLG**

[Variable]

Controls how DWIMIFY treats the arguments in a "call" to a macro, i.e., where the CAR of the form is undefined, but has a macro definition. If DWIMINMACROSFLG is T, then macros are treated as LAMBDA functions, i.e., the arguments are assumed to be evaluated, which means that DWIMIFY will descend into the argument list. If DWIMINMACROSFLG is NIL, macros are treated as NLAMBDA functions. DWIMINMACROSFLG is initially T.

**INFO**

[Property Name]

Used to inform DWIMIFY of nonstandard behavior of particular forms with respect to evaluation, binding of arguments, etc. The INFO property of a symbol is a single atom or list of atoms chosen from among the following:
EVAL  Informs DWIMIFY (and CLISP and Masterscope) that an
nlambda function does evaluate its arguments. Can also be
placed on a macro name to override the behavior of
DWIMINMACROSFLG = NIL.

NOEVAL  Informs DWIMIFY that a macro does not evaluate all of its
arguments, even when DWIMINMACROSFLG = T.

BINDS  Placed on the INFO property of a function or the CAR of a
special form to inform DWIMIFY that the function or form
binds variables. In this case, DWIMIFY assumes that CADR
of the form is the variable list, i.e., a list of symbols, or lists
of the form (VAL VALUE). LAMBDA, NLAMBDA, PROG, and
RESETVARS are handled in this fashion.

LABELS  Informs CLISPIFY that the form interprets top-level
symbols as labels, so that CLISPIFY will never introduce
an atom (by packing) at the top level of the expression.
PROG is handled in this fashion.

NOFIXFNSLST  [Variable]
List of functions that DWIMIFY will not try to correct.

NOFIXVARSLST  [Variable]
List of variables that DWIMIFY will not try to correct.

NOSPELLFLG  [Variable]
If T, DWIMIFY will not perform any spelling corrections. Initially NIL. NOSPELLFLG is
reset to T when compiling functions whose definitions are obtained from a file, as
opposed to being in core.

CLISPHELPFLG  [Variable]
If NIL, DWIMIFY will not ask you for approval of any CLISP transformations. Instead, in
those situations where approval would be required, the effect is the same as though you
had been asked and said NO. Initially T.

DWIMIFYCOMPFLG  [Variable]
If T, DWIMIFY is called before compiling an expression. Initially NIL.

DWIMCHECK#ARGSFLG  [Variable]
If T, causes DWIMIFY to check for too many arguments in a form. Initially T.

DWIMCHECKPROGLABELSFLG  [Variable]
If T, causes DWIMIFY to check whether a PROG label contains a CLISP character. Initially
T.
DWIMESSGAG

[Variable]
If T, suppresses all DWIMIFY error messages. Initially NIL.

CLISPRETRANFLG

[Variable]
If T, informs DWIMIFY to (re)translate all expressions which have remote translations in the CLISP hash array. Initially NIL.

CLISPIFY

CLISPIFY converts Interlisp expressions to CLISP. Note that the expression given to CLISPIFY need not have originally been input as CLISP, i.e., CLISPIFY can be used on functions that were written before CLISP was even implemented. CLISPIFY is cognizant of declaration rules as well as all of the precedence rules. For example, CLISPIFY will convert (IPLUS A (ITIMES B C)) into A+B*C, but (ITIMES A (IPLUS B C)) into A*(B+C). CLISPIFY handles such cases by first DWIMIFYing the expression. CLISPIFY also knows how to handle expressions consisting of a mixture of Interlisp and CLISP, e.g., (IPLUS A B*C) is converted to A+B*C, but (ITIMES A B+C) to (A*(B+C)). CLISPIFY converts calls to the six basic mapping functions, MAP, MAPC, MAPCAR, MAPLIST, MAPCONC, and MAPCON, into equivalent iterative statements. It also converts certain easily recognizable internal PROG loops to the corresponding iterative statements. CLISPIFY can convert all iterative statements input in CLISP back to CLISP, regardless of how complicated the translation was, because the original CLISP is saved.

CLISPIFY is not destructive to the original Interlisp expression, i.e., CLISPIFY produces a new expression without changing the original. The new expression may however contain some "pieces" of the original, since CLISPIFY attempts to minimize the number of CONSes by not copying structure whenever possible.

CLISPIFY will not convert expressions appearing as arguments to NLAMBDA functions, except for those functions whose INFO property is or contains the atom EVAL. CLISPIFY also contains built in information enabling it to process special forms such as PROG, SELECTQ, etc. If the INFO property is or contains the atom LABELS, CLISPIFY will never create an atom (by packing) at the top level of the expression. PROG is handled in this fashion.

Note: Disabling a CLISP operator with CLDISABLE (see the Miscellaneous Functions and Variables section) will also disable the corresponding CLISPIFY transformation. Thus, if ← is "turned off", A←B will not transform to (SETQ A B), nor vice versa.

(CLISPIFY X EDITCHAIN)

[Function]
Clisifies X. If X is an atom and EDITCHAIN is NIL, X is treated as the name of a function, and its definition (or EXPR property) is clisified. After CLISPIFY has finished, X is redefined (using /PUTD) with its new CLISP definition. The value of CLISPIFY is X. If X
CLISP

is atomic and not the name of a function, spelling correction is attempted. If this fails, an error is generated.

If X is a list, or EditChain is not NIL, X itself is the expression to be clispified. If EditChain is not NIL, it is the edit push-down list leading to X and is used to determine context as with Dwimify, as well as to obtain the local declarations, if any. The value of Clispy is the clispified version of X.

(CLISPIFYFNs FN1 ... FNN)[NLambda NoSpread Function]

Like DwimifyFs except calls Clispy instead of Dwimify.

CL:FLG [Variable]

Affects Clispy’s handling of forms beginning with car, cdr, ... cdddr, as well as pattern match and record expressions. If CL:FLG is NIL, these are not transformed into the equivalent : expressions. This will prevent Clispy from constructing any expression employing a : infix operator, e.g., (Cadr X) will not be transformed to X:2. If CL:FLG is T, Clispy will convert to : notation only when the argument is atomic or a simple list (a function name and one atomic argument). If CL:FLG is ALL, Clispy will convert to : expressions whenever possible.

CL:FLG is initially T.

CLREMPARSLG [Variable]

If T, Clispy will remove parentheses in certain cases from simple forms, where "simple" means a function name and one or two atomic arguments. For example, (Cond ((Atom X) --)) will Clispy to (If Atom X Then --). However, if Clremparsflg is set to NIL, Clispy will produce (If (Atom X) Then --). Regardless of the flag setting, the expression can be input in either form.

CLREMPARSLG is initially NIL.

CLISPIFYPACKFLG [Variable]

ClispyPackflg affects the treatment of infix operators with atomic operands. If ClispyPackflg is T, Clispy will pack these into single atoms, e.g., (Iplus A (ITimes B C)) becomes A+B*C. If ClispyPackflg is NIL, no packing is done, e.g., the above becomes A + B * C.

CLISPIFYPACKFLG is initially T.

CLISPIFYUSERFN [Variable]

If T, causes the function ClispyUserfn, which should be a function of one argument, to be called on each form (list) not otherwise recognized by Clispy. If a non-NIL value is returned, it is treated as the clispified form. Initially NIL.

Note that ClispyUserfn must be both set and defined to use this feature.
Suppose you have variables named A, B, and A*B. If CLISPIFY were to convert (ITIMES A B) to A*B, A*B would not translate back correctly to (ITIMES A B), since it would be the name of a variable, and therefore would not cause an error. You can prevent this from happening by adding A*B to the list FUNNYATOMLST. Then, (ITIMES A B) would CLISPIFY to A * B.

Note that A*B’s appearance on FUNNYATOMLST would not enable DWIM and CLISP to decode A*B+C as (IPLUS A*B C); FUNNYATOMLST is used only by CLISPIFY. Thus, if an identifier contains a CLISP character, it should always be separated (with spaces) from other operators. For example, if X* is a variable, you should write (SETQ X* FORM) in CLISP as X* ← FORM, not X*← FORM. In general, it is best to avoid use of identifiers containing CLISP character operators as much as possible.

### Miscellaneous Functions and Variables

**CLISPFILG**

A list of the operators that can appear in the interior of an atom. Currently (+ - * / ↑ - ') = ← : < > + - ~ @ !).

**CLISPFILG**

If CLISPFILG = NIL, disables all CLISP infix or prefix transformations (but does not affect IF/THEN/ELSE statements, or iterative statements).

If CLISPFILG = TYPE-IN, CLISP transformations are performed only on expressions that are typed in for evaluation, i.e., not on user programs.

If CLISPFILG = T, CLISP transformations are performed on all expressions.

The initial value for CLISPFILG is T. CLISPIFYing anything will cause CLISPFILG to be set to T.

**CLISPCCHARS**

A list of the operators that can appear in the interior of an atom. Currently (+ - * / ↑ - ') = ← : < > + - ~ @ !).

**CLISPCARRAY**

A bit table of the characters on CLISPCCHARS used for calls to STRPOSL (Chapter 4). CLISPCARRAY is initialized by performing (SETQ CLISPCARRAY (MAKEBITTABLE CLISPCCHARS)).

**CLISPINFIXSPLST**

A list of infix operators used for spelling correction.

**CLISSPARRAY**

A hash array used for storing CLISP translations. CLISSPARRAY is checked by FAULTEVAL and FAULTAPPLY on erroneous forms before calling DWIM, and by the compiler.
Macro and CLISP expansions are cached in CLISPARRAY, the systems CLISP hash array. When anything changes that would invalidate an expansion, it needs to be removed from the cache. CLEARCLISPARRAY does this for you. The system does this automatically whenever you define redefine a CLISP or macro form. If you have changed something that a CLISP word or a macro depends on the system will not be able to detect this, so you will have to invalidate the cache by calling CLEARCLISPARRAY. You can clear the whole cache by calling (CLRHASH CLISPARRAY).

Gives X the translation TRAN by storing (key X, value TRAN) in the hash array CLISPARRAY. CLISPTRAN is called for all CLISP translations, via a non-linked, external function call, so it can be advised.

Puts into effect the declarations in DECLST. CLISPDEC performs spelling corrections on words not recognized as declarations. CLISPDEC is undoable.

Disables the CLISP operator OP. For example, (CLDISABLE ‘-’) makes - be just another character. CLDISABLE can be used on all CLISP operators, e.g., infix operators, prefix operators, iterative statement operators, etc. CLDISABLE is undoable.

Note: Simply removing a character operator from CLISPCHARS will prevent it from being treated as a CLISP operator when it appears as part of an atom, but it will continue to be an operator when it appears as a separate atom, e.g. (FOO + X) vs FOON+X.

Affects handling of translations of IF-THEN-ELSE statements (see Chapter 9). If T, the translations are stored elsewhere, and the (modified) CLISP retained. If NIL, the corresponding COND expression replaces the CLISP. Initially T.

If non-NIL, causes PRETTYPRINT (and therefore PP and MAKEFILE) to CLISPIFY selected function definitions before printing them according to the following interpretations of CLISPIFYPRETTYFLG:

- ALL: Clispyfiy all functions.
- T or EXPRS: Clispyfiy all functions currently defined as EXPRs.
- CHANGES: Clispyfiy all functions marked as having been changed.
- a list: Clispyfiy all functions in that list.
CLISPIFYPRETTYFLG is (temporarily) reset to T when MAKEFILE is called with the option CLISPIFY, and reset to CHANGES when the file being dumped has the property FILETYPE value CLISP. CLISPIFYPRETTYFLG is initially NIL.

Note: If CLISPIFYPRETTYFLG is non-NIL, and the only transformation performed by DWIM are well formed CLISP transformations, i.e., no spelling corrections, the function will not be marked as changed, since it would only have to be re-clispified and re-prettyprinted when the file was written out.

(PPT X) [NLambda NoSpread Function]
Both a function and an edit macro for prettyprinting translations. It performs a PP after first resetting PRETTYTRANFLG to T, thereby causing any translations to be printed instead of the corresponding CLISP.

CLISP: [Editor Command]
Edit macro that obtains the translation of the correct expression, if any, from CLISPARRAY, and calls EDITE on it.

CL [Editor Command]
Edit macro. Replaces current expression with CLISPIFYed current expression. Current expression can be an element or tail.

DW [Editor Command]
Edit macro. DWIMIFYs current expression, which can be an element (atom or list) or tail.
Both CL and DW can be called when the current expression is either an element or a tail and will work properly. Both consult the declarations in the function being edited, if any, and both are undoable.

(LOWERCASE FLG) [Function]
If FLG = T, LOWERCASE makes the necessary internal modifications so that CLISPIFY will use lower case versions of AND, OR, IF, THEN, ELSE, ELSEIF, and all i.s. operators. This produces more readable output. Note that you can always type in either upper or lower case (or a combination), regardless of the action of LOWERCASE. If FLG = NIL, CLISPIFY will use uppercase versions of AND, OR, et al. The value of LOWERCASE is its previous "setting". LOWERCASE is undoable. The initial setting for LOWERCASE is T.

CLISP Internal Conventions

CLISP is almost entirely table driven by the property lists of the corresponding infix or prefix operators. For example, much of the information used for translating the + infix operator is stored on the property list of the symbol "+". Thus it is relatively easy to add new infix or prefix operators or change old ones, simply by adding or changing selected property values. (There is some built in
information for handling minus, ;, ‘, and --, i.e., you could not yourself add such "special" operators, although you can disable or redefine them.)

Global declarations operate by changing the LISPFN and CLISPINFIX properties of the appropriate operators.

**CLISPTYPE**

The property value of the property CLISPTYPE is the precedence number of the operator: higher values have higher precedence, i.e., are tighter. Note that the actual value is unimportant, only the value relative to other operators. For example, CLISPTYPE for ;, ↑, and * are 14, 6, and 4 respectively. Operators with the same precedence group left to right, e.g., / also has precedence 4, so A/B*C is (A/B)*C.

An operator can have a different left and right precedence by making the value of CLISPTYPE be a dotted pair of two numbers, e.g., CLISPTYPE of ← is (8 . -12). In this case, CAR is the left precedence, and CDR the right, i.e., CAR is used when comparing with operators on the left, and CDR with operators on the right. For example, A*B←C+D is parsed as A*(B←(C+D)) because the left precedence of ← is 8, which is higher than that of *, which is 4. The right precedence of ← is -12, which is lower than that of +, which is 2.

If the CLISPTYPE property for any operator is removed, the corresponding CLISP transformation is disabled, as well as the inverse CLISPIFY transformation.

**UNARYOP**

The value of property UNARYOP must be T for unary operators or brackets. The operand is always on the right, i.e., unary operators or brackets are always prefix operators.

**BROADSCOPE**

The value of property BROADSCOPE is T if the operator has lower precedence than Interlisp forms, e.g., LT, EQUAL, AND, etc. For example, (FOO X AND Y) parses as ((FOO X) AND Y). If the BROADSCOPE property were removed from the property list of AND, (FOO X AND Y) would parse as (FOO (X AND Y)).

**LISPFN**

The value of the property LISPFN is the name of the function to which the infix operator translates. For example, the value of LISPFN for ↑ is EXPT, for ‘ QUOTE, etc. If the value of the property LISPFN is NIL, the infix operator itself is also the function, e.g., AND, OR, EQUAL.

**SETFN**

If FOO has a SETFN property FIE, then (FOO --)←X translates to (FIE -- X). For example, if you make ELT be an infix operator, e.g. #, by putting appropriate CLISPTYPE and LISPFN properties on the property list of # then you can also make # followed by ← translate to SETA, e.g., X#N←Y to (SETA X N Y), by putting SETA on the property list of
ELT under the property SETFN. Putting the list (ELT) on the property list of SETA under property SETFN will enable SETA forms to CLISIFY back to ELT's.

**CLISPINFIX** [Property Name]

The value of this property is the CLISP infix to be used in CLISIFYing. This property is stored on the property list of the corresponding Interlisp function, e.g., the value of property CLISPINFIX for EXPT is ↑, for QUOTE is ' etc.

**CLISPWORD** [Property Name]

Appears on the property list of clisp operators which can appear as CAR of a form, such as FETCH, REPLACE, IF, iterative statement operators, etc. Value of property is of the form (KEYWORD . NAME), where NAME is the lowercase version of the operator, and KEYWORD is its type, e.g. FORWARD, IFWORD, RECORDWORD, etc.

KEYWORD can also be the name of a function. When the atom appears as CAR of a form, the function is applied to the form and the result taken as the correct form. In this case, the function should either physically change the form, or call CLISPTRAN to store the translation.

As an example, to make & be an infix character operator meaning OR, you could do the following:

```
← (PUTPROP ' & 'CLISPTYPE (GETPROP ' OR ' CLISPTYPE))
← (PUTPROP ' & 'LISPFN ' OR)
← (PUTPROP ' & ' BROADSCOPE T)
← (PUTPROP ' OR ' CLISPINFIX ' &)
← (SETQ CLISPCHARS (CONS ' & CLISPCHARS))
← (SETQ CLISPCHARRAY (MAKEBITTABLE CLISPCHARS))
```
21. PERFORMANCE ISSUES

This chapter describes a number of areas that often contribute to performance problems in Medley programs. Many performance problems can be improved by optimizing the use of storage, since allocating and reclaiming large amounts of storage is expensive. Another tactic that can sometimes yield performance improvements is to change the use of variable bindings on the stack to reduce variable lookup time. There are a number of tools that can be used to determine which parts of a computation cause performance bottlenecks.

Storage Allocation and Garbage Collection

As an Medley application program runs, it creates data structures (allocated out of free storage space), manipulates them, and then discards them. If there were no way to reclaim this space, over time the Medley memory would fill up, and the computation would come to a halt. Actually, long before this could happen the system would probably become intolerably slow, due to "data fragmentation," which occurs when the data currently in use are spread over many virtual memory pages, so that most of the computer time must be spent swapping disk pages into physical memory. The problem of fragmentation will occur in any situation where the virtual memory is significantly larger than the real physical memory. To reduce swapping, you want to keep the "working set" (the set of pages containing actively referenced data) as small as possible.

You can write programs that don't generate much "garbage" data, or which recycle data, but such programs tend to be complex and hard to debug. Spending effort writing such programs defeats the whole point of using a system with automatic storage allocation. An important part of any Lisp implementation is the "garbage collector" that finds discarded data and reclaims its space.

There are several well-known approaches to garbage collection. One method is the traditional mark-and-sweep, which identifies "garbage" data by marking all accessible data structures, and then sweeping through the data spaces to find all unmarked objects (i.e., not referenced by any other object). This method is guaranteed to reclaim all garbage, but it takes time proportional to the number of allocated objects, which may be very large. Also, the time that a mark-and-sweep garbage collection takes is independent of the amount of garbage collected; it is possible to sweep through the whole virtual memory, and only recover a small amount of garbage.

For interactive applications, it is not acceptable to have long interruptions in a computation for garbage collect. Medley solves this problem by using a reference-counting garbage collector. With this scheme, there is a table containing counts of how many times each object is referenced. This table is updated as pointers are created and discarded, incurring a small overhead distributed over the computation as a whole. (Note: References from the stack are not counted, but are handled separately at "sweep" time; thus the vast majority of data manipulations do not cause updates to this table.) At opportune moments, the garbage collector scans this table, and reclaims all objects that are no longer accessible (have a reference count of zero). The pause while objects are reclaimed is only the time for scanning the reference count tables (small) plus time proportional to the amount of garbage that has to
be collected (typically less than a second). “Opportune” times occur when a certain number of cells have been allocated or when the system has been waiting for you to type something for long enough. The frequency of garbage collection is controlled by the functions and variables described below. For the best system performance, it is desirable to adjust these parameters for frequent, short garbage collections, which will not interrupt interactive applications for very long, and which will have the added benefit of reducing data fragmentation, keeping the working set small.

One problem with the Medley garbage collector is that not all garbage is guaranteed to be collected. Circular data structures, which point to themselves directly or indirectly, are never reclaimed, since their reference counts are always at least one. With time, this unreclaimable garbage may increase the working set to unacceptable levels. Some users have worked with the same Medley virtual memory for a very long time, but it is a good idea to occasionally save all of your functions in files, reinitialize Medley, and rebuild your system. Many users end their working day by issuing a command to rebuild their system and then leaving the machine to perform this task in their absence. If the system seems to be spending too much time swapping (an indication of fragmented working set), this procedure is definitely recommended.

Another limitation of the reference-counting garbage collector is that the table in which reference counts are maintained is of fixed size. For typical Lisp objects that are pointed to from exactly one place (e.g., the individual conses in a list), no burden is placed on this table, since objects whose reference count is 1 are not explicitly represented in the table. However, large, “rich” data structures, with many interconnections, backward links, cross references, etc, can contribute many entries to the reference count table. For example, if you created a data structure that functioned as a doubly-linked list, such a structure would contribute an entry (reference count 2) for each element.

When the reference count table fills up, the garbage collector can no longer maintain consistent reference counts, so it stops doing so altogether. At this point, a window appears on the screen with the following message, and the debugger is entered:

```
Internal garbage collector tables have overflowed, due
to too many pointers with reference count greater than 1.
*** The garbage collector is now disabled. ***
Save your work and reload as soon as possible.
```

[This message is slightly misleading, in that it should say “count not equal to 1”. In the current implementation, the garbage collection of a large pointer array whose elements are not otherwise pointed to can place a special burden on the table, as each element’s reference count simultaneously drops to zero and is thus added to the reference count table for the short period before the element is itself reclaimed.]

If you exit the debugger window (e.g., with the RETURN command), your computation can proceed; however, the garbage collector is no longer operating. Thus, your virtual memory will become cluttered with objects no longer accessible, and if you continue for long enough in the same virtual memory image you will eventually fill up the virtual memory backing store and grind to a halt.
PERFORMANCE ISSUES

Garbage collection in Medley is controlled by the following functions and variables:

(RECLAIM) [Function]
Initiates a garbage collection. Returns 0.

(RECLAIMMIN N) [Function]
Sets the frequency of garbage collection. Interlisp keeps track of the number of cells of any type that have been allocated; when it reaches a given number, a garbage collection occurs. If N is non-NIL, this number is set to N. Returns the current setting of the number.

RECLAIMWAIT [Variable]
Medley will invoke a RECLAIM if the system is idle and waiting for your input for RECLAIMWAIT seconds (currently set for 4 seconds).

(GCGAG MESSAGE) [Function]
Sets the behavior that occurs while a garbage collection is taking place. If MESSAGE is non-NIL, the cursor is complemented during a RECLAIM; if MESSAGE = NIL, nothing happens. The value of GCGAG is its previous setting.

(GCTRP) [Function]
Returns the number of cells until the next garbage collection, according to the RECLAIMMIN number.

The amount of storage allocated to different data types, how much of that storage is in use, and the amount of data fragmentation can be determined using the following function:

(STORAGE TYPES PAGETHRESHOLD) [Function]

STORAGE prints out a summary, for each data type, of the amount of space allocated to the data type, and how much of that space is currently in use. If TYPES is non-NIL, STORAGE only lists statistics for the specified types. TYPES can be a symbol or a list of types. If PAGETHRESHOLD is non-NIL, then STORAGE only lists statistics for types that have at least PAGETHRESHOLD pages allocated to them.

STORAGE prints out a table with the column headings Type, Assigned, Free Items, In use, and Total alloc. Type is the name of the data type. Assigned is how much of your virtual memory is set aside for items of this type. Currently, memory is allocated in quanta of two pages (1024 bytes). The numbers under Assigned show the number of pages and the total number of items that fit on those pages. Free Items shows how many items are available to be allocated (using the create construct, Chapter 8); these constitute the "free list" for that data type. In use shows how many items of this type are currently in use, i.e., have pointers to them and hence have not been garbage collected. If this number is higher than your program seems to warrant, you may want to look for storage leaks. The sum of Free Items and In use is always the same
as the total Assigned items. Total alloc is the total number of items of this type that have ever been allocated (see BOXCOUNT, in the Performance Measuring section below).

Note: The information about the number of items of type LISTP is only approximate, because list cells are allocated in a special way that precludes easy computation of the number of items per page.

Note: When a data type is redeclared, the data type name is reassigned. Pages which were assigned to instances of the old data type are labeled **DEALLOC**.

At the end of the table printout, STORAGE prints a "Data Spaces Summary" listing the number of pages allocated to the major data areas in the virtual address space: the space for fixed-length items (including datatypes), the space for variable-length items, and the space for symbols. Variable-length data types such as arrays have fixed-length "headers," which is why they also appear in the printout of fixed-length data types. Thus, the line printed for the BITMAP data type says how many bitmaps have been allocated, but the "assigned pages" column counts only the headers, not the space used by the variable-length part of the bitmap. This summary also lists "Remaining Pages" in relation to the largest possible virtual memory, not the size of the virtual memory backing file in use. This file may fill up, causing a STORAGE FULL error, long before the "Remaining Pages" numbers reach zero.

STORAGE also prints out information about the sizes of the entries on the variable-length data free list. The block sizes are broken down by the value of the variable STORAGE.ARRAYSIZES, initially (4 16 64 256 1024 4096 16384 NIL), which yields a printout of the form:

```
variable-datum free list:
le 4   26 items; 104 cells.
le 16  72 items; 783 cells.
le 64  36 items; 964 cells.
le 256 28 items; 3155 cells.
le 1024 3 items; 1175 cells.
le 4096 5 items; 8303 cells.
le 16384 3 items; 17067 cells.
others 1 item; 17559 cells.
```

This information can be useful in determining if the variable-length data space is fragmented. If most of the free space is composed of small items, then the allocator may not be able to find room for large items, and will extend the variable datum space. If this is extended too much, this could cause an ARRAYS FULL error, even if there is a lot of space left in little chunks.

(STORAGE.LEFT) [Function]

Provides a programmatic way of determining how much storage is left in the major data areas in the virtual address space. Returns a list of the form (MDSFREE MDSFRAC SMSFRAC ATOMFREE ATOMFRAC), where the elements are interpreted as follows:

MDSFREE The number of free pages left in the main data space (which includes both fixed-length and variable-length data types).
PERFORMANCE ISSUES

**MDSFRAC** The fraction of the total possible main data space that is free.

**SMBFRAC** The fraction of the total main data space that is free, relative to eight megabytes.

This number is useful when using Medley on some early computers where the hardware limits the address space to eight megabytes. The function `32MADDRESSABLE` returns non-NIL if the currently running Medley system can use the full 32 megabyte address space.

**ATOMFREE** The number of free pages left in the symbol space.

**ATOMFRAC** The fraction of the total symbol space that is free.

Note: Another important space resource is the amount of the virtual memory backing file in use (see `VMEMSIZE`, Chapter 12). The system will crash if the virtual memory file is full, even if the address space is not exhausted.

---

**Variable Bindings**

Different implementations of Lisp use different methods of accessing free variables. The binding of variables occurs when a function or a `PROG` is entered. For example, if the function `FOO` has the definition `(LAMBDA (A B) BODY)`, the variables A and B are bound so that any reference to A or B from `BODY` or any function called from `BODY` will refer to the arguments to the function `FOO` and not to the value of A or B from a higher level function. All variable names (symbols) have a top level value cell which is used if the variable has not been bound in any function. In discussions of variable access, it is useful to distinguish between three types of variable access: local, special and global. Local variable access is the use of a variable that is bound within the function from which it is used. Special variable access is the use of a variable that is bound by another function. Global variable access is the use of a variable that has not been bound in any function. We will often refer to a variable all of whose accesses are local as a "local variable." Similarly, a variable all of whose accesses are global we call a "global variable."

In a “deep” bound system, a variable is bound by saving on the stack the variable’s name together with a value cell which contains that variable’s new value. When a variable is accessed, its value is found by searching the stack for the most recent binding (occurrence) and retrieving the value stored there. If the variable is not found on the stack, the variable’s top level value cell is used.

In a “shallow” bound system, a variable is bound by saving on the stack the variable name and the variable’s old value and putting the new value in the variable’s top level value cell. When a variable is accessed, its value is always found in its top level value cell.

The deep binding scheme has one disadvantage: the amount of cpu time required to fetch the value of a variable depends on the stack distance between its use and its binding. The compiler can determine
local variable accesses and compiles them as fetches directly from the stack. Thus this computation cost only arises in the use of variable not bound in the local frame ("free" variables). The process of finding the value of a free variable is called free variable lookup.

In a shallow bound system, the amount of cpu time required to fetch the value of a variable is constant regardless of whether the variable is local, special or global. The disadvantages of this scheme are that the actual binding of a variable takes longer (thus slowing down function call), the cells that contain the current in use values are spread throughout the space of all symbol value cells (thus increasing the working set size of functions) and context switching between processes requires unwinding and rewinding the stack (thus effectively prohibiting the use of context switching for many applications).

Medley uses deep binding, because of the working set considerations and the speed of context switching. The free variable lookup routine is microcoded, thus greatly reducing the search time. In benchmarks, the largest percentage of free variable lookup time was 20 percent of the total elapsed time; the normal time was between 5 and 10 percent.

Because of the deep binding, you can sometimes significantly improve performance by declaring global variables. If a variable is declared global, the compiler will compile an access to that variable as a retrieval of its top level value, completely bypassing a stack search. This should be done only for variables that are never bound in functions, such as global databases and flags.

Global variable declarations should be done using the GLOBALVARS file manager command (Chapter 17). Its form is `(GLOBALVARS VAR₁ ... VARₘ)`. 

Another way of improving performance is to declare variables as local within a function. Normally, all variables bound within a function have their names put on the stack, and these names are scanned during free variable lookup. If a variable is declared to be local within a function, its name is not put on the stack, so it is not scanned during free variable lookup, which may increase the speed of lookups. The compiler can also make some other optimizations if a variable is known to be local to a function.

A variable may be declared as local within a function by including the form `(DECLARE (LOCALVARS VAR₁ ... VARₙ))` following the argument list in the definition of the function. Local variable declarations only effect the compilation of a function. Interpreted functions put all of their variable names on the stack, regardless of any declarations.

Performance Measuring

This section describes functions that gather and display statistics about a computation, such as the elapsed time, and the number of data objects of different types allocated. `TIMEALL` and `TIME` gather statistics on the evaluation of a specified form. `BREAKDOWN` gathers statistics on individual functions called during a computation. These functions can be used to determine which parts of a computation are consuming the most resources (time, storage, etc.), and could most profitably be improved.
Evaluates the form \texttt{TIMEFORM} and prints statistics on time spent in various categories (elapsed, keyboard wait, swapping time, gc) and data type allocation.

For more accurate measurement on small computations, \texttt{NUMBEROFTIMES} may be specified (its default is 1) to cause \texttt{TIMEFORM} to be executed \texttt{NUMBEROFTIMES} times. To improve the accuracy of timing open-coded operations in this case, \texttt{TIMEALL} compiles a form to execute \texttt{TIMEFORM NUMBEROFTIMES} times (unless \texttt{INTERPFLG} is non-NIL), and then times the execution of the compiled form.

Note: If \texttt{TIMEALL} is called with \texttt{NUMBEROFTIMES} > 1, the dummy form is compiled with compiler optimizations on. This means that it is not meaningful to use \texttt{TIMEALL} with very simple forms that are optimized out by the compiler. For example, \texttt{(TIMEALL ' (IPLUS 2 3) 1000)} will time a compiled function which simply returns the number 5, since \texttt{(IPLUS 2 3)} is optimized to the integer 5.

\texttt{TIMEWHAT} restricts the statistics to specific categories. It can be an atom or list of datatypes to monitor, and/or the atom \texttt{TIME} to monitor time spent. Note that ordinarily, \texttt{TIMEALL} monitors all time and datatype usage, so this argument is rarely needed.

\texttt{TIMEALL} returns the value of the last evaluation of \texttt{TIMEFORM}.

\texttt{TIME} evaluates the form \texttt{TIMEX}, and prints out the number of CONS cells allocated and computation time. Garbage collection time is subtracted out. This function has been largely replaced by \texttt{TIMEALL}.

If \texttt{TIMEN} is greater than 1, \texttt{TIMEX} is executed \texttt{TIMEN} times, and \texttt{TIME} prints out (number of conses)/\texttt{TIMEN}, and (computation time)/\texttt{TIMEN}. If \texttt{TIMEN} = NIL, it defaults to 1. This is useful for more accurate measurement on small computations.

If \texttt{TIMETYP} is 0, \texttt{TIME} measures and prints total real time as well as computation time. If \texttt{TIMETYP} = 3, \texttt{TIME} measures and prints garbage collection time as well as computation time. If \texttt{TIMETYP} = T, \texttt{TIME} measures and prints the number of pagefaults.

\texttt{TIME} returns the value of the last evaluation of \texttt{TIMEX}.

\texttt{BOXCOUNT \texttt{TYPE} \texttt{N}}

Returns the number of data objects of type \texttt{TYPE} allocated since this Interlisp system was created. \texttt{TYPE} can be any data type name (see \texttt{TYPENAME}, Chapter 8). If \texttt{TYPE} is NIL, it defaults to \texttt{FIXP}. If \texttt{N} is non-NIL, the corresponding counter is reset to \texttt{N}.

\texttt{CONSCOUNT \texttt{N}}

Returns the number of CONS cells allocated since this Interlisp system was created. If \texttt{N} is non-NIL, resets the counter to \texttt{N}. Equivalent to \texttt{(BOXCOUNT 'LISTP \texttt{N})}. 

21-7
(PAGEFAULTS)

Returns the number of page faults since this Interlisp system was created.

BREAKDOWN

TIMEALL collects statistics for whole computations. BREAKDOWN is available to analyze the breakdown of computation time (or any other measurable quantity) function by function.

(BREAKDOWN FN1 ... FNn)

[NLlambda NoSpread Function]

You call BREAKDOWN giving it a list of function names (unevaluated). These functions are modified so that they keep track of various statistics.

To remove functions from those being monitored, simply UNBREAK (Chapter 15) the functions, thereby restoring them to their original state. To add functions, call BREAKDOWN on the new functions. This will not reset the counters for any functions not on the new list. However (BREAKDOWN) will zero the counters of all functions being monitored.

The procedure used for measuring is such that if one function calls other and both are "broken down", then the time (or whatever quantity is being measured) spent in the inner function is not charged to the outer function as well.

BREAKDOWN will not give accurate results if a function being measured is not returned from normally, e.g., a lower RETFROM (or ERROR) bypasses it. In this case, all of the time (or whatever quantity is being measured) between the time that function is entered and the time the next function being measured is entered will be charged to the first function.

(BRKDWNRESULTS RETURNVALUESFLG)

[Function]

BRKDWNRESULTS prints the analysis of the statistics requested as well as the number of calls to each function. If RETURNVALUESFLG is non-NIL, BRKDWNRESULTS will not to print the results, but instead return them in the form of a list of elements of the form (FNNAME #CALLS VALUE).

Example:

← (BREAKDOWN SUPERPRINT SUBPRINT COMMENT1)
← (PRETTYDEF 'SUPERPRINT) 'FOO)
← (BREAKDOWN RESULTS)
FUNCTIONS  TIME    #CALLS PER CALL   %
SUPERPRINT  8.261  365  0.023     20
SUBPRINT  31.910  141  0.226     76
COMMENT1    1.612   8  0.201      4
TOTAL      41.783  514  0.081
NIL
← (BREAKDOWN RESULTS T)
BREAKDOWN can be used to measure other statistics, by setting the following variables:

**BRKDWNTYPE**

To use BREAKDOWN to measure other statistics, before calling BREAKDOWN, set the variable BRKDWNTYPE to the quantity of interest, e.g., TIME, CONSES, etc, or a list of such quantities. Whenever BREAKDOWN is called with BRKDWNTYPE not NIL, BREAKDOWN performs the necessary changes to its internal state to conform to the new analysis. In particular, if this is the first time an analysis is being run with a particular statistic, a measuring function will be defined, and the compiler will be called to compile it. The functions being broken down will be redefined to call this measuring function. When BREAKDOWN is through initializing, it sets BRKDWNTYPE back to NIL. Subsequent calls to BREAKDOWN will measure the new statistic until BRKDWNTYPE is again set and a new BREAKDOWN performed.

**BRKDWNTYPES**

The list BRKDWNTYPES contains the information used to analyze new statistics. Each entry on BRKDWNTYPES should be of the form (TYPE FORM FUNCTION), where TYPE is a statistic name (as would appear in BRKDWNTYPE), FORM computes the statistic, and FUNCTION (optional) converts the value of form to some more interesting quantity. For example, (TIME (CLOCK 2) (LAMBDA (X) (FQUOTIENT X 1000))) measures computation time and reports the result in seconds instead of milliseconds. BRKDWNTYPES currently contains entries for TIME, CONSES, PAGEFAULTS, BOXES, and FBOXES.

Example:

```lisp
(SETQ BRKDWNTYPE '(TIME CONSES))
(TIME CONSES)
```

Occasionally, a function being analyzed is sufficiently fast that the overhead involved in measuring it obscures the actual time spent in the function. If you were using TIME, you would specify a value for TIMEN greater than 1 to give greater accuracy. A similar option is available for BREAKDOWN. You can specify that a function(s) be executed a multiple
number of times for each measurement, and the average value reported, by including a number in the list of functions given to BREAKDOWN. For example, BREAKDOWN (EDITCOM EDIT4F 10 EDIT4E EQP) means normal breakdown for EDITCOM and EDIT4F but executes (the body of) EDIT4E and EQP 10 times each time they are called. Of course, the functions so measured must not cause any harmful side effects, since they are executed more than once for each call. The printout from BRKDWNRESULTS will look the same as though each function were run only once, except that the measurement will be more accurate.

Another way of obtaining more accurate measurement is to expand the call to the measuring function in-line. If the value of BRKDWNCOMPFLG is non-NIL (initially NIL), then whenever a function is broken-down, it will be redefined to call the measuring function, and then recompiled. The measuring function is expanded in-line via an appropriate macro. In addition, whenever BRKDWNTYPE is reset, the compiler is called for all functions for which BRKDWNCOMPFLG was set at the time they were originally broken-down, i.e. the setting of the flag at the time a function is broken-down determines whether the call to the measuring code is compiled in-line.

GAINSPACE

If you have large programs and databases, you may sometimes find yourself in a situation where you need to obtain more space, and are willing to pay the price of eliminating some or all of the context information that the various user-assistance facilities such as the programmer's assistant, file package, CLISP, etc., have accumulated during the course of his session. The function GAINSPACE provides an easy way to selectively throw away accumulated data:

(GAINSPACE)  [Function]

Prints a list of deletable objects, allowing you to specify at each point what should be discarded and what should be retained. For example:

← (GAINSPACE)
purge history lists ? Yes
 purge everything, or just the properties, e.g.,
 SIDE, LISPXPRINT, etc. ?
 just the properties
 discard definitions on property lists ? Yes
discard old values of variables ? Yes
 erase properties ? No
 erase CLISP translations? Yes

GAINSPACE is driven by the list GAINSPACEFORMS. Each element on GAINSPACEFORMS is of the form (PRECHECK MESSAGE FORM KEYLST). If PRECHECK, when evaluated, returns NIL, GAINSPACE skips to the next entry. For example, you will not be asked whether or not to purge the history list if it is not enabled. Otherwise, ASKUSER (Chapter 26) is called with the indicated MESSAGE and the (optional) KEYLST. If you respond No, i.e., ASKUSER returns N, GAINSPACE skips to the next entry. Otherwise, FORM is evaluated with the variable RESPONSE bound to the value of ASKUSER. In the above example, the FORM for the "purge history lists" question calls ASKUSER to ask
PERFORMANCE ISSUES

"purge everything, ..." only if you had responded Yes. If you had responded with Everything, the second question would not have been asked.

The "erase properties" question is driven by a list SMASHPROPSMENU. Each element on this list is of the form (MESSAGE, PROPS). You are prompted with MESSAGE (by ASKUSER), and if your response is Yes, PROPS is added to the list SMASHPROPS. The "discard definitions on property lists" and "discard old values of variables" questions also add to SMASHPROPS. You will not be prompted for any entry on SMASHPROPSMENU for which all of the corresponding properties are already on SMASHPROPS. SMASHPROPS is initially set to the value of SMASHPROPSLST. This permits you to specify in advance those properties which you always want discarded, and not be asked about them subsequently. After finishing all the entries on GAINSPACEFORMS, GAINSPACE checks to see if the value of SMASHPROPS is non-NIL, and if so, does a MAPATOMS, i.e., looks at every atom in the system, and erases the indicated properties.

You can change or add new entries to GAINSPACEFORMS or SMASHPROPSMENU, so that GAINSPACE can also be used to purge structures that your programs have accumulated.

Using Data Types Instead of Records

If a program uses large numbers of large data structures, there are several advantages to representing them as user data types rather than as list structures. The primary advantage is increased speed: accessing and setting the fields of a data type can be significantly faster than walking through a list with repeated CARs and CDRs. Also,

Compiled code for referencing data types is usually smaller. Finally, by reducing the number of objects created (one object against many list cells), this can reduce the expense of garbage collection.

User data types are declared by using the DATATYPE record type (Chapter 8). If a list structure has been defined using the RECORD record type (Chapter 8), and all accessing operations are written using the record package's fetch, replace, and create operations, changing from RECORDs to DATATYPES only requires editing the record declaration (using EDITREC, Chapter 8) to replace declaration type RECORD by DATATYPE, and recompiling.

Note: There are some minor disadvantages: First, there is an upper limit on the number of data types that can exist. Also, space for data types is allocated two pages at a time. Each data type which has any instances allocated has at least two pages assigned to it, which may be wasteful of space if there are only a few examples of a given data type. These problems should not effect most applications programs.
Using “Fast” and “Destructive” Functions

Among the functions used for manipulating objects of various data types, there are a number of functions which have "fast" and "destructive" versions. You should be aware of what these functions do, and when they should be used.

“Fast” functions: By convention, a function named by prefixing an existing function name with Ф indicates that the new function is a "fast" version of the old. These usually have the same definitions as the slower versions, but they compile open and run without any "safety" error checks. For example, FNTH runs faster than NTH, however, it does not make as many checks (for lists ending with anything but NIL, etc). If these functions are given arguments that are not in the form that they expect, their behavior is unpredictable; they may run forever, or cause a system error. In general, you should only use "fast" functions in code that has already been completely debugged, to speed it up.

“Destructive” functions: By convention, a function named by prefixing an existing function with Д indicates the new function is a "destructive" version of the old one, which does not make any new structure but cannibalizes its argument(s). For example, REMOVE returns a copy of a list with a particular element removed, but DREMOVE actually changes the list structure of the list. (Unfortunately, not all destructive functions follow this naming convention: the destructive version of APPEND is NCONC.) You should be careful when using destructive functions that they do not inadvertently change data structures.
This chapter describes a number of areas that often contribute to performance problems in Interlisp-D programs. Many performance problems can be improved by optimizing the use of storage, since allocating and reclaiming large amounts of storage is expensive. Another tactic that can sometimes yield performance improvements is to change the use of variable bindings on the stack to reduce variable lookup time. There are a number of tools that can be used to determine which parts of a computation cause performance bottlenecks.

Storage Allocation and Garbage Collection

As an Interlisp-D applications program runs, it creates data structures (allocated out of free storage space), manipulates them, and then discards them. If there were no way of reclaiming this space, over time the Interlisp-D memory (both the physical memory in the machine and the virtual memory stored on the disk) would fill up, and the computation would come to a halt. Actually, long before this could happen the system would probably become intolerably slow, due to "data fragmentation," which occurs when the data currently in use are spread over many virtual memory pages, so that most of the computer time must be spent swapping disk pages into physical memory.

The problem of fragmentation will occur in any situation where the virtual memory is significantly larger than the real physical memory. To reduce swapping, it is desirable to keep the "working set" (the set of pages containing actively referenced data) as small as possible.

It is possible to write programs that don't generate much "garbage" data, or which recycle data, but such programs tend to be overly complicated and difficult to debug. Spending effort writing such programs defeats the whole point of using a system with automatic storage allocation. An important part of any Lisp implementation is the "garbage collector" which identifies discarded data and reclaims its space. There are several well-known approaches to garbage collection. One method is the traditional mark-and-sweep garbage collection algorithm, which identifies "garbage" data by marking all accessible data structures, and then sweeping through the data spaces to find all unmarked objects (i.e., not referenced by any other object). Although this method is guaranteed to reclaim all garbage, it takes time proportional to the number of allocated objects, which may be very large. (Some allocated objects will have been marked during the "mark" phase, and the remainder will be collected during the "sweep" phase; so all will have to be touched in some way.) Also, the time that a mark-and-sweep garbage collection takes is independent of the amount of garbage collected; it
is possible to sweep through the whole virtual memory, and only recover a small amount of garbage.

For interactive applications, it is not acceptable to have long interruptions in a computation for the purpose of garbage collection. Interlisp-D solves this problem by using a reference-counting garbage collector. With this scheme, there is a table containing counts of how many times each object is referenced. This table is incrementally updated as pointers are created and discarded, incurring a small overhead distributed over the computation as a whole. (Note: References from the stack are not counted, but are handled separately at “sweep” time; thus the vast majority of data manipulations do not cause updates to this table.) At opportune moments, the garbage collector scans this table, and reclaims all objects that are no longer accessible (have a reference count of zero). The pause while objects are reclaimed is only the time for scanning the reference count tables (small) plus time proportional to the amount of garbage that has to be collected (typically less than a second). "Opportune" times occur when a certain number of cells have been allocated or when the system has been waiting for the user to type something for long enough. The frequency of garbage collection is controlled by the functions and variables described below. For the best system performance, it is desirable to adjust these parameters for frequent, short garbage collections, which will not interrupt interactive applications for very long, and which will have the added benefit of reducing data fragmentation, keeping the working set small.

One problem with the Interlisp-D garbage collector is that not all garbage is guaranteed to be collected. Circular data structures, which point to themselves directly or indirectly, are never reclaimed, since their reference counts are always at least one. With time, this unreclaimable garbage may increase the working set to unacceptable levels. Some users have worked with the same Interlisp-D virtual memory for a very long time, but it is a good idea to occasionally save all of your functions in files, reinitialize Interlisp-D, and rebuild your system. Many users end their working day by issuing a command to rebuild their system and then leaving the machine to perform this task in their absence. If the system seems to be spending too much time swapping (an indication of fragmented working set), this procedure is definitely recommended.

Garbage collection in Interlisp-D is controlled by the following functions and variables:

(RECLAIM) [Function]
Initiates a garbage collection. Returns 0.

(RECLAIMMIN N) [Function]
Sets the frequency of garbage collection. Interlisp keeps track of the number of cells of any type that have been allocated; when it reaches a given number, a garbage collection occurs. If N is non-NIL, this number is set to N. Returns the current setting of the number.
RECLAIMWAIT [Variable]

Interlisp-D will invoke a RECLAIM if the system is idle and waiting for your input for RECLAIMWAIT seconds (currently set for 4 seconds).

(GCGAG MESSAGE) [Function]

Sets the behavior that occurs while a garbage collection is taking place. If MESSAGE is non-NIL, the cursor is complemented during a RECLAIM; if MESSAGE = NIL, nothing happens. The value of GCGAG is its previous setting.

(GCTRIP) [Function]

Returns the number of cells until the next garbage collection, according to the RECLAIMMIN number.

The amount of storage allocated to different data types, how much of that storage is in use, and the amount of data fragmentation can be determined using the following function:

(STORAGE TYPES PAGETHRESHOLD) [Function]

STORAGE prints out a summary, for each data type, of the amount of space allocated to the data type, and how much of that space is currently in use. If TYPES is non-NIL, STORAGE only lists statistics for the specified types. TYPES can be a litatom or a list of types. If PAGETHRESHOLD is non-NIL, then STORAGE only lists statistics for types that have at least PAGETHRESHOLD pages allocated to them.
STORAGE prints out a table with the column headings Type, Assigned, Free Items, In use, and Total alloc. Type is the name of the data type. Assigned is how much of your virtual memory is set aside for items of this type. Currently, memory is allocated in quanta of two pages (1024 bytes). The numbers under Assigned show the number of pages and the total number of items that fit on those pages. Free Items shows how many items are available to be allocated (using the create construct, Chapter 8); these constitute the “free list” for that data type. In use shows how many items of this type are currently in use, i.e., have pointers to them and hence have not been garbage collected. If this number is higher than your program seems to warrant, you may want to look for storage leaks. The sum of Free Items and In use is always the same as the total Assigned items. Total alloc is the total number of items of this type that have ever been allocated (see BOXCOUNT, in the Performance Measuring section below).

Note: The information about the number of items of type LISTP is only approximate, because list cells are allocated in a special way that precludes easy computation of the number of items per page.

Note: When a data type is redeclared, the data type name is reassigned. Pages which were assigned to instances of the old data type are labeled **DEALLOC**.

At the end of the table printout, STORAGE prints a “Data Spaces Summary” listing the number of pages allocated to the major data areas in the virtual address space: the space for fixed-length items (including datatypes), the space for variable-length items, and the space for litatoms. Variable-length data types such as arrays have fixed-length “headers,” which is why they also appear in the printout of fixed-length data types. Thus, the line printed for the BITMAP data type says how many bitmaps have been allocated, but the “assigned pages” column counts only the headers, not the space used by the variable-length part of the bitmap. This summary also lists “Remaining Pages” in relation to the largest possible virtual memory, not the size of the virtual memory backing file in use. This file may fill up, causing a STORAGE FULL error, long before the “Remaining Pages” numbers reach zero.

STORAGE also prints out information about the sizes of the entries on the variable-length data free list. The block sizes are broken down by the value of the variable STORAGE.ARRAY SIZES, initially (4 16 64 256 1024 4096 16384 NIL), which yields a printout of the form:

```
variable-datum free list:
le 4  26 items;  104 cells.
le 16 72 items;  783 cells.
le 64 36 items;  964 cells.
le 256 28 items; 3155 cells.
le 1024 3 items;  1175 cells.
```
<table>
<thead>
<tr>
<th>Capacity</th>
<th>Items</th>
<th>Cells</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;= 4096</td>
<td>5</td>
<td>8303</td>
</tr>
<tr>
<td>&lt;= 16384</td>
<td>3</td>
<td>17067</td>
</tr>
<tr>
<td>Others</td>
<td>1</td>
<td>17559</td>
</tr>
</tbody>
</table>

This information can be useful in determining if the variable-length data space is fragmented. If most of the free space is composed of small items, then the allocator may not be able to find room for large items, and will extend the variable datum space. If this is extended too much, this could cause an ARRAYS FULL error, even if there is a lot of space left in little chunks.
Provides a programmatic way of determining how much storage is left in the major data areas in the virtual address space. Returns a list of the form (MDSFREE MDSFRAC 8MBFRAC ATOMFREE ATOMFRAC), where the elements are interpreted as follows:

- **MDSFREE**: The number of free pages left in the main data space (which includes both fixed-length and variable-length data types).
- **MDSFRAC**: The fraction of the total possible main data space that is free.
- **8MBFRAC**: The fraction of the total main data space that is free, relative to eight megabytes.
  
  This number is useful when using Interlisp-D on some early computers where the hardware limits the address space to eight megabytes. The function 32MBADDRESSABLE returns non-NIL if the currently running Interlisp-D system can use the full 32 megabyte address space.
- **ATOMFREE**: The number of free pages left in the litatom space.
- **ATOMFRAC**: The fraction of the total litatom space that is free.

Note: Another important space resource is the amount of the virtual memory backing file in use (see VMEMSIZE, Chapter 12). The system will crash if the virtual memory file is full, even if the address space is not exhausted.

**Variable Bindings**

Different implementations of lisp use different methods of accessing free variables. The binding of variables occurs when a function or a PROG is entered. For example, if the function FOO has the definition (LAMBDA (A B) BODY), the variables A and B are bound so that any reference to A or B from BODY or any function called from BODY will refer to the arguments to the function FOO and not to the value of A or B from a higher level function. All variable names (litatoms) have a top level value cell which is used if the variable has not been bound in any function. In discussions of variable access, it is useful to distinguish between three types of variable access: local, special and global. Local variable access is the use of a variable that is bound within the function from which it is used. Special variable access is the use of a variable that is bound by another function. Global variable access is the use of a variable that has not been bound in any function. We will often refer to a variable all of whose accesses are local as a "local variable." Similarly, a variable all of whose accesses are global we call a "global variable."
In a "deep" bound system, a variable is bound by saving on the stack the variable's name together with a value cell which contains that variable's new value. When a variable is accessed, its value is found by searching the stack for the most recent binding (occurrence) and retrieving the value stored there. If the variable is not found on the stack, the variable's top level value cell is used.

In a "shallow" bound system, a variable is bound by saving on the stack the variable name and the variable's old value and putting the new value in the variable's top level value cell. When a variable is accessed, its value is always found in its top level value cell.
The deep binding scheme has one disadvantage: the amount of CPU time required to fetch the value of a variable depends on the stack distance between its use and its binding. The compiler can determine local variable accesses and compiles them as fetches directly from the stack. Thus this computation cost only arises in the use of variable not bound in the local frame ("free" variables). The process of finding the value of a free variable is called free variable lookup.

In a shallow bound system, the amount of CPU time required to fetch the value of a variable is constant regardless of whether the variable is local, special or global. The disadvantages of this scheme are that the actual binding of a variable takes longer (thus slowing down function call), the cells that contain the current in use values are spread throughout the space of all litatom value cells (thus increasing the working set size of functions) and context switching between processes requires unwinding and rewinding the stack (thus effectively prohibiting the use of context switching for many applications).

Interlisp-D uses deep binding, because of the working set considerations and the speed of context switching. The free variable lookup routine is microcoded, thus greatly reducing the search time. In benchmarks, the largest percentage of free variable lookup time was 20 percent of the total elapsed time; the normal time was between 5 and 10 percent.

One consequence of Interlisp-D's deep binding scheme is that users may significantly improve performance by declaring global variables in certain situations. If a variable is declared global, the compiler will compile an access to that variable as a retrieval of its top level value, completely bypassing a stack search. This should be done only for variables that are never bound in functions, such as global databases and flags.

Global variable declarations should be done using the GLOBALVARS file package command (Chapter 17). Its form is (GLOBALVARS VAR₁ ... VARₙ).

Another way of improving performance is to declare variables as local within a function. Normally, all variables bound within a function have their names put on the stack, and these names are scanned during free variable lookup. If a variable is declared to be local within a function, its name is not put on the stack, so it is not scanned during free variable lookup, which may increase the speed of lookups. The compiler can also make some other optimizations if a variable is known to be local to a function.

A variable may be declared as local within a function by including the form (DECLARE (LOCALVARS VAR₁ ... VARₙ)) following the argument list in the definition of the function. Local variable declarations only effect the compilation of a function. Interpreted functions put all of their variable names on the stack, regardless of any declarations.
Performance Measuring

This section describes functions that gather and display statistics about a computation, such as the elapsed time, and the number of data objects of different types allocated. \texttt{TIMEALL} and \texttt{TIME} gather statistics on the evaluation of a specified form. \texttt{BREAKDOWN} gathers statistics on individual functions called during a computation. These functions can be used to determine which parts of a computation are consuming the most resources (time, storage, etc.), and could most profitably be improved.

\texttt{(TIMEALL TIMEFORM NUMBEROFTIMES TIMEWHAT INTERPFLG — \#)}

\texttt{[NLambda Function]}  

Evaluates the form \texttt{TIMEFORM} and prints statistics on time spent in various categories (elapsed, keyboard wait, swapping time, gc) and data type allocation.

For more accurate measurement on small computations, \texttt{NUMBEROFTIMES} may be specified (its default is 1) to cause \texttt{TIMEFORM} to be executed \texttt{NUMBEROFTIMES} times. To improve the accuracy of timing open-coded operations in this case, \texttt{TIMEALL} compiles a form to execute \texttt{TIMEFORM} \texttt{NUMBEROFTIMES} times (unless \texttt{INTERPFLG} is non-\texttt{NIL}), and then times the execution of the compiled form.

Note: If \texttt{TIMEALL} is called with \texttt{NUMBEROFTIMES} $>1$, the dummy form is compiled with compiler optimizations on. This means that it is not meaningful to use \texttt{TIMEALL} with very simple forms that are optimized out by the compiler. For example, \texttt{(TIMEALL '(IPLUS 2 3) 1000)} will time a compiled function which simply returns the number 5, since \texttt{(IPLUS 2 3)} is optimized to the integer 5.

\texttt{TIMEWHAT} restricts the statistics to specific categories. It can be an atom or list of datatypes to monitor, and/or the atom \texttt{TIME} to monitor time spent. Note that ordinarily, \texttt{TIMEALL} monitors all time and datatype usage, so this argument is rarely needed.

\texttt{TIMEALL} returns the value of the last evaluation of \texttt{TIMEFORM}.

\texttt{(TIME TIMEX TIMEN TIMETYP)} \texttt{[NLambda Function]}  

\texttt{TIME} evaluates the form \texttt{TIMEX}, and prints out the number of \texttt{CONS} cells allocated and computation time. Garbage collection time is subtracted out. This function has been largely replaced by \texttt{TIMEALL}.

If \texttt{TIMEN} is greater than 1, \texttt{TIMEX} is executed \texttt{TIMEN} times, and \texttt{TIME} prints out (number of conses)/\texttt{TIMEN}, and (computation time)/\texttt{TIMEN}. If \texttt{TIMEN=}\texttt{NIL}, it defaults to 1. This is useful for more accurate measurement on small computations.
If TIMETYP is 0, TIME measures and prints total real time as well as computation time. If TIMETYP = 3, TIME measures and prints garbage collection time as well as computation time. If TIMETYP=T, TIME measures and prints the number of pagefaults.

TIME returns the value of the last evaluation of TIMEX.

(BOXCOUNT TYPE N) [Function]
Returns the number of data objects of type TYPE allocated since this Interlisp system was created. TYPE can be any data type name (see TYPENAME, Chapter 8). If TYPE is NIL, it defaults to FIXP. If N is non-NIL, the corresponding counter is reset to N.

(CONSCOUNT N) [Function]
Returns the number of CONS cells allocated since this Interlisp system was created. If N is non-NIL, resets the counter to N. Equivalent to (BOXCOUNT 'LISP N).

(PAGEFAULSTS) [Function]
Returns the number of page faults since this Interlisp system was created.

BREAKDOWN

TIMEALL collects statistics for whole computations. BREAKDOWN is available to analyze the breakdown of computation time (or any other measureable quantity) function by function.

(BREAKDOWN F1N1 ... FN1N) [NLambda NoSpread Function]
The user calls BREAKDOWN giving it a list of function names (unevaluated). These functions are modified so that they keep track of various statistics.

To remove functions from those being monitored, simply UNBREAK (Chapter 15) the functions, thereby restoring them to their original state. To add functions, call BREAKDOWN on the new functions. This will not reset the counters for any functions not on the new list. However (BREAKDOWN) will zero the counters of all functions being monitored.

The procedure used for measuring is such that if one function calls other and both are "broken down", then the time (or whatever quantity is being measured) spent in the inner function is not charged to the outer function as well.
BREAKDOWN will not give accurate results if a function being measured is not returned from normally, e.g., a lower RETFROM (or ERROR) bypasses it. In this case, all of the time (or whatever quantity is being measured) between the time that function is entered and the time the next function being measured is entered will be charged to the first function.

(BRKDWNRESULTS RETURNVALUESFLG) [Function]

BRKDWNRESULTS prints the analysis of the statistics requested as well as the number of calls to each function. If RETURNVALUESFLG is non-NIL, BRKDWNRESULTS will not to print the results, but instead return them in the form of a list of elements of the form (FNNAME #CALLS VALUE).

Example:

← (BREAKDOWN SUPERPRINT SUBPRINT COMMENT1)
(SUPERPRINT SUBPRINT COMMENT1)
← (PRETTYDEF '(SUPERPRINT) 'FOO)
FOO.;3
← (BRKDWNRESULTS)
FUNCTIONS TIME #CALLS PER CALL %
SUPERPRINT 8.261 365 0.023 20
SUBPRINT 31.910 141 0.226 76
COMMENT1 1.612 8 0.201 4
TOTAL 41.783 514 0.081
NIL
← (BRKDWNRESULTS T)
((SUPERPRINT 365 8261) (SUBPRINT 141 31910) (COMMENT1 8 1612))

BREAKDOWN can be used to measure other statistics, by setting the following variables:

BRKDWNTYPE [Variable]

To use BREAKDOWN to measure other statistics, before calling BREAKDOWN, set the variable BRKDWNTYPE to the quantity of interest, e.g., TIME, CONSES, etc, or a list of such quantities. Whenever BREAKDOWN is called with BRKDWNTYPE not NIL, BREAKDOWN performs the necessary changes to its internal state to conform to the new analysis. In particular, if this is the first time an analysis is being run with a particular statistic, a measuring function will be defined, and the compiler will be called to compile it. The functions being broken down will be redefined to call this measuring function. When BREAKDOWN is through initializing, it sets BRKDWNTYPE back to NIL. Subsequent calls to BREAKDOWN will measure the new statistic until BRKDWNTYPE is again set and a new BREAKDOWN performed.
The list \texttt{BRKDWTYPES} contains the information used to analyze new statistics. Each entry on \texttt{BRKDWTYPES} should be of the form (\texttt{TYPE FORM FUNCTION}), where \texttt{TYPE} is a statistic name (as would appear in \texttt{BRKDWTYPE}), \texttt{FORM} computes the statistic, and \texttt{FUNCTION} (optional) converts the value of form to some more interesting quantity. For example, (\texttt{TIME (CLOCK 2) (LAMBDA (X) (FQUOTIENT X 1000)))} measures computation time and reports the result in seconds instead of milliseconds. \texttt{BRKDWTYPES} currently contains entries for \texttt{TIME}, \texttt{CONSES}, \texttt{PAGEFAULTS}, \texttt{BOXES}, and \texttt{FBOXES}.

Example:

\begin{verbatim}
\textbf{←(SETQ BRKDWTYPE '(TIME CONSES))
\textbf{(TIME CONSES)
\textbf{←(BREAKDOWN MATCH CONSTRUCT)
\textbf{(MATCH CONSTRUCT)
\textbf{←(FLIP '(A B C D E F G H C Z) '(.. $1 .. #2 ..) '(.. #3 ..))
\textbf{(A B D E F G H Z)
\textbf{←(BRKDWNRESULTS)
\textbf{FUNCTIONS TIME #CALLS PER CALL %
\textbf{MATCH 0.036 1 0.036 54
\textbf{CONSTRUCT 0.031 1 0.031 46
\textbf{TOTAL 0.067 2 0.033
\textbf{FUNCTIONS CONSES #CALLS PER CALL %
\textbf{MATCH 32 1 32.000 40
\textbf{CONSTRUCT 49 1 49.000 60
\textbf{TOTAL 81 2 40.500
\textbf{NIL}
\end{verbatim}

Occasionally, a function being analyzed is sufficiently fast that the overhead involved in measuring it obscures the actual time spent in the function. If you were using \texttt{TIME}, you would specify a value for \texttt{TIMEN} greater than 1 to give greater accuracy. A similar option is available for \texttt{BREAKDOWN}. You can specify that a function(s) be executed a multiple number of times for each measurement, and the average value reported, by including a number in the list of functions given to \texttt{BREAKDOWN}. For example, \texttt{BREAKDOWN(EDITCOM EDIT4F 10 EDIT4E EQP)} means normal breakdown for \texttt{EDITCOM} and \texttt{EDIT4F} but executes (the body of) \texttt{EDIT4E} and \texttt{EQP} 10 times each time they are called. Of course, the functions so measured must not cause any harmful side effects, since they are executed more than once for each call. The printout from \texttt{BRKDWNRESULTS} will look the same as though each function were run only once, except that the measurement will be more accurate.

Another way of obtaining more accurate measurement is to expand the call to the measuring function in-line. If the value of \texttt{BRKDWNCOMPFLG} is non-\texttt{NIL} (initially \texttt{NIL}), then whenever a function is broken-down, it will be redefined to
call the measuring function, and then recompiled. The measuring function is expanded in-line via an appropriate macro. In addition, whenever `BRKDWNTYPE` is reset, the compiler is called for all functions for which `BRKDWNCOMPFLG` was set at the time they were originally broken-down, i.e. the setting of the flag at the time a function is broken-down determines whether the call to the measuring code is compiled in-line.

**GAINSPACE**

If you have large programs and databases, you may sometimes find yourself in a situation where you need to obtain more space, and are willing to pay the price of eliminating some or all of the context information that the various user-assistance facilities such as the programmer's assistant, file package, CLISP, etc., have accumulated during the course of his session. The function **GAINSPACE** provides an easy way to selectively throw away accumulated data:

```lisp
(GAINSPACE)
```

Prints a list of deletable objects, allowing you to specify at each point what should be discarded and what should be retained. For example:

```lisp
←(GAINSPACE)
purge history lists ? Yes
purge everything, or just the properties, e.g., SIDE, LISPXPRINT, etc.? just the properties
discard definitions on property lists? Yes
discard old values of variables? Yes
erase properties? No
erase CLISP translations? Yes
```

**GAINSPACE** is driven by the list **GAINSPACEFORMS**. Each element on **GAINSPACEFORMS** is of the form `(PRECHECK MESSAGE FORM KEYLST)`. If PRECHECK, when evaluated, returns `NIL`, **GAINSPACE** skips to the next entry. For example, you will not be asked whether or not to purge the history list if it is not enabled. Otherwise, **ASKUSER** (Chapter 26) is called with the indicated MESSAGE and the (optional) KEYLST. If you respond `No`, i.e., **ASKUSER** returns `N`, **GAINSPACE** skips to the next entry. Otherwise, FORM is evaluated with the variable `RESPONSE` bound to the value of **ASKUSER**. In the above example, the FORM for the "purge history lists" question calls **ASKUSER** to ask "purge everything, ..." only if you had responded `Yes`. If you had responded with `Everything`, the second question would not have been asked.

The "erase properties" question is driven by a list **SMASHPROPSMENU**. Each element on this list is of the form `(MESSAGE PROPS)`. You are prompted with MESSAGE
(by ASKUSER), and if your response is yes, PROPS is added to the list SMASHPROPS. The "discard definitions on property lists" and "discard old values of variables" questions also add to SMASHPROPS. You will not be prompted for any entry on SMASHPROPSMENU for which all of the corresponding properties are already on SMASHPROPS. SMASHPROPS is initially set to the value of SMASHPROPSLST. This permits you to specify in advance those properties which you always want discarded, and not be asked about them subsequently. After finishing all the entries on GAINSPACEFORMS, GAINSPACE checks to see if the value of SMASHPROPS is non-NIL, and if so, does a MAPATOMS, i.e., looks at every atom in the system, and erases the indicated properties.

You can change or add new entries to GAINSPACEFORMS or SMASHPROPSMENU, so that GAINSPACE can also be used to purge structures that your programs have accumulated.

Using Data Types Instead of Records

If a program uses large numbers of large data structures, there are several advantages to representing them as user data types rather than as list structures. The primary advantage is increased speed: accessing and setting the fields of a data type can be significantly faster than walking through a list with repeated CARs and CDRs. Also,
compiled code for referencing data types is usually smaller. Finally, by reducing the number of objects created (one object against many list cells), this can reduce the expense of garbage collection.

User data types are declared by using the `DATATYPE` record type (Chapter 8). If a list structure has been defined using the `RECORD` record type (Chapter 8), and all accessing operations are written using the record package's `fetch`, `replace`, and `create` operations, changing from `RECORD` s to `DATATYPE` s only requires editing the record declaration (using `EDITREC`, Chapter 8) to replace declaration type `RECORD` by `DATATYPE`, and recompiling.

Note: There are some minor disadvantages with allocating new data types: First, there is an upper limit on the number of data types which can exist. Also, space for data types is allocated a page at a time, so each data type has at least one page assigned to it, which may be wasteful of space if there are only a few examples of a given data type. These problems should not effect most applications programs.

---

**Using Incomplete File Names**

Currently, Interlisp allows you to specify an open file by giving the file name. If the file name is incomplete (it doesn't have the device/host, directory, name, extension, and version number all supplied), the system converts it to a complete file name, by supplying defaults and searching through directories (which may be on remote file servers), and then searches the open streams for one corresponding to that file name. This file name-completion process happens whenever any I/O function is given an incomplete file name, which can cause a serious performance problem if I/O operations are done repeatedly. In general, it is much faster to convert an incomplete file name to a stream once, and use the stream from then on. For example, suppose a file is opened with `(SETQ STRM (OPENSTREAM 'MNAME 'INPUT))`. After doing this, `(READC 'MNAME)` and `(READC STRM)` would both work, but `(READC 'MNAME)` would take longer (sometimes orders of magnitude longer). This could seriously effect the performance if a program which is doing many I/O operations.

At some point in the future, when multiple streams are supported to a single file, the feature of mapping file names to streams will be removed. This is yet another reason why programs should use streams as handles to open files, instead of file names.

For more information on efficiency considerations when using files, see Chapter 24.
Using "Fast" and "Destructive" Functions

Among the functions used for manipulating objects of various data types, there are a number of functions which have "fast" and "destructive" versions. You should be aware of what these functions do, and when they should be used.

"Fast" functions: By convention, a function named by prefixing an existing function name with $F$ indicates that the new function is a "fast" version of the old. These usually have the same definitions as the slower versions, but they compile open and run without any "safety" error checks. For example, $\text{FNTH}$ runs faster than $\text{NTH}$, however, it does not make as many checks (for lists ending with anything but $\text{NIL}$, etc). If these functions are given arguments that are not in the form that they expect, their behavior is unpredictable; they may run forever, or cause a system error. In general, you should only use "fast" functions in code that has already been completely debugged, to speed it up.
"Destructive" functions: By convention, a function named by prefixing an existing function with \texttt{D} indicates the new function is a "destructive" version of the old one, which does not make any new structure but cannibalizes its argument(s). For example, \texttt{REMOVE} returns a copy of a list with a particular element removed, but \texttt{DREMOVE} actually changes the list structure of the list. (Unfortunately, not all destructive functions follow this naming convention: the destructive version of \texttt{APPEND} is \texttt{NCONC}.) You should be careful when using destructive functions that they do not inadvertently change data structures.
The Medley Process mechanism provides an environment in which multiple Lisp processes can run in parallel. Each executes in its own stack space, but all share a global address space. The current process implementation is cooperative; i.e., process switches happen voluntarily, either when the process in control has nothing to do or when it is in a convenient place to pause. There is no preemption or guaranteed service, so you cannot run something demanding (e.g., Chat) at the same time as something that runs for long periods without yielding control. Keyboard input and network operations block with great frequency, so processes currently work best for highly interactive tasks (editing, making remote files).

In Medley, the process mechanism is already turned on, and is expected to stay on during normal operations, as some system facilities (in particular, most network operations) require it. However, under exceptional conditions, the following function can be used to turn the world off and on:

\[
\text{(PROCESSWORLD FLG)}
\]

(\text{Function})

Starts up the process world, or if FLG = OFF, kills all processes and turns it off. Normally does not return. The environment starts out with two processes: a top-level EVALQT (the initial "tty" process) and the "background" process, which runs the window mouse handler and other system background tasks.

PROCESSWORLD is intended to be called at the top level of Interlisp, not from within a program. It does not toggle some sort of switch; rather, it constructs some new processes in a new part of the stack, leaving any callers of PROCESSWORLD in a now inaccessible part of the stack. Calling (PROCESSWORLD ‘OFF) is the only way the call to PROCESSWORLD ever returns.

\[
\text{(HARDRESET)}
\]

(\text{Function})

Resets the whole world, and rebuilds the stack from scratch. This is "harder" than doing RESET to every process, because it also resets system internal processes (such as the keyboard handler).

HARDRESET automatically turns the process world on (or resets it if it was on), unless the variable AUTOPROCESSFLG is NIL.

Creating and Destroying Processes

\[
\text{(ADD.PROCESS FORM PROP\textsubscript{1} VALUE\textsubscript{1} \ldots PROP\textsubscript{N} VALUE\textsubscript{N})}
\]

(\text{NoSpread Function})

Creates a new process evaluating FORM, and returns its process handle. The process’s stack environment is the top level, i.e., the new process does not have access to the environment in which ADD.PROCESS was called; all such information must be passed as arguments in FORM. The process runs until FORM returns or the process is explicitly deleted. An untrapped error within the process also deletes the process (unless its RESTARTABLE property is T), in which case a message is printed to that effect.
The remaining arguments are alternately property names and values. Any property/value pairs acceptable to \texttt{PROCESSPROP} may be given, but the following two are directly relevant to \texttt{ADD.PROCESS}:

**NAME**  Value can be a symbol or a string; if not given, the process name is taken from \texttt{(CAR FORM)}. \texttt{ADD.PROCESS} may pack the name with a number to make it unique. Process names are treated as case-insensitive strings. This name is solely for the convenience of manipulating processes at Lisp type-in; e.g., the name can be given as the \texttt{PROC} argument to most process functions, and the name appears in menus of processes. However, programs should normally only deal in process handles, both for efficiency and to avoid the confusion that can result if two processes have the same defining form.

**SUSPEND**  If the value is non-\texttt{NIL}, the new process is created but then immediately suspended; i.e., the process does not actually run until woken by a \texttt{WAKE.PROCESS} (below).

\texttt{(PROCESSPROP PROC PROP NEWVALUE)}  [NoSpread Function]

Used to get or set the values of certain properties of process \texttt{PROC} in a manner analogous to \texttt{WINDOWPROP}. If \texttt{NEWVALUE} is supplied (including if it is \texttt{NIL}), property \texttt{PROP} is given that value. In all cases, returns the old value of the property. The following properties have special meaning for processes; all others are uninterpreted:

**NAME**  Value is a symbol used for identifying the process to the user.

**FORM**  Value is the Lisp form used to start the process (readonly).

**RESTARTABLE**  Value is a flag indicating the disposition of the process following errors or hard resets:

- \texttt{NIL} or \texttt{NO} (the default): If an untrapped error (or Control-E or Control-D) causes its form to be exited, the process is deleted. The process is also deleted if a \texttt{HARDRESET} (or Control-D from \texttt{RAID}) occurs, causing the entire Process world to be reinitialized.

- \texttt{T} or \texttt{YES}: The process is automatically restarted on errors or \texttt{HARDRESET}. This is the normal setting for persistent "background" processes, such as the mouse process, that can safely restart themselves on errors.

- \texttt{HARDRESET}: The process is deleted as usual if an error causes its form to be exited, but it \textit{is} restarted on a \texttt{HARDRESET}. This setting is preferred for persistent processes for which an error is an unusual condition, one
that might repeat itself if the process were simply blindly restarted.

**RESTARTFORM**

If the value is non-NIL, it is the form used if the process is restarted (instead of the value of the FORM property). Of course, the process must also have a non-NIL RESTARTABLE prop for this to have any effect.

**BEFOREEXIT**

If the value is the atom DON’T, it will not be interrupted by a LOGOUT. If LOGOUT is attempted before the process finishes, a message will appear saying that Interlisp is waiting for the process to finish. If you want the LOGOUT to proceed without waiting, you must use the process status window (from the background menu) to delete the process.

**AFTEREXIT**

Value indicates the disposition of the process following a resumption of Lisp after some exit (LOGOUT, SYSOUT, MAKESYS). Possible values are:

- **DELETE**: Delete the process.
- **SUSPEND**: Suspend the process; i.e., do not let it run until it is explicitly woken.
- An event: Cause the process to be suspended waiting for the event (See the Events section below).

**INFOHOOK**

Value is a function or form used to provide information about the process, in conjunction with the INFO command in the process status window (see the Process Status Window section below).

**WINDOW**

Value is a window associated with the process, the process’s "main” window. Used to switch the tty process to this process when you click in this window (see the Switching the TTY Process section below).

Setting the WINDOW property does not set the primary I/O stream (NIL) or the terminal I/O stream (T) to the window. When a process is created, I/O operations to the NIL or T stream will cause a new window to appear. TTYDISPLAYSTREAM (see Chapter 26) should be used to set the terminal I/O stream of a process to a specific window.

**TTYENTRYFN**

Value is a function that is applied to the process when the process is made the tty process (see the Switching the TTY Process section below).
TTYEXITFN  Value is a function that is applied to the process when the
process ceases to be the tty process (see the Switching the
TTY Process section below).

(TTHIS.PROCESS)  [Function]
Returns the handle of the currently running process, or NIL if the Process world is turned
off.

(DDEL.PROCESS PROC)  [Function]
Deletes process PROC. PROC may be a process handle (returned by ADD.PROCESS), or its
name. If PROC is the currently running process, DEL.PROCESS does not return!

(PROCESS.RETURN VALUE)  [Function]
Terminates the currently running process, causing it to "return" VALUE. There is an
implicit PROCESS.RETURN around the FORM argument given to ADD.PROCESS, so that
normally a process can finish by simply returning; PROCESS.RETURN is supplied for
earlier termination.

(PROCESS.RESULT PROCESS WAITFORRESULT)  [Function]
If PROCESS has terminated, returns the value, if any, that it returned. This is either the
value of a PROCESS.RETURN or the value returned from the form given to ADD.PROCESS.
If the process was aborted, the value is NIL. If WAITFORRESULT is true,
PROCESS.RESULT blocks until PROCESS finishes, if necessary; otherwise, it returns NIL
immediately if PROCESS is still running. PROCESS must be the actual process handle
returned from ADD.PROCESS, not a process name, as the association between handle and
name disappears when the process finishes (and the process handle itself is then garbage
collected if no one else has a pointer to it).

(PROCESS.FINISHEDP PROCESS)  [Function]
True if PROCESS has terminated. The value returned is an indication of how it finished:
NORMAL or ERROR.

(PROCESSP PROC)  [Function]
True if PROC is the handle of an active process, i.e., one that has not yet finished.

(RELPROCESSP PROCHANDLE)  [Function]
True if PROCHANDLE is the handle of a deleted process. This is analogous to RELSTKP. It
differs from PROCESS.FINISHEDP in that it never causes an error, while
PROCESS.FINISHEDP can cause an error if its PROC argument is not a process at all.

(RESTART.PROCESS PROC)  [Function]
Unwinds PROC to its top level and reevaluates its form. This is effectively a
DEL.PROCESS followed by the original ADD.PROCESS.
(MAP . PROCESSES MAPFN)  [Function]
Maps over all processes, calling MAPFN with three arguments: the process handle, its name, and its form.

(FIND . PROCESS PROC ERRORFLG)  [Function]
If PROC is a process handle or the name of a process, returns the process handle for it, else NIL. If ERRORFLG is T, generates an error if PROC is not, and does not name, a live process.

Process Control Constructs

(BLOCK MSECSWAIT TIMER)  [Function]
Yields control to the next waiting process, assuming any is ready to run. If MSECSWAIT is specified, it is a number of milliseconds to wait before returning, or T, meaning wait forever (until explicitly woken). Alternatively, TIMER can be given as a millisecond timer (as returned by SETUPTIMER, Chapter 12) of an absolute time at which to wake up. In any of those cases, the process enters the waiting state until the time limit is up. BLOCK with no arguments leaves the process in the runnable state, i.e., it returns as soon as every other runnable process of the same priority has had a chance.

BLOCK can be aborted by interrupts such as Control-D, Control-E, or Control-B. BLOCK will return before its timeout is completed, if the process is woken by WAKE . PROCESS, PROCESS . EVAL, or PROCESS . APPLY.

(DISMISS MSECSWAIT TIMER NOBLOCK)  [Function]
DISMISS is used to dismiss the current process for a given period of time. Similar to BLOCK, except that:

• DISMISS is guaranteed not to return until the specified time has elapsed
• MSECSWAIT cannot be T to wait forever
• If NOBLOCK is T, DISMISS will not allow other processes to run, but will busy-wait until the amount of time given has elapsed.

(WAKE . PROCESS PROC STATUS)  [Function]
Explicitly wakes process PROC, i.e., makes it runnable, and causes its call to BLOCK (or other waiting function) to return STATUS. This is one simple way to notify a process of some happening; however, note that if WAKE . PROCESS is applied to a process more than once before the process actually gets its turn to run, it sees only the latest STATUS.
Blocks process `PROC` indefinitely, i.e., `PROC` will not run until it is woken by a `WAKE.PROCESS`.

The following three functions allow access to the stack context of some other process. They require a little bit of care, and are computationally non-trivial, but they do provide a more powerful way of manipulating another process than `WAKE.PROCESS` allows.

**(PROCESS.EVALV PROC VAR)**  
Performs `(EVALV VAR)` in the stack context of `PROC`.

**(PROCESS.EVAL PROC FORM WAITFORRESULT)**  
Evaluates `FORM` in the stack context of `PROC`. If `WAITFORRESULT` is true, blocks until the evaluation returns a result, else allows the current process to run in parallel with the evaluation. Any errors that occur will be in the context of `PROC`, so be careful. In particular, note that

```
(PROCESS.EVAL PROC '(NLSETQ (FOO)))
```

and

```
(NLSETQ (PROCESS.EVAL PROC '(FOO)))
```

behave quite differently if `FOO` causes an error. And it is quite permissible to intentionally cause an error in proc by performing

```
(PROCESS.EVAL PROC '(ERROR!))
```

If `WAITFORRESULT` is true and the computation in the other process aborts or the other process is killed `PROCESS.EVAL` returns `:ABORTED`.

After `FORM` is evaluated in `PROC`, the process `PROC` is woken up, even if it was running `BLOCK` or `AWAIT.EVENT`. This is necessary because an event of interest may have occurred while the process was evaluating `FORM`.

**(PROCESS.APPLY PROC FN ARGS WAITFORRESULT)**  
Performs `(APPLY FN ARGS)` in the stack context of `PROC`. Note the same warnings as with `PROCESS.EVAL`.

### Events

An "event" is a synchronizing primitive used to coordinate related processes, typically producers and consumers. Consumer processes can "wait" on events, and producers "notify" events.
(CREATE.EVENT NAME) [Function]

Returns an instance of the EVENT datatype, to be used as the event argument to functions listed below. NAME is arbitrary, and is used for debugging or status information.

(AWAIT.EVENT EVENT TIMEOUT TIMERP) [Function]

Suspends the current process until EVENT is notified, or until a timeout occurs. If TIMEOUT is NIL, there is no timeout. Otherwise, timeout is either a number of milliseconds to wait, or, if TIMERP is T, a millisecond timer set to expire at the desired time using SETUPTIMER (see Chapter 12).

(NOTIFY.EVENT EVENT ONCEONLY) [Function]

If there are processes waiting for EVENT to occur, causes those processes to be placed in the running state, with EVENT returned as the value from AWAIT.EVENT. If ONCEONLY is true, only runs the first process waiting for the event (this should only be done if the programmer knows that there can only be one process capable of responding to the event at once).

The meaning of an event is up to the programmer. In general, however, the notification of an event is merely a hint that something of interest to the waiting process has happened; the process should still verify that the conceptual event actually occurred. That is, the process should be written so that it operates correctly even if woken up before the timeout and in the absence of the notified event. In particular, the completion of PROCESS.EVAL and related operations in effect wakes up the process in which they were performed, since there is no secure way of knowing whether the event of interest occurred while the process was busy performing the PROCESS.EVAL.

There is currently one class of system-defined events, used with the network code. Each Pup and NS socket has associated with it an event that is notified when a packet arrives on the socket; the event can be obtained by calling PUPSOCKETEVENT or NSOCKETEVENT, respectively (see Chapter 30).

Monitors

It is often the case that cooperating processes perform operations on shared structures, and some mechanism is needed to prevent more than one process from altering the structure at the same time. Some languages have a construct called a monitor, a collection of functions that access a common structure with mutual exclusion provided and enforced by the compiler via the use of monitor locks. Medley has taken this implementation notion as the basis for a mutual exclusion capability suitable for a dynamically-scoped environment.

A monitorlock is an object created by you and associated with (e.g., stored in) some shared structure that is to be protected from simultaneous access. To access the structure, a program waits for the lock to be free, then takes ownership of the lock, accesses the structure, then releases the lock. The functions and macros below are used:
(CREATE.MONITORLOCK NAME)  
Returns an instance of the MONITORLOCK datatype, to be used as the lock argument to functions listed below. NAME is arbitrary, and is used for debugging or status information.

(WITH.MONITOR LOCK FORM₁ ... FORMₙ)  
Evaluates FORM₂ ... FORMₙ while owning LOCK, and returns the value of FORMₙ. This construct is implemented so that the lock is released even if the form is exited via error (currently implemented with RESETLST).

Ownership of a lock is dynamically scoped: if the current process already owns the lock (e.g., if the caller was itself inside a WITH.MONITOR for this lock), WITH.MONITOR does not wait for the lock to be free before evaluating FORM₁ ... FORMₙ.

(WITH.FAST.MONITOR LOCK FORM₁ ... FORMₙ)  
Like WITH.MONITOR, but implemented without the RESETLST. User interrupts (e.g., Control-E) are inhibited during the evaluation of FORM₁ ... FORMₙ.

Programming restriction: the evaluation of FORM₁ ... FORMₙ must not error (the lock would not be released). This construct is mainly useful when the forms perform a small, safe computation that never errors and need never be interrupted.

(MONITOR.AWAIT.EVENT RELEASELOCK EVENT TIMEOUT TIMERP)  
For use in blocking inside a monitor. Performs (AWAIT.EVENT EVENT TIMEOUT TIMERP), but releases RELEASELOCK first, and reobtains the lock (possibly waiting) on wakeup.

Typical use for MONITOR.AWAIT.EVENT: A function wants to perform some operation on FOO, but only if it is in a certain state. It has to obtain the lock on the structure to make sure that the state of the structure does not change between the time it tests the state and performs the operation. If the state turns out to be bad, it then waits for some other process to make the state good, meanwhile releasing the lock so that the other process can alter the structure.

(WITH.MONITOR FOO-LOCK  
  (until CONDITION-OF-FOO  
    do (MONITOR.AWAIT.EVENT FOO-LOCK EVENT-FOO-CHANGED TIMEOUT) )  
  OPERATE-ON-FOO)  

It is sometimes convenient for a process to have WITH.MONITOR at its top level and then do all its interesting waiting using MONITOR.AWAIT.EVENT. Not only is this often cleaner, but in the present implementation in cases where the lock is frequently accessed, it saves the RESETLST overhead of WITH.MONITOR.

Programming restriction: There must not be an ERRORSET between the enclosing WITH.MONITOR and the call to MONITOR.AWAIT.EVENT such that the ERRORSET would catch an ERROR! and continue inside the monitor, for the lock would not have been
reobtained. (The reason for this restriction is that, although `MONITOR.AWAIT.EVENT` won’t itself error, you could have caused an error with an interrupt, or a `PROCESS.EVAL` in the context of the waiting process that produced an error.)

On rare occasions it may be useful to manipulate monitor locks directly. The following two functions are used in the implementation of `WITH.MONITOR`:

```
(OBTAIN.MONITORLOCK LOCK DONTWAIT UNWINDSAVE) [Function]
Takes possession of `LOCK`, waiting if necessary until it is free, unless `DONTWAIT` is true, in which case it returns `NIL` immediately. If `UNWINDSAVE` is true, performs a `RESETSAVE` to be unwound when the enclosing `RESETLST` exits. Returns `LOCK` if `LOCK` was successfully obtained, `T` if the current process already owned `LOCK`.
```

```
(RELEASE.MONITORLOCK LOCK EVENIFNOTMINE) [Function]
Releases `LOCK` if it is owned by the current process, and wakes up the next process, if any, waiting to obtain the lock.

If `EVENIFNOTMINE` is non-`NIL`, the lock is released even if it is not owned by the current process.
```

When a process is deleted, any locks it owns are released.

Global Resources

The biggest source of problems in the multi-processing environment is the matter of global resources. Two processes cannot both use the same global resource if there can be a process switch in the middle of their use (currently this means calls to `BLOCK`, but ultimately with a preemptive scheduler means anytime). Thus, user code should be wary of its own use of global variables, if it ever makes sense for the code to be run in more than one process at a time. “State” variables private to a process should generally be bound in that process; structures that are shared among processes (or resources used privately but expensive to duplicate per process) should be protected with monitor locks or some other form of synchronization.

Aside from user code, however, there are many system global variables and resources. Most of these arise historically from the single-process Interlisp-10 environment, and will eventually be changed in Medley to behave appropriately in a multi-processing environment. Some have already been changed, and are described below. Two other resources not generally thought of as global variables—the keyboard and the mouse—are particularly idiosyncratic, and are discussed in the next section.

are allocated per process in Medley: primary input and output (the streams affected by `INPUT` and `OUTPUT`), terminal input and output (the streams designated by the name `T`), the primary read table and primary terminal table, and dribble files. Thus, each process can print to its own primary output,
print to the terminal, read from a different primary input, all without interfering with another process's reading and printing.

Each process begins life with its primary and terminal input/output streams set to a dummy stream. If the process attempts input or output using any of those dummy streams, e.g., by calling (READ T), or (PRINT & T), a tty window is automatically created for the process, and that window becomes the primary input/output and terminal input/output for the process. The default tty window is created at or near the region specified in the variable DEFAULTTTYREGION.

A process can, of course, call TTYDISPLAYSTREAM explicitly to give itself a tty window of its own choosing, in which case the automatic mechanism never comes into play. Calling TTYDISPLAYSTREAM when a process has no tty window not only sets the terminal streams, but also sets the primary input and output streams to be that window, assuming they were still set to the dummy streams.

(HASTTYWINDOWP PROCESS) [Function]

Returns T if the process PROCESS has a tty window; NIL otherwise. If PROCESS is NIL, it defaults to the current process.

Other system resources that are typically changed by RESETFORM, RESETLST, or RESETVARS are all global entities. In the multiprocessing environment, these constructs are suspect, as there is no provision for “undoing” them when a process switch occurs. For example, in the current release of Medley, it is not possible to set the print radix to 8 inside only one process, as the print radix is a global entity.

Note that RESETFORM and similar expressions are perfectly valid in the process world, and even quite useful, when they manipulate things strictly within one process. The process world is arranged so that deleting a process also unwinds any RESETxxx expressions that were performed in the process and are still waiting to be unwound, exactly as if a Control-D had reset the process to the top. Additionally, there is an implicit RESETLST at the top of each process, so that RESETSAVE can be used as a way of providing “cleanup” functions for when a process is deleted. For these, the value of RESETSTATE (see Chapter 14) is NIL if the process finished normally, ERROR if it was aborted by an error, RESET if the process was explicitly deleted, and HARDRESET if the process is being restarted after a HARDRESET or a RESTART.PROCESS.

Typein and the TTY Process

There is one global resource, the keyboard, that is particularly problematic to share among processes. Consider, for example, having two processes both performing (READ T). Since the keyboard input routines block while there is no input, both processes would spend most of their time blocking, and it would simply be a matter of chance which process received each character of type-in.
To resolve such dilemmas, the system designates a distinguished process, termed the *tty process*, that is assumed to be the process that is involved in terminal interaction. Any type-in from the keyboard goes to that process. If a process other than the tty process requests keyboard input, it blocks until it becomes the tty process. When the tty process is switched (in any of the ways described further below), any typeahead that occurred before the switch is saved and associated with the current tty process. Thus, it is always the case that keystrokes are sent to the process that is the tty process at the time of the keystrokes, regardless of when that process actually gets around to reading them.

**BACKGROUNDFNS**

A list of functions to call "in the background". The system runs a process (called "BACKGROUND") whose sole task is to call each of the functions on the list BACKGROUNDFNS repeatedly. Each element is the name of a function of no arguments. This is a good place to put cheap background tasks that only do something once in a while and hence do not want to spend their own separate process on it. However, note that it is considered good citizenship for a background function with a time-consuming task to spawn a separate process to do it, so that the other background functions are not delayed.

**TTYBACKGROUNDFNS**

This list is like BACKGROUNDFNS, but the functions are only called while in a tty input wait. That is, they always run in the tty process, and only when the user is not actively typing. For example, the flashing caret is implemented by a function on this list. Again, functions on this list should spend very little time (much less than a second), or else spawn a separate process.

It is less immediately obvious how to handle keyboard interrupt characters, as their action is asynchronous and not always tied to type-in. Interrupt handling is described in the Handling of Interrupts section below.

**Switching the TTY Process**

Any process can make itself be the tty process by calling **TTY.PROCESS**.

**(TTY.PROCESS PROC)**

Returns the handle of the current tty process. In addition, if PROC is non-NIL, makes it be the tty process. The special case of PROC = T is interpreted to mean the executive process; this is sometimes useful when a process wants to explicitly give up being the tty process.

**(TTY.PROCESSP PROC)**

True if PROC is the tty process; PROC defaults to the running process. Thus, (TTY.PROCESSP) is true if the caller is the tty process.
(\texttt{WAIT.FOR.TTY} \texttt{MSECS NEEDWINDOW}) \quad \textbf{[Function]}

Efficiently waits until \texttt{(TTY.PROCESSP)} is true. \texttt{WAIT.FOR.TTY} is called internally by the system functions that read from the terminal; user code thus need only call it in special cases.

If \texttt{MSECS} is non-NIL, it is the number of milliseconds to wait before timing out. If \texttt{WAIT.FOR.TTY} times out before \texttt{(TTY.PROCESSP)} is true, it returns \texttt{NIL}, otherwise it returns \texttt{T}. If \texttt{MSECS} is \texttt{NIL}, \texttt{WAIT.FOR.TTY} will not time out.

If \texttt{NEEDWINDOW} is non-NIL, \texttt{WAIT.FOR.TTY} opens a TTY window for the current process if one isn’t already open.

\texttt{WAIT.FOR.TTY} spawns a new mouse process if called under the mouse process (see \texttt{SPAWN.MOUSE}, in the Keeping the Mouse Alive section below).

In some cases, such as in functions invoked as a result of mouse action or a user’s typed-in call, it is reasonable for the function to invoke \texttt{TTY.PROCESS} itself so that it can take subsequent user type in. In other cases, however, this is too undisciplined; it is desirable to let you designate which process type-in should be directed to. This is most conveniently done by mouse action.

The system supports the model that “to type to a process, you click in its window.” To cooperate with this model, any process desiring keyboard input should put its process handle as the \texttt{PROCESS} property of its window(s). To handle the common case, the function \texttt{TTYDISPLAYSTREAM} does this automatically when the ttydisplaystream is switched to a new window. A process can own any number of windows; clicking in any of those windows gives the process the tty.

This mechanism suffices for most casual process writers. For example, if a process wants all its input/output interaction to occur in a particular window that it has created, it should just make that window be its tty window by calling \texttt{TTYDISPLAYSTREAM}. Thereafter, it can \texttt{PRINT} or \texttt{READ} to/from the \texttt{T} stream; if the process is not the tty process at the time that it calls \texttt{READ}, it will block until the user clicks in the window.

For those needing tighter control over the tty, the default behavior can be overridden or supplemented. The remainder of this section describes the mechanisms involved.

There is a window property \texttt{WINDOWENTRYFN} that controls whether and how to switch the tty to the process owning a window. The mouse handler, before invoking any normal \texttt{BUTTONEVENTFN}, specifically notices the case of a button going down in a window that belongs to a process (i.e., has a \texttt{PROCESS} window property) that is not the tty process. In this case, it invokes the window’s \texttt{WINDOWENTRYFN} of one argument (\texttt{WINDOW}). \texttt{WINDOWENTRYFN} defaults to \texttt{GIVE.TTY.PROCESS}:

\begin{verbatim}
(GIVE.TTY.PROCESS WINDOW) \quad \textbf{[Function]}

If \texttt{WINDOW} has a \texttt{PROCESS} property, performs \texttt{(TTY.PROCESS (WINDOWPROP WINDOW 'PROCESS))} and then invokes \texttt{WINDOW}'s \texttt{BUTTONEVENTFN} function (or \texttt{RIGHTBUTTONFN} if the right button is down).
\end{verbatim}
There are some cases where clicking in a window does not always imply that the user wants to talk to that window. For example, clicking in a text editor window with a shift key held down means to "shift-select" some piece of text into the input buffer of the current tty process. The editor supports this by supplying a WINDOWENTRYFN that performs GIVE.TTY.PROCESS if no shift key is down, but goes into its shift-select mode, without changing the tty process, if a shift key is down. The shift-select mode performs a BKSYSBUF of the selected text when the shift key is let up, the BKSYSBUF feeding input to the current tty process.

Sometimes a process wants to be notified when it becomes the tty process, or stops being the tty process. To support this, there are two process properties, TTYEXITFN and TTYENTRYFN. The actions taken by TTY.PROCESS when it switches the tty to a new process are as follows: the former tty process’s TTYEXITFN is called with two arguments (OLDTTYPROCESS NEWTTYPROCESS); the new process is made the tty process; finally, the new tty process’s TTYENTRYFN is called with two arguments (NEWTTYPROCESS OLDTTYPROCESS). Normally the TTYENTRYFN and TTYEXITFN need only their first argument, but the other process involved in the switch is supplied for completeness. In the present system, most processes want to interpret the keyboard in the same way, so it is considered the responsibility of any process that changes the keyboard interpretation to restore it to the normal state by its TTYEXITFN.

A window is "owned" by the last process that anyone gave as the window’s PROCESS property. Ordinarily there is no conflict here, as processes tend to own disjoint sets of windows (though, of course, cooperating processes can certainly try to confuse each other). The only likely problem arises with that most global of windows, PROMPTWINDOW. Programs should not be tempted to read from PROMPTWINDOW. This is not usually necessary anyway, as the first attempt to read from T in a process that has not set its TTYDISPLAYSTREAM to its own window causes a tty window to be created for the process (see the Global Resources section above).

Handling of Interrupts

At the time that a keyboard interrupt character (see Chapter 29) is struck, any process could be running, and some decision must be made as to which process to actually interrupt. To the extent that keyboard interrupts are related to type-in, most interrupts are taken in the tty process; however, the following are handled specially:

RESET (initially Control-D)
ERROR (initially Control-E)

These interrupts are taken in the mouse process, if the mouse is not in its idle state; otherwise they are taken in the tty process. Thus, Control-E can be used to abort some mouse-invoked window action, such as the Shape command. As a consequence, note that if the mouse invokes some lengthy computation that the user thinks of as "background", Control-E still aborts it, even though that may not have been what the user intended. Such lengthy computations, for various reasons, should generally be
performed by spawning a separate process to perform them. The \texttt{RESET} interrupt in a process other than the executive is interpreted exactly as if an error unwound the process to its top level: if the process was designated \texttt{RESTARTABLE = T}, it is restarted; otherwise it is killed.

\textbf{HELP (initially Control-G)} A menu of processes is presented to the user, who is asked to select which one the interrupt should occur in. The current tty process appears with a * next to its name at the top of the menu. The menu also includes an entry "[Spawn Mouse]", for the common case of needing a mouse because the mouse process is currently tied up running someone's \texttt{BUTTONEVENTFN}; selecting this entry spawns a new mouse process, and no break occurs.

\textbf{BREAK (initially Control-B)} Performs the HELP interrupt in the mouse process, if the mouse is not in its idle state; otherwise it is performed in the tty process.

\textbf{RUBOUT (initially DELETE)} This interrupt clears typeahead in \emph{all} processes.

\textbf{RAID, STACK OVERFLOW, STORAGE FULL} These interrupts always occur in whatever process was running at the time the interrupt struck. In the cases of \texttt{STACK OVERFLOW} and \texttt{STORAGE FULL}, this means that the interrupt is more likely to strike in the offending process (especially if it is a "runaway" process that is not blocking). Note, however, that this process is still not necessarily the guilty party; it could be an innocent bystander that just happened to use up the last of a resource prodigiously consumed by some other process.

\begin{quote}
\textbf{Keeping the Mouse Alive}

Since the window mouse handler runs in its own process, it is not available while a window's \texttt{BUTTONEVENTFN} function (or any of the other window functions invoked by mouse action) is running. This leads to two sorts of problems: (1) a long computation underneath a \texttt{BUTTONEVENTFN} deprives the user of the mouse for other purposes, and (2) code that runs as a \texttt{BUTTONEVENTFN}
cannot rely on other BUTTONEVENTFNs running, which means that there some pieces of code that run differently from normal when run under the mouse process. These problems are addressed by the following functions:

\( \text{(SPAWN.MOUSE \rightarrow)} \) [Function]

Spawns another mouse process, allowing the mouse to run even if it is currently "tied up" under the current mouse process. This function is intended mainly to be typed in at the Lisp executive when you notice the mouse is busy.

\( \text{(ALLOW.BUTTON.EVENTS)} \) [Function]

Performs a (SPAWN.MOUSE) only when called underneath the mouse process. This should be called (once, on entry) by any function that relies on BUTTONEVENTFNs for completion, if there is any possibility that the function will itself be invoked by a mouse function.

It never hurts, at least logically, to call SPAWN.MOUSE or ALLOW.BUTTON.EVENTS needlessly, as the mouse process arranges to quietly kill itself if it returns from the user’s BUTTONEVENTFN and finds that another mouse process has sprung up in the meantime. (There is, of course, some computational expense.)

Process Status Window

The background menu command \texttt{PSW} (see Chapter 27) and the function \texttt{PROCESS.STATUS.WINDOW} (below) create a "Process Status Window", that allows you to examine and manipulate all of the existing processes:

![Process Status Window Diagram]

The window consists of two menus. The top menu lists all the processes at the moment. Commands in the bottom menu operate on the process selected in the top menu (\texttt{EXEC} in the example above). The commands are:

\texttt{BT, BTV, BTV*, BTV!} Displays a backtrace of the selected process.
WHO? Changes the selection to the tty process, i.e., the one currently in control of the keyboard.

KBD← Associates the keyboard with the selected process; i.e., makes the selected process be the tty process.

INFO If the selected process has an INFOHOOK property, calls it. The hook may be a function, which is then applied to two arguments, the process and the button (LEFT or MIDDLE) used to invoke INFO, or a form, which is simply EVAL’ed. The APPLY or EVAL happens in the context of the selected process, using PROCESS.APPLY or PROCESS.EVAL. The INFOHOOK process property can be set using PROCESSPROP (see the Creating and Destroying Processes section above).

BREAK Enter a break under the selected process. This has the side effect of waking the process with the value returned from the break.

KILL Deletes the selected process.

RESTART Restarts the selected process.

WAKE Wakes the selected process. Prompts for a value to wake it with (see WAKE.PROCESS).

SUSPEND Suspends the selected process; i.e., causes it to block indefinitely (until explicitly woken).

(PROCESS.STATUS.WINDOW WHERE) [Function]

Puts up a process status window that provides several debugging commands for manipulating running processes. If the window is already up, PROCESS.STATUS.WINDOW refreshes it. If WHERE is a position, the window is placed in that position; otherwise, you are prompted for a position.

Currently, the process status window runs under the mouse process, like other menus, so if the mouse is unavailable (e.g., a mouse function is performing an extensive computation), you may be unable to use the process status window (you can try SPAWN.MOUSE, of course).

Non-Process Compatibility

This section describes some considerations for authors of programs that ran in the old single-process Medley environment, and now want to make sure they run properly in the multi-processing world. The biggest problem to watch out for is code that runs underneath the mouse handler. Writers of mouse handler functions should remember that in the process world the mouse handler runs in its own process, and hence (a) you cannot depend on finding information on the stack (stash it in the
window instead), and (b) while your function is running, the mouse is not available (if you have any
non-trivial computation to do, spawn a process to do it, notify one of your existing processes to do it,
or use PROCESS.EVAL to run it under some other process).

The following functions are meaningful even if the process world is not on: BLOCK (invokes the
system background routine, which includes handling the mouse); TTY.PROCESS, THIS.PROCESS
(both return NIL); and TTY.PROCESSP (returns T, i.e., anyone is allowed to take tty input). In
addition, the following two functions exist in both worlds:

(EVAL.AS.PROCESS FORM) [Function]
Same as (ADD.PROCESS FORM 'RESTARTABLE 'NO), when processes are running, EVAL
when not. This is highly recommended for mouse functions that perform any non-trivial
activity.

(EVAL.IN.TTY.PROCESS FORM WAITFORRESULT) [Function]
Same as (PROCESS.EVAL (TTY.PROCESS) FORM WAITFORRESULT), when processes
are running, EVAL when not.

Most of the process functions that do not take a process argument can be called even if processes
aren’t running. ADD.PROCESS creates, but does not run, a new process (it runs when PROCESSWORLD
is called).
23. PROCESSES

The Interlisp-D Process mechanism provides an environment in which multiple Lisp processes can run in parallel. Each executes in its own stack space, but all share a global address space. The current process implementation is cooperative; i.e., process switches happen voluntarily, either when the process in control has nothing to do or when it is in a convenient place to pause. There is no preemption or guaranteed service, so you cannot run something demanding (e.g., Chat) at the same time as something that runs for long periods without yielding control. Keyboard input and network operations block with great frequency, so processes currently work best for highly interactive tasks (editing, making remote files).

In Interlisp-D, the process mechanism is already turned on, and is expected to stay on during normal operations, as some system facilities (in particular, most network operations) require it. However, under exceptional conditions, the following function can be used to turn the world off and on:

\[(\text{PROCESSWORLD FLG})\]  
\[\text{[Function]}\]

Starts up the process world, or if FLG = \text{OFF}, kills all processes and turns it off. Normally does not return. The environment starts out with two processes: a top-level \text{EVALQT} (the initial "tty" process) and the "background" process, which runs the window mouse handler and other system background tasks.

\text{PROCESSWORLD} is intended to be called at the top level of Interlisp, not from within a program. It does not toggle some sort of switch; rather, it constructs some new processes in a new part of the stack, leaving any callers of \text{PROCESSWORLD} in a now inaccessible part of the stack. Calling \[(\text{PROCESSWORLD 'OFF})\] is the only way the call to \text{PROCESSWORLD} ever returns.

\[(\text{HARDRESET})\]  
\[\text{[Function]}\]

Resets the whole world, and rebuilds the stack from scratch. This is "harder" than doing \text{RESET} to every process, because it also resets system internal processes (such as the keyboard handler).

\text{HARDRESET} automatically turns the process world on (or resets it if it was on), unless the variable \text{AUTOPROCESSFLG} is \text{NIL}.
Creating and Destroying Processes

(ADD.PROCESS FORM PROP1 VALUE1 ... PROPN VALUEN)     [NoSpread Function]

Creates a new process evaluating FORM, and returns its process handle. The process's stack environment is the top level, i.e., the new process does not have access to the environment in which ADD.PROCESS was called; all such information must be passed as arguments in FORM. The process runs until FORM returns or the process is explicitly deleted. An untrapped error within the process also deletes the process (unless its RESTARTABLE property is T), in which case a message is printed to that effect.

The remaining arguments are alternately property names and values. Any property/value pairs acceptable to PROCESSPROP may be given, but the following two are directly relevant to ADD.PROCESS:

NAME   Value should be a litatom; if not given, the process name is taken from (CAR FORM). ADD.PROCESS may pack the name with a number to make it unique. This name is solely for the convenience of manipulating processes at Lisp typein; e.g., the name can be given as the PROC argument to most process functions, and the name appears in menus of processes. However, programs should normally only deal in process handles, both for efficiency and to avoid the confusion that can result if two processes have the same defining form.

SUSPEND If the value is non-NIL, the new process is created but then immediately suspended; i.e., the process does not actually run until woken by a WAKE.PROCESS (below).

(PROCESSPROP PROC PROP NEWVALUE)          [NoSpread Function]

Used to get or set the values of certain properties of process PROC, in a manner analogous to WINDOWPROP. If NEWVALUE is supplied (including if it is NIL), property PROP is given that value. In all cases, returns the old value of the property. The following properties have special meaning for processes; all others are uninterpreted:

NAME   Value is a litatom used for identifying the process to the user.

FORM   Value is the Lisp form used to start the process (readonly).

RESTARTABLE   Value is a flag indicating the disposition of the process following errors or hard resets:
NIL or NO (the default): If an untrapped error (or Control-E or Control-D) causes its form to be exited, the process is deleted. The process is also deleted if a HARDRESET (or Control-D from RAID) occurs, causing the entire Process world to be reinitialized.

T or YES: The process is automatically restarted on errors or HARDRESET. This is the normal setting for persistent "background" processes, such as the mouse process, that can safely restart themselves on errors.

HARDRESET: The process is deleted as usual if an error causes its form to be exited, but it is restarted on a HARDRESET. This setting is preferred for persistent processes for which an error is an unusual condition, one that might repeat itself if the process were simply blindly restarted.

RESTARTFORM If the value is non-NIL, it is the form used if the process is restarted (instead of the value of the FORM property). Of course, the process must also have a non-NIL RESTARTABLE prop for this to have any effect.

BEFOREEXIT If the value is the atom DON'T, it will not be interrupted by a LOGOUT. If LOGOUT is attempted before the process finishes, a message will appear saying that Interlisp is waiting for the process to finish. If you want the LOGOUT to proceed without waiting, you must use the process status window (from the background menu) to delete the process.

AFTEREXIT Value indicates the disposition of the process following a resumption of Lisp after some exit (LOGOUT, SYSOUT, MAKESYS). Possible values are:

DELETE: Delete the process.

SUSPEND: Suspend the process; i.e., do not let it run until it is explicitly woken.

An event: Cause the process to be suspended waiting for the event (See the Events section below).

INFOHOOK Value is a function or form used to provide information about the process, in conjunction with the INFO command in the process status window (see the Process Status Window section below).
WINDOW
Value is a window associated with the process, the process's "main" window. Used to switch the tty process to this process when you click in this window (see the Switching the TTY Process section below).

Setting the WINDOW property does not set the primary I/O stream (NIL) or the terminal I/O stream (T) to the window. When a process is created, I/O operations to the NIL or T stream will cause a new window to appear. TTYDISPLAYSTREAM (see Chapter 28) should be used to set the terminal i/o stream of a process to a specific window.

TTYENTRYFN
Value is a function that is applied to the process when the process is made the tty process (see the Switching the TTY Process section below).

TTYEXITFN
Value is a function that is applied to the process when the process ceases to be the tty process (see the Switching the TTY Process section below).

(THIS.PROCESS)
[Function]
Returns the handle of the currently running process, or NIL if the Process world is turned off.

(DEL.PROCESS PROC —)
[Function]
Deletes process PROC. PROC may be a process handle (returned by ADD.PROCESS), or its name. If PROC is the currently running process, DEL.PROCESS does not return!

(PROCESS.RETURN VALUE)
[Function]
Terminates the currently running process, causing it to "return" VALUE. There is an implicit PROCESS.RETURN around the FORM argument given to ADD.PROCESS, so that normally a process can finish by simply returning; PROCESS.RETURN is supplied for earlier termination.

(PROCESS.RESULT PROCESS WAITFORRESULT)
[Function]
If PROCESS has terminated, returns the value, if any, that it returned. This is either the value of a PROCESS.RETURN or the value returned from the form given to ADD.PROCESS. If the process was aborted, the value is NIL. If WAITFORRESULT is true, PROCESS.RESULT blocks until PROCESS finishes, if necessary; otherwise, it returns NIL immediately if PROCESS is still running. PROCESS must be the actual process handle returned from
ADD.PROCESS, not a process name, as the association between handle and name
disappears when the process finishes (and the process handle itself is then
garbage collected if no one else has a pointer to it).

(PROCESS.FINISHEDP PROCESS) [Function]
True if PROCESS has terminated. The value returned is an indication of how it
finished: NORMAL or ERROR.

(PROCESSP PROC) [Function]
True if PROC is the handle of an active process, i.e., one that has not yet
finished.

(RELPROCESSP PROCHANDLE) [Function]
True if PROCHANDLE is the handle of a deleted process. This is analogous to
RELSTKP. It differs from PROCESS.FINISHEDP in that it never causes an error,
while PROCESS.FINISHEDP can cause an error if its PROC argument is not a
process at all.

(RESTART.PROCESS PROC) [Function]
Unwinds PROC to its top level and reevaluates its form. This is effectively a
DEL.PROCESS followed by the original ADD.PROCESS.

(MAP.PROCESSES MAPFN) [Function]
Maps over all processes, calling MAPFN with three arguments: the process
handle, its name, and its form.

(FIND.PROCESS PROC ERRORFLG) [Function]
If PROC is a process handle or the name of a process, returns the process
handle for it, else NIL. If ERRORFLG is T, generates an error if PROC is not,
and does not name, a live process.

---

Process Control Constructs

(BLOCK MSECSWAIT TIMER) [Function]
Yields control to the next waiting process, assuming any is ready to run. If
MSECSWAIT is specified, it is a number of milliseconds to wait before
returning, or T, meaning wait forever (until explicitly woken). Alternatively,
TIMER can be given as a millisecond timer (as returned by SETUPTIMER,
Chapter 12) of an absolute time at which to wake up. In any of those cases, the
process enters the waiting state until the time limit is up. BLOCK with no arguments leaves the process in the runnable state, i.e., it returns as soon as every other runnable process of the same priority has had a chance.

BLOCK can be aborted by interrupts such as Control-D, Control-E, or Control-B. BLOCK will return before its timeout is completed, if the process is woken by WAKE.PROCESS, PROCESS.EVAL, or PROCESS.APPLY.

(DISMISS MSECSWAIT TIMER NOBLOCK)

DISMISS is used to dismiss the current process for a given period of time. Similar to BLOCK, except that:
- DISMISS is guaranteed not to return until the specified time has elapsed
- MSECSWAIT cannot be T to wait forever
- If NOBLOCK is T, DISMISS will not allow other processes to run, but will busy-wait until the amount of time given has elapsed.

(WAKE.PROCESS PROC STATUS)

Explicitly wakes process PROC, i.e., makes it runnable, and causes its call to BLOCK (or other waiting function) to return STATUS. This is one simple way to notify a process of some happening; however, note that if WAKE.PROCESS is applied to a process more than once before the process actually gets its turn to run, it sees only the latest STATUS.

(SUSPEND.PROCESS PROC)

Blocks process PROC indefinitely, i.e., PROC will not run until it is woken by a WAKE.PROCESS.

The following three functions allow access to the stack context of some other process. They require a little bit of care, and are computationally non-trivial, but they do provide a more powerful way of manipulating another process than WAKE.PROCESS allows.

(PROCESS.EVALV PROC VAR)

Performs (EVALV VAR) in the stack context of PROC.

(PROCESS.EVAL PROC FORM WAITFORRESULT)

Evaluates FORM in the stack context of PROC. If WAITFORRESULT is true, blocks until the evaluation returns a result, else allows the current process to run in parallel with the evaluation. Any errors that occur will be in the context of PROC, so be careful. In particular, note that

(PROCESS.EVAL PROC '(NLSETQ (FOO)))
and

(NLSETQ (PROCESS.EVAL PROC '(FOO)))

behave quite differently if \texttt{FOO} causes an error. And it is quite permissible to intentionally cause an error in \texttt{proc} by performing

(PROCESS.EVAL PROC '(ERROR!))

If errors are possible and \texttt{WAITFORRESULT} is true, the caller should almost certainly make sure that \texttt{FORM} traps the errors; otherwise the caller could end up waiting forever if \texttt{FORM} unwinds back into the pre-existing stack context of \texttt{PROC}.

After \texttt{FORM} is evaluated in \texttt{PROC}, the process \texttt{PROC} is woken up, even if it was running \texttt{BLOCK} or \texttt{AWAIT.EVENT}. This is necessary because an event of interest may have occurred while the process was evaluating \texttt{FORM}.

(PROCESS.APPLY PROC FN ARGS WAITFORRESULT) \hspace{1cm} \text{[Function]}

Performs \texttt{(APPLY FN ARGS)} in the stack context of \texttt{PROC}. Note the same warnings as with \texttt{PROCESS.EVAL}.

### Events

An "event" is a synchronizing primitive used to coordinate related processes, typically producers and consumers. Consumer processes can "wait" on events, and producers "notify" events.

(CREATE.EVENT NAME) \hspace{1cm} \text{[Function]}

Returns an instance of the \texttt{EVENT} datatype, to be used as the event argument to functions listed below. \texttt{NAME} is arbitrary, and is used for debugging or status information.

(AWAIT.EVENT EVENT TIMEOUT TIMERP) \hspace{1cm} \text{[Function]}

Suspends the current process until \texttt{EVENT} is notified, or until a timeout occurs. If \texttt{TIMEOUT} is \texttt{NIL}, there is no timeout. Otherwise, timeout is either a number of milliseconds to wait, or, if \texttt{TIMERP} is \texttt{T}, a millisecond timer set to expire at the desired time using \texttt{SETUPTIMER} (see Chapter 12).

(NOTIFY.EVENT EVENT ONCEONLY) \hspace{1cm} \text{[Function]}

If there are processes waiting for \texttt{EVENT} to occur, causes those processes to be placed in the running state, with \texttt{EVENT} returned as the value from \texttt{AWAIT.EVENT}. If \texttt{ONCEONLY} is true, only runs the first process waiting for
the event (this should only be done if the programmer knows that there can only
be one process capable of responding to the event at once).

The meaning of an event is up to the programmer. In general, however, the notification
of an event is merely a hint that something of interest to the waiting process has
happened; the process should still verify that the conceptual event actually occurred.
That is, the process should be written so that it operates correctly even if woken up before
the timeout and in the absence of the notified event. In particular, the completion of
\texttt{PROCESS.EVAL} and related operations in effect wakes up the process in which they
were performed, since there is no secure way of knowing whether the event of interest
occurred while the process was busy performing the \texttt{PROCESS.EVAL}.

There is currently one class of system-defined events, used with the network code.
Each Pup and NS socket has associated with it an event that is notified when a packet
arrives on the socket; the event can be obtained by calling \texttt{PUPSOCKETEVENT} or
\texttt{NSOCKETEVENT}, respectively (see Chapter 32).

### Monitors

It is often the case that cooperating processes perform operations on shared structures,
and some mechanism is needed to prevent more than one process from altering the
structure at the same time. Some languages have a construct called a monitor, a
collection of functions that access a common structure with mutual exclusion provided
and enforced by the compiler via the use of monitor locks. Interlisp-D has taken this
implementation notion as the basis for a mutual exclusion capability suitable for a
dynamically-scoped environment.

A monitorlock is an object created by you and associated with (e.g., stored in) some
shared structure that is to be protected from simultaneous access. To access the
structure, a program waits for the lock to be free, then takes ownership of the lock,
accesses the structure, then releases the lock. The functions and macros below are
used:

\begin{verbatim}
(CREATE.MONITORLOCK NAME —) [Function]
Returns an instance of the \texttt{MONITORLOCK} datatype, to be used as the lock
argument to functions listed below. \texttt{NAME} is arbitrary, and is used for
debugging or status information.

(WITH.MONITOR LOCK FORM1 ... FORMN) [Macro]
Evaluates \texttt{FORM1} ... \texttt{FORMN} while owning \texttt{LOCK}, and returns the value of
\texttt{FORMN}. This construct is implemented so that the lock is released even if the
form is exited via error (currently implemented with \texttt{RESETLST}).
\end{verbatim}
Ownership of a lock is dynamically scoped: if the current process already owns the lock (e.g., if the caller was itself inside a WITH.MONITOR for this lock),
WITH.MONITOR does not wait for the lock to be free before evaluating FORM₁ ... FORMₙ.

(WITH.FAST.MONITOR LOCK FORM₁ ... FORMₙ)                       [Macro]

Like WITH.MONITOR, but implemented without the RESETLIST. User interrupts (e.g., Control-E) are inhibited during the evaluation of FORM₁ ... FORMₙ.

Programming restriction: the evaluation of FORM₁ ... FORMₙ must not error (the lock would not be released). This construct is mainly useful when the forms perform a small, safe computation that never errors and need never be interrupted.

(MONITOR.AWAIT.EVENT RELEASELOCK EVENT TIMEOUT TIMERP)    [Function]

For use in blocking inside a monitor. Performs (AWAIT.EVENT EVENT TIMEOUT TIMERP), but releases RELEASELOCK first, and reobtains the lock (possibly waiting) on wakeup.

Typical use for MONITOR.AWAIT.EVENT: A function wants to perform some operation on FOO, but only if it is in a certain state. It has to obtain the lock on the structure to make sure that the state of the structure does not change between the time it tests the state and performs the operation. If the state turns out to be bad, it then waits for some other process to make the state good, meanwhile releasing the lock so that the other process can alter the structure.

(WITH.MONITOR FOO-LOCK
  (until CONDITION-OF-FOO
    do (MONITOR.AWAIT.EVENT FOO-LOCK EVENT-FOO-CHANGED TIMEOUT))
  OPERATE-ON-FOO)

It is sometimes convenient for a process to have WITH.MONITOR at its top level and then do all its interesting waiting using MONITOR.AWAIT.EVENT. Not only is this often cleaner, but in the present implementation in cases where the lock is frequently accessed, it saves the RESETLIST overhead of WITH.MONITOR.

Programming restriction: There must not be an ERRORSET between the enclosing WITH.MONITOR and the call to MONITOR.AWAIT.EVENT such that the ERRORSET would catch an ERROR! and continue inside the monitor, for the lock would not have been reobtained. (The reason for this restriction is that, although MONITOR.AWAIT.EVENT won't itself error, you could have caused an error with an interrupt, or a PROCESS.EVAL in the context of the waiting process that produced an error.)
On rare occasions it may be useful to manipulate monitor locks directly. The following two functions are used in the implementation of \texttt{WITH\_MONITOR}: 
(OBTAIN.MONITORLOCK LOCK DONTWAIT UNWINDSAVE) [Function]
Takes possession of LOCK, waiting if necessary until it is free, unless DONTWAIT is true, in which case it returns NIL immediately. If UNWINDSAVE is true, performs a RESETSAVE to be unwound when the enclosing RESETLST exits. Returns LOCK if LOCK was successfully obtained, T if the current process already owned LOCK.

(RELEASE.MONITORLOCK LOCK EVENIFNOTMINE) [Function]
Releases LOCK if it is owned by the current process, and wakes up the next process, if any, waiting to obtain the lock.
If EVENIFNOTMINE is non-NIL, the lock is released even if it is not owned by the current process.

When a process is deleted, any locks it owns are released.

Global Resources

The biggest source of problems in the multi-processing environment is the matter of global resources. Two processes cannot both use the same global resource if there can be a process switch in the middle of their use (currently this means calls to BLOCK, but ultimately with a preemptive scheduler means anytime). Thus, user code should be wary of its own use of global variables, if it ever makes sense for the code to be run in more than one process at a time. "State" variables private to a process should generally be bound in that process; structures that are shared among processes (or resources used privately but expensive to duplicate per process) should be protected with monitor locks or some other form of synchronization.

Aside from user code, however, there are many system global variables and resources. Most of these arise historically from the single-process Interlisp-10 environment, and will eventually be changed in Interlisp-D to behave appropriately in a multi-processing environment. Some have already been changed, and are described below. Two other resources not generally thought of as global variables—the keyboard and the mouse—are particularly idiosyncratic, and are discussed in the next section.

The following resources, which are global in Interlisp-10, are allocated per process in Interlisp-D: primary input and output (the streams affected by INPUT and OUTPUT), terminal input and output (the streams designated by the name T), the primary read table and primary terminal table, and dribble files. Thus, each process can print to its own primary output, print to the terminal, read from a different primary input, all without interfering with another process's reading and printing.
Each process begins life with its primary and terminal input/output streams set to a
dummy stream. If the process attempts input or output using any of those dummy
streams, e.g., by calling (READ T), or (PRINT & T), a tty window is automatically
created for the process, and that window becomes the primary input/output and
terminal input/output for the process. The default tty window is created at or near the
region specified in the variable DEFAULTTTYREGION.

A process can, of course, call TTYDISPLAYSTREAM explicitly to give itself a tty window of
its own choosing, in which case the automatic mechanism never comes into play.
Calling TTYDISPLAYSTREAM when a process has no tty window not only sets the
terminal streams, but also sets the primary input and output streams to be that
window, assuming they were still set to the dummy streams.

(HASTTYWINDOWP PROCESS)  [Function]

Returns T if the process PROCESS has a tty window; NIL otherwise. If
PROCESS is NIL, it defaults to the current process.

Other system resources that are typically changed by RESETFORM, RESETLST, or
RESETVARS are all global entities. In the multiprocessing environment, these
constructs are suspect, as there is no provision for "undoing" them when a process
switch occurs. For example, in the current release of Interlisp-D, it is not possible to set
the print radix to 8 inside only one process, as the print radix is a global entity.

Note that RESETFORM and similar expressions are perfectly valid in the process world,
and even quite useful, when they manipulate things strictly within one process. The
process world is arranged so that deleting a process also unwinds any RESETxxx
expressions that were performed in the process and are still waiting to be unwound,
exactly as if a Control-D had reset the process to the top. Additionally, there is an
implicit RESETLST at the top of each process, so that RESETSAVE can be used as a way
of providing "cleanup" functions for when a process is deleted. For these, the value of
RESETSTATE (see Chapter 14) is NIL if the process finished normally, ERROR if it was
aborted by an error, RESET if the process was explicitly deleted, and HARDRESET if the
process is being restarted after a HARDRESET or a RESTART.PROCESS.

**Typein and the TTY Process**

There is one global resource, the keyboard, that is particularly problematic to share
among processes. Consider, for example, having two processes both performing (READ
T). Since the keyboard input routines block while there is no input, both processes
would spend most of their time blocking, and it would simply be a matter of chance
which process received each character of typein.
To resolve such dilemmas, the system designates a distinguished process, termed the tty process, that is assumed to be the process that is involved in terminal interaction. Any typein from the keyboard goes to that process. If a process other than the tty process requests keyboard input, it blocks until it becomes the tty process. When the tty process is switched (in any of the ways described further below), any typeahead that occurred before the switch is saved and associated with the current tty process. Thus, it is always the case that keystrokes are sent to the process that is the tty process at the time of the keystrokes, regardless of when that process actually gets around to reading them.

It is less immediately obvious how to handle keyboard interrupt characters, as their action is asynchronous and not always tied to typein. Interrupt handling is described in the Handling of Interrupts section below.

Switching the TTY Process

Any process can make itself be the tty process by calling TTY.PROCESS.

(TTY.PROCESS PROC) [Function]

Returns the handle of the current tty process. In addition, if PROC is non-NIL, makes it be the tty process. The special case of PROC = T is interpreted to mean the executive process; this is sometimes useful when a process wants to explicitly give up being the tty process.

(TTY.PROCESSP PROC) [Function]

True if PROC is the tty process; PROC defaults to the running process. Thus, (TTY.PROCESSP) is true if the caller is the tty process.

(WAIT.FOR.TTY MSECS NEEDWINDOW) [Function]

Efficiently waits until (TTY.PROCESSP) is true. WAIT.FOR.TTY is called internally by the system functions that read from the terminal; user code thus need only call it in special cases.

If MSECS is non-NIL, it is the number of milliseconds to wait before timing out. If WAIT.FOR.TTY times out before (TTY.PROCESSP) is true, it returns NIL, otherwise it returns T. If MSECS is NIL, WAIT.FOR.TTY will not time out.

If NEEDWINDOW is non-NIL, WAIT.FOR.TTY opens a TTY window for the current process if one isn't already open.

WAIT.FOR.TTY spawns a new mouse process if called under the mouse process (see SPAN.MOUSE, in the Keeping the Mouse Alive section below).
In some cases, such as in functions invoked as a result of mouse action or a user's typed-in call, it is reasonable for the function to invoke `TTY.PROCESS` itself so that it can take subsequent user type in. In other cases, however, this is too undisciplined; it is desirable to let the user designate which process typein should be directed to. This is most conveniently done by mouse action.

The system supports the model that "to type to a process, you click in its window." To cooperate with this model, any process desiring keyboard input should put its process handle as the `PROCESS` property of its window(s). To handle the common case, the function `TTYDISPLAYSTREAM` does this automatically when the ttydisplaystream is switched to a new window. A process can own any number of windows; clicking in any of those windows gives the process the tty.

This mechanism suffices for most casual process writers. For example, if a process wants all its input/output interaction to occur in a particular window that it has created, it should just make that window be its tty window by calling `TTYDISPLAYSTREAM`. Thereafter, it can PRINT or READ to/from the T stream; if the process is not the tty process at the time that it calls READ, it will block until the user clicks in the window.

For those needing tighter control over the tty, the default behavior can be overridden or supplemented. The remainder of this section describes the mechanisms involved.

There is a window property `WINDOWENTRYFN` that controls whether and how to switch the tty to the process owning a window. The mouse handler, before invoking any normal `BUTTONEVENTFN`, specifically notices the case of a button going down in a window that belongs to a process (i.e., has a `PROCESS` window property) that is not the tty process. In this case, it invokes the window's `WINDOWENTRYFN` of one argument (WINDOW). `WINDOWENTRYFN` defaults to `GIVE.TTY.PROCESS`:

```
(GIVE.TTY.PROCESS WINDOW)                      [Function]

If WINDOW has a PROCESS property, performs (TTY.PROCESS (WINDOWPROP WINDOW 'PROCESS)) and then invokes WINDOW's BUTTONEVENTFN function (or RIGHTBUTTONFN if the right button is down).
```

There are some cases where clicking in a window does not always imply that the user wants to talk to that window. For example, clicking in a text editor window with a shift key held down means to "shift-select" some piece of text into the input buffer of the current tty process. The editor supports this by supplying a `WINDOWENTRYFN` that performs `GIVE.TTY.PROCESS` if no shift key is down, but goes into its shift-select mode, without changing the tty process, if a shift key is down. The shift-select mode performs a `BKSYSBUF` of the selected text when the shift key is let up, the `BKSYSBUF` feeding input to the current tty process.
Sometimes a process wants to be notified when it becomes the tty process, or stops being the tty process. To support this, there are two process properties, `TTYEXITFN` and `TTYENTRYFN`. The actions taken by `TTY.PROCESS` when it switches the tty to a new process are as follows: the former tty process's `TTYEXITFN` is called with two arguments (OLDDTTYPROCESS NEWTTYPROCESS); the new process is made the tty process; finally, the new tty process's `TTYENTRYFN` is called with two arguments (NEWTTYPROCESS OLDDTTYPROCESS). Normally the `TTYENTRYFN` and `TTYEXITFN` need only their first argument, but the other process involved in the switch is supplied for completeness. In the present system, most processes want to interpret the keyboard in the same way, so it is considered the responsibility of any process that changes the keyboard interpretation to restore it to the normal state by its `TTYEXITFN`.

A window is "owned" by the last process that anyone gave as the window's `PROCESS` property. Ordinarily there is no conflict here, as processes tend to own disjoint sets of windows (though, of course, cooperating processes can certainly try to confuse each other). The only likely problem arises with that most global of windows, `PROMPTWINDOW`. Programs should not be tempted to read from `PROMPTWINDOW`. This is not usually necessary anyway, as the first attempt to read from `T` in a process that has not set its `TTYDISPLAYSTREAM` to its own window causes a tty window to be created for the process (see the Global Resources section above).

**Handling of Interrupts**

At the time that a keyboard interrupt character (see Chapter 30) is struck, any process could be running, and some decision must be made as to which process to actually interrupt. To the extent that keyboard interrupts are related to typein, most interrupts are taken in the tty process; however, the following are handled specially:

- **RESET** (initially Control-D)
- **ERROR** (initially Control-E)

These interrupts are taken in the mouse process, if the mouse is not in its idle state; otherwise they are taken in the tty process. Thus, Control-E can be used to abort some mouse-invoked window action, such as the Shape command. As a consequence, note that if the mouse invokes some lengthy computation that the user thinks of as "background", Control-E still aborts it, even though that may not have been what the user intended. Such lengthy computations, for various reasons, should generally be performed by spawning a separate process to perform them. The `RESET` interrupt in a process other than the executive is interpreted exactly as if an error unwound the process to its top level: if the process was
designated \texttt{RESTARTABLE} = \texttt{T}, it is restarted; otherwise it is killed.

**HELP** (initially Control-G) A menu of processes is presented to the user, who is asked to select which one the interrupt should occur in. The current tty process appears with a * next to its name at the top of the menu. The menu also includes an entry "[Spawn Mouse]", for the common case of needing a mouse because the mouse process is currently tied up running someone's \texttt{BUTTONEVENTFN}; selecting this entry spawns a new mouse process, and no break occurs.

**BREAK** (initially Control-B) Performs the \texttt{HELP} interrupt in the mouse process, if the mouse is not in its idle state; otherwise it is performed in the tty process.

**RUBOUT** (initially DELETE) This interrupt clears typeahead in all processes.

**RAID, STACK OVERFLOW, STORAGE FULL** These interrupts always occur in whatever process was running at the time the interrupt struck. In the cases of \texttt{STACK OVERFLOW} and \texttt{STORAGE FULL}, this means that the interrupt is more likely to strike in the offending process (especially if it is a "runaway" process that is not blocking). Note, however, that this process is still not necessarily the guilty party; it could be an innocent bystander that just happened to use up the last of a resource prodigiously consumed by some other process.

---

**Keeping the Mouse Alive**

Since the window mouse handler runs in its own process, it is not available while a window’s \texttt{BUTTONEVENTFN} function (or any of the other window functions invoked by mouse action) is running. This leads to two sorts of problems: (1) a long computation underneath a \texttt{BUTTONEVENTFN} deprives the user of the mouse for other purposes, and (2) code that runs as a \texttt{BUTTONEVENTFN} cannot rely on other \texttt{BUTTONEVENTFN}s running, which means that there some pieces of code that run differently from normal when run under the mouse process. These problems are addressed by the following functions:
(SPAWN.MOUSE —)  [Function]

Spawns another mouse process, allowing the mouse to run even if it is currently "tied up" under the current mouse process. This function is intended mainly to be typed in at the Lisp executive when the user notices the mouse is busy.

(ALLOW.BUTTON.EVENTS)  [Function]

Performs a (SPAWN.MOUSE) only when called underneath the mouse process. This should be called (once, on entry) by any function that relies on BUTTONEVENTFNS for completion, if there is any possibility that the function will itself be invoked by a mouse function.

It never hurts, at least logically, to call SPAWN.MOUSE or ALLOW.BUTTON.EVENTS needlessly, as the mouse process arranges to quietly kill itself if it returns from the user's BUTTONEVENTFNS and finds that another mouse process has sprung up in the meantime. (There is, of course, some computational expense.)

Process Status Window

The background menu command PSW (see Chapter 28) and the function PROCESS.STATUS.WINDOW (below) create a "Process Status Window", that allows the user to examine and manipulate all of the existing processes:

The window consists of two menus. The top menu lists all the processes at the moment. Commands in the bottom menu operate on the process selected in the top menu (EXEC in the example above). The commands are:

- SPACEWINDOW
- Edit
- MOUSE
- ERIS#LEAF
- \10MBWATCHER
- \EXEC
- \NSGATELISTENER
- \PUPGATELISTENER
- \TIMER.PROCESS
- BACKGROUND

- BT
- WHO?
- KILL
- BTV
- KEED
- RESTART
- BTY
- INFO
- WAKE
- BTV!
- BREAK
- SUSPEND
BT, BTV, BTV*, BTV! Displays a backtrace of the selected process.

WHO? Changes the selection to the tty process, i.e., the one currently in control of the keyboard.

KDB← Associates the keyboard with the selected process; i.e., makes the selected process be the tty process.

INFO If the selected process has an INFOHOOK property, calls it. The hook may be a function, which is then applied to two arguments, the process and the button (LEFT or MIDDLE) used to invoke INFO, or a form, which is simply EVAL’ed. The APPLY or EVAL happens in the context of the selected process, using PROCESS.APPLY or PROCESS.EVAL. The INFOHOOK process property can be set using PROCESSPROP (see the Creating and Destroying Processes section above).

BREAK Enter a break under the selected process. This has the side effect of waking the process with the value returned from the break.

KILL Deletes the selected process.

RESTART Restarts the selected process.

WAKE Wakes the selected process. Prompts for a value to wake it with (see WAKE.PROCESS).

SUSPEND Suspends the selected process; i.e., causes it to block indefinitely (until explicitly woken).

(PROCESS.STATUS.WINDOW WHERE) [Function]

Puts up a process status window that provides several debugging commands for manipulating running processes. If the window is already up, PROCESS.STATUS.WINDOW refreshes it. If WHERE is a position, the window is placed in that position; otherwise, the user is prompted for a position.
Currently, the process status window runs under the mouse process, like other menus, so if the mouse is unavailable (e.g., a mouse function is performing an extensive computation), you may be unable to use the process status window (you can try `SPAWN.MOUSE`, of course).

**Non-Process Compatibility**

This section describes some considerations for authors of programs that ran in the old single-process Interlisp-D environment, and now want to make sure they run properly in the Multi-processing world. The biggest problem to watch out for is code that runs underneath the mouse handler. Writers of mouse handler functions should remember that in the process world the mouse handler runs in its own process, and hence (a) you cannot depend on finding information on the stack (stash it in the window instead), and (b) while your function is running, the mouse is not available (if you have any non-trivial computation to do, spawn a process to do it, notify one of your existing processes to do it, or use `PROCESS.EVAL` to run it under some other process).

The following functions are meaningful even if the process world is not on: `BLOCK` (invokes the system background routine, which includes handling the mouse); `TTY.PROCESS`, `THIS.PROCESS` (both return `NIL`); and `TTY.PROCESSP` (returns `T`, i.e., anyone is allowed to take tty input). In addition, the following two functions exist in both worlds:

- `(EVAL.AS.PROCESS FORM)`
  
  Same as `(ADD.PROCESS FORM 'RESTARTABLE 'NO)`, when processes are running, `EVAL` when not. This is highly recommended for mouse functions that perform any non-trivial activity.

- `(EVAL.IN.TTY.PROCESS FORM WAITFORRESULT)`
  
  Same as `(PROCESS.EVAL (TTY.PROCESS) FORM WAITFORRESULT)`, when processes are running, `EVAL` when not.

Most of the process functions that do not take a process argument can be called even if processes aren't running. `ADD.PROCESS` creates, but does not run, a new process (it runs when `PROCESSWORLD` is called).
A stream is an object that provides an interface to a physical or logical device. The stream object contains local data and methods that operate on the stream object. Medley’s general-purpose I/O functions take a stream as one of their arguments. Not every device is capable of implementing every I/O operation, while some devices offer special functions for that device alone. Such restrictions and extensions are noted in the documentation of each device. The majority of the streams used in Medley fall into two categories: file streams and image streams.

A file is a sequence of data stored on some device that allows the data to be retrieved at a later time. Files are identified by a name specifying their storage devices. Input or output to a file is performed through a stream to the file, using \texttt{OPENSTREAM} (below). In addition, there are functions that manipulate the files themselves, rather than their data content.

An image stream is an output stream to a display device, such as the display screen or a printer. In addition to the standard output operations, an image stream implements a variety of graphics operations, such as drawing lines and displaying characters in multiple fonts. Unlike a file, the “content” of an image stream cannot be retrieved. Image streams are described in Chapter 26.

This chapter describes operations specific to file devices: how to name files, how to open streams to files, and how to manipulate files on their devices.

### Opening and Closing File Streams

To perform input from or output to a file, you must create a stream to the file, using \texttt{OPENSTREAM}:

\[
\text{(OPENSTREAM \ FILE \ ACCESS \ RECOG \ PARAMETERS \ \rightarrow)}
\]

Opens and returns a stream for the file specified by \texttt{FILE}, a file name. \texttt{FILE} can be either a string or a symbol. The syntax and manipulation of file names is described at length in the \texttt{FILENAME} section below. Incomplete file names are interpreted with respect to the connected directory (below).

\texttt{RECOG} specifies the recognition mode of \texttt{FILE} (below). If \texttt{RECOG = NIL}, it defaults according to the value of \texttt{ACCESS}.

\texttt{ACCESS} specifies the “access rights” to be used when opening the file. Possible values are:

- **INPUT**: Only input operations are permitted on the already existing file. Starts reading at the beginning of the file. \texttt{RECOG} defaults to \texttt{OLD}.

- **OUTPUT**: Only output operations are permitted on the initially empty file. Starts writing at the beginning of the file. While the file is open, other users or processes are unable to open the file for either input or output. \texttt{RECOG} defaults to \texttt{NEW}.

- **BOTH**: Both input and output operations are permitted on the file. Starts reading or writing at the beginning of the file. \texttt{RECOG} defaults to \texttt{OLD/NEW}. \texttt{ACCESS = BOTH} implies random access (Chapter 25), and may not be possible for files on some devices.
APPEND  Only sequential output operations are permitted on the file. Starts
writing at the end of the file.  RECOG defaults to OLD/NEW.  ACCESS =
APPEND may not be allowed for files on some devices.

Note:  ACCESS = OUTPUT implies that you intend to write a new or different
file, even if a version number was specified and the corresponding file
already exists. Any previous contents of the file are discarded, and the
file is empty immediately after the OPENSTREAM. If you want to write
on an already existing file while preserving the old contents, the file
must be opened for access BOTH or APPEND.

PARAMETERS is a list of pairs (ATTRIB VALUE), where ATTRIB is a file attribute (see
SETFILEINFO below). A non-list ATTRIB in PARAMETERS is treated as the pair (ATTRIB
T). Generally speaking, attributes that belong to the permanent file (e.g., TYPE) can only
be set when creating a new file, while attributes that belong only to a particular opening
of a file (e.g., ENDOFSTREAMOP) can be set on any call to OPENSTREAM. Not all devices
honor all attributes; those not recognized by a particular device are simply ignored.

In addition to the attributes permitted by SETFILEINFO, the following attributes are
accepted by OPENSTREAM as values of ATTRIB in its PARAMETERS argument:

DON'T.CHANGE.DATE  If VALUE is non-NIL, the file's creation date is not changed when the file
is opened. This option is meaningful only for old files opened for BOTH
access. You should use this only for specialized applications where the
caller does not want the file system to believe the file's content has been
changed.

SEQUENTIAL  If VALUE is non-NIL, this opening of the file need support only
sequential access; i.e., the caller intends never to use SETFILEPTR. For
some devices, sequential access to files is much more efficient than
random access. Note that the device may choose to ignore this attribute
and still open the file in a manner that permits random access. Also
note that this attribute does not make sense with ACCESS = BOTH.

If FILE is not recognized by the file system, OPENSTREAM causes the error FILE NOT
FOUND. Ordinarily, this error is intercepted via an entry on ERRORTYPELST (Chapter 24),
which causes SPELLFILE (see the Searching File Directories below) to be called.
SPELLFILE searches alternate directories and possibly attempts spelling correction on the
file name. Only if SPELLFILE is unsuccessful will the FILE NOT FOUND error actually
occur.

If FILE exists but cannot be opened, OPENSTREAM causes one of several other errors:
FILE WON'T OPEN if the file is already opened for conflicting access by someone else;
PROTECTION VIOLATION if the file is protected against the operation; FILE SYSTEM
RESOURCES EXCEEDED if there is no more room in the file system.
CLOSEF FILE

Closes FILE and returns its full file name. Generates an error, FILE NOT OPEN, if FILE does not designate an open stream. After closing a stream, no further input/output operations are permitted on it.

If FILE is NIL, it is defaulted to the primary input stream if that is not the terminal stream, or else the primary output stream if that is not the terminal stream. If both primary input and output streams are the terminal input/output streams, CLOSEF returns NIL. If CLOSEF closes either the primary input stream or the primary output stream (either explicitly or in the FILE = NIL case), it resets the primary stream for that direction to be the corresponding terminal stream. See Chapter 25 for information on the primary input/output streams.

WHENCLOSE (below) allows you to "advise" CLOSEF to perform various operations when a file is closed.

Because of buffering, the contents of a file open for output are not guaranteed to be written to the actual physical file device until CLOSEF is called. Buffered data can be forced out to a file without closing the file by using the function FORCEOUTPUT (Chapter 25).

Some network file devices perform their transactions in the background. As a result, it is possible for a file to be closed by CLOSEF and yet not be "fully" closed for a small time period afterward. During this time the file appears to be busy and cannot be opened for conflicting access by others.

CLOSEF? FILE

Closes FILE if it is open, returning the value of CLOSEF; otherwise does nothing and returns NIL.

In the present implementation of Medley, all open streams to files are kept in a registry of "open files". This registry does not include nameless streams, such as string streams (below), display streams (Chapter 28), and the terminal input and output streams; nor streams explicitly hidden from you, such as dribble streams (Chapter 30). This registry may not persist in future implementations of Medley, but at the present time it is accessible by the following two functions:

OPENP FILE ACCESS

ACCESS is an access mode for a stream opening (see OPENSTREAM), or NIL for any access.

If FILE is a stream, returns its full name if it is open for the specified access, otherwise NIL.

If FILE is a file name (a symbol), FILE is processed according to the rules of file recognition (below). If a stream open to a file by that name is registered and open for the specified access, then the file’s full name is returned. If the file name is not recognized, or no stream is open to the file with the specified access, NIL is returned.

If FILE is NIL, returns a list of the full names of all registered streams that are open for the specified access.
(CLOSEALL ALLFLG) [Function]

Closes all streams in the value of (OPENP). Returns a list of the files closed.

WHENCLOSE (below) allows certain files to be "protected" from CLOSEALL. If ALLFLG is T, all files, including those protected by WHENCLOSE, are closed.

File Names

A file name in Medley is a string or symbol whose characters specify a "path" to the actual file: on what host or device the file resides, in which directory, and so forth. Because Medley supports a variety of non-local file devices, parts of the path could be device-dependent. However, it is desirable for programs to be able to manipulate file names in a device-independent manner. To this end, Medley specifies a uniform file name syntax over all devices; the functions that perform the actual file manipulation for a particular device are responsible for any translation to that device's naming conventions.

A file name is composed of a collection of fields, some of which have specific meanings. The functions described below refer to each field by a field name, a literal atom from among the following: HOST, DEVICE, DIRECTORY, NAME, EXTENSION, and VERSION. The standard syntax for a file name is {HOST}DEVICE:<DIRECTORY>NAME.EXTENSION;VERSION. Some host's file systems do not use all of those fields in their file names.

HOST Specifies the host whose file system contains the file. In the case of local file devices, the "host" is the name of the device, e.g., DSK or FLOPPY.

DEVICE Specifies, for those hosts that divide their file system's name space among multiple physical devices, the device or logical structure on which the file resides. This should not be confused with Medley's abstract "file device", which denotes either a host or a local physical device and is specified by the HOST field.

DIRECTORY Specifies the "directory" containing the file. A directory usually is a grouping of a possibly large set of loosely related files, e.g., the personal files of a particular user, or the files belonging to some project. The DIRECTORY field usually consists of a principal directory and zero or more subdirectories that together describe a path through a file system's hierarchy. Each subdirectory name is set off from the previous directory or subdirectory by the character " >"; e.g., "LISP>LIBRARY>NEW".

NAME This field carries no specific meaning, but generally names a set of files thought of as being different renditions of the "same" abstract file.

EXTENSION This field also carries no specific meaning, but generally distinguishes the form of files having the same name. Most files systems have some "conventional" extensions that denote something about the content of the file. For example, in Medley, the extension DCOM, LCOM or DFASL denotes files containing compiled function definitions.
STREAMS & FILES

VERSION  A number used to distinguish the versions or "generations" of the files having a common name and extension. The version number is incremented each time a new file by the same name is created.

Most functions that take as input "a directory" accept either a directory name (the contents of the DIRECTORY field of a file name) or a "full" directory specification—a file name fragment consisting of only the fields HOST, DEVICE, and DIRECTORY. In particular, the "connected directory" (see below) consists, in general, of all three fields.

For convenience in dealing with certain operating systems, Medley also recognizes [ ] and ( ) as host delimiters (synonymous with [ ]), and / as a directory delimiter (synonymous with < at the beginning of a directory specification and > to terminate directory or subdirectory specification). For example, a file on a Unix file server UNX with the name /usr/foo/bar/stuff.tedit, whose DIRECTORY field is thus usr/foo/bar, could be specified as {UNX}/usr/foo/bar/stuff.tedit, or (UNX)<usr/foo/bar>stuff.tedit, or several other variations. Note that when using [ ] or ( ) as host delimiters, they usually must be escaped with the reader's escape character if the file name is expressed as a symbol rather than a string.

Different hosts have different requirements for valid characters in file names. In Medley, all characters are valid. However, in order to be able to parse a file name into its component fields, it is necessary that those characters that are conventionally used as file name delimiters be quoted when they appear inside of fields where there could be ambiguity. The file name quoting character is " ' " (single quote). Thus, the following characters must be quoted when not used as delimiters: », ; ; ; /, and ' itself. The character . (period) need only be quoted if it is to be considered a part of the EXTENSION field. The characters }, ]], and ) need only be quoted in a file name when the host field of the name is introduced by {, [ ], and (, respectively. The characters {, [ ], and < need only be quoted if they appear as the first character of a file name fragment, where they would otherwise be assumed to introduce the HOST or DIRECTORY fields.

The following functions are the standard way to manipulate file names in Medley. Their operation is purely syntactic—they perform no file system operations themselves.

(UNPACKFILENAME.STRING FILENAME)  [Function]

Parses FILENAME, returning a list in property list format of alternating field names and field contents. The field contents are returned as strings. If it is a stream, its full name is used.

Only those fields actually present in FILENAME are returned. A field is considered present if its delimiting punctuation is present, even if the field itself is empty. Empty fields are denoted by " " (the empty string).

Examples:

(UNPACKFILENAME.STRING "FOO.BAR") =>
(NAME "FOO" EXTENSION "BAR")

(UNPACKFILENAME.STRING "FOO.;2") =>
(NAME "FOO" EXTENSION "" VERSION "2")

(UNPACKFILENAME.STRING "FOO;") =>
(NAME "FOO" VERSION "")
(UNPACKFILENAME FILE) [Function]
Old version of UNPACKFILENAME.STRING that returns the field values as atoms, rather than as strings. UNPACKFILENAME.STRING is now considered the "correct" way of unpacking file names, because it does not lose information when the contents of a field are numeric. For example,

(UNPACKFILENAME 'STUFF.TXT) =>
(NAME STUFF EXTENSION TXT)

but

(UNPACKFILENAME 'STUFF.029) =>
(NAME STUFF EXTENSION 29)

Explicitly omitted fields are denoted by the atom NIL, rather than the empty string.

Note: Both UNPACKFILENAME and UNPACKFILENAME.STRING leave the trailing colon on the device field, so that the Tenex device NIL: can be distinguished from the absence of a device. Although UNPACKFILENAME.STRING is capable of making the distinction, it retains this behavior for backward compatibility. Thus,

(UNPACKFILENAME.STRING '{TOAST}DSK:FOO) =>
(HOST "TOAST" DEVICE "DSK:" NAME "FOO")

(FILENAMEFIELD FILENAME FIELDNAME) [Function]
Returns, as an atom, the contents of the FIELDNAME field of FILENAME. If FILENAME is a stream, its full name is used.

(PACKFILENAME.STRING FIELD₁ CONTENTS₁ ... FIELDₙ CONTENTSₙ) [NoSpread Function]
Takes a sequence of alternating field names and field contents (atoms or strings), and returns the corresponding file name, as a string.

If PACKFILENAME.STRING is given a single argument, it is interpreted as a list of alternating field names and field contents. Thus PACKFILENAME.STRING and UNPACKFILENAME.STRING operate as inverses.

If the same field name is given twice, the first occurrence is used.

The contents of the field name DIRECTORY may be either a directory name or a full directory specification as described above.

PACKFILENAME.STRING also accepts the "field name" BODY to mean that its contents should itself be unpacked and spliced into the argument list at that point. This feature, in conjunction with the rule that fields early in the argument list override later duplicates, is useful for altering existing file names. For example, to provide a default field, place BODY
first in the argument list, then the default fields. To override a field, place the new fields first and BODY last.

If the value of the BODY field is a stream, its full name is used.

Examples:

(PACKFILENAME.STRING 'DIRECTORY "LISP"
 'NAME "NET")
=> "<LISP>NET"

(PACKFILENAME.STRING 'NAME "NET"
 'DIRECTORY "{DSK}<LISPFILES>;"
 => "{DSK}<LISPFILES>NET"

(PACKFILENAME.STRING 'DIRECTORY "{DSK}"
 'BODY "{TOAST}<FOO>BAR")
=> "{DSK}BAR"

(PACKFILENAME.STRING 'DIRECTORY "FRED"
 'BODY "{TOAST}<FOO>BAR")
=> "{TOAST}<FRED>BAR"

(PACKFILENAME.STRING 'BODY "{TOAST}<FOO>BAR"
 'DIRECTORY "FRED")
=> "{TOAST}<FOO>BAR"

(PACKFILENAME.STRING 'VERSION NIL
 'BODY "{TOAST}<FOO>BAR.DCOM;2"
 => "{TOAST}<FOO>BAR.DCOM"

(PACKFILENAME.STRING 'BODY "{TOAST}<FOO>BAR.DCOM"
 'VERSION 1)
=> "{TOAST}<FOO>BAR.DCOM;1"

(PACKFILENAME.STRING 'BODY "{TOAST}<FOO>BAR.DCOM;"
 'VERSION 1)
=> "{TOAST}<FOO>BAR.DCOM;"

(PACKFILENAME.STRING 'BODY "BAR.;1"
 'EXTENSION "DCOM")
=> "BAR.;1"

(PACKFILENAME.STRING 'BODY "BAR;1"
 'EXTENSION "DCOM")
=> "BAR.DCOM;1"

In the last two examples, note that in one case the extension is explicitly present in the body (as indicated by the preceding period), while in the other there is no indication of an extension, so the default is used.

(PACKFILENAME FIELD1 CONTENTS1 ... FIELDN CONTENTSN) [NoSpread Function]

The same as PACKFILENAME.STRING, except that it returns the file name as a symbol, instead of a string.

Incomplete File Names

In general, it is not necessary to pass a complete file name (one containing all the fields listed above) to functions that take a file name as an argument. Interlisp supplies suitable defaults for certain fields (below). Functions that return names of actual files, however, always return the full file name.
If the version field is omitted from a file name, Interlisp performs version recognition, as described below.

If the host, device and/or directory field are omitted from a file name, Interlisp uses the currently connected directory. You can change the currently connected directory by calling CNDIR (below) or using the programmer’s assistant command CONN.

Defaults are added to the partially specified name "left to right" until a host, device or directory field is encountered. Thus, if the connected directory is \{TWENTY\} PS: <FRED>, then

BAR.DCOM means
{TWENTY} PS: <FRED> BAR.DCOM

<GRANOLA>BAR.DCOM means
{TWENTY} PS: <GRANOLA>BAR.DCOM

MTA0:<GRANOLA>BAR.DCOM means
{TWENTY} MTA0: <GRANOLA>BAR.DCOM

{THIRTY}<GRANOLA>BAR.DCOM means
{THIRTY}<GRANOLA>BAR.DCOM

In addition, if the partially specified name contains a subdirectory, but no principal directory, then the subdirectory is appended to the connected directory. For example,

ISO>BAR.DCOM means
{TWENTY} PS: <FRED> ISO> BAR.DCOM

Or, if the connected directory is the Unix directory \{UNIX\}/usr/fred/, then iso/bar.dcom means \{UNIX\}/usr/fred/iso/bar.dcom, but /other/bar.dcom means \{UNIX\}/other/bar.dcom.

**(CNDIR HOST/DIR)**  
[Function]  
Connects to the directory HOST/DIR, which can either be a directory name or a full directory specification including host and/or device. If the specification includes just a host, and the host supports directories, the directory is defaulted to the value of (USERNAME); if the host is omitted, connection is made to another directory on the same host as before. If HOST/DIR is NIL, connects to the value of LOGINHOST/DIR.

CNDIR returns the full name of the now-connected directory. Causes an error, Non-existent directory, if HOST/DIR is not a valid directory.

Note that CNDIR does not necessarily require or provide any directory access privileges. Access privileges are checked when a file is opened.

**CONN HOST/DIR**  
[Prog. Asst. Command]  
Command form of CNDIR for use at the executive. Connects to HOST/DIR, or to the value of LOGINHOST/DIR if HOST/DIR is omitted. This command is undoable. —Undoing it causes the system to connect to the previously connected directory.

**LOGINHOST/DIR**  
[Variable]  
CONN with no argument connects to the value of the variable LOGINHOST/DIR, initially \{DSK\}, but usually reset in your greeting file (Chapter 12).
(DIRECTORYNAME DIRNAME STRPTR)  [Function]

If DIRNAME is T, returns the full specification of the currently connected directory. If DIRNAME is NIL, returns the value of LOGINHOST/DIR. For any other value of DIRNAME, returns a full directory specification if DIRNAME designates an existing directory (satisfies DIRECTORYNAMEP), otherwise NIL.

If STRPTR is T, the value is returned as an atom, otherwise it is returned as a string.

(DIRECTORYNAMEP DIRNAME HOSTNAME)  [Function]

Returns T if DIRNAME is a valid directory on host HOSTNAME, or on the host of the currently connected directory if HOSTNAME is NIL. DIRNAME may be either a directory name or a full directory specification containing host and/or device.

If DIRNAME includes subdirectories, this function may or may not pass judgment on their validity. Some hosts support "true" subdirectories, distinct entities manipulable by the file system, while others only provide them as a syntactic convenience.

(HOSTNAMEP NAME)  [Function]

Returns T if NAME is recognized as a valid host or file device name at the moment HOSTNAMEP is called.

Version Recognition

Most of the file devices in Interlisp support file version numbers. That is, you can have several files of the exact same name, differing only in their VERSION field, which is incremented for each new "version" of the file that is created. When the filesystem encounters a file name without a version number, it must figure out which version was intended. This process is known as version recognition.

When OPENSTREAM opens a file for input and no version number is given, the highest existing version number is used. Similarly, when a file is opened for output and no version number is given, a new file is created with a version number one higher than the highest one currently in use with that file name. You can change the version number defaulting for OPENSTREAM by specifying a different value for its RECOG argument (see FULLNAME below).

Other functions that accept file names as arguments generally perform default version recognition, which is newest version for existing files, or a new version if using the file name to create a new file. The one exception is DELFILE, which uses the oldest existing version of the file.

The functions below can be used to perform version recognition without actually calling OPENSTREAM to open the file. Note that these functions only tell the truth at the moment they are called, and thus cannot be used to anticipate the name of the file opened by a comparable OPENSTREAM. They are best used as helpful hints.

(FULLNAME X RECOG)  [Function]

If X is an open stream, simply returns the full file name of the stream. Otherwise, if X is a file name given as a string or symbol, performs version recognition, as follows:
If \( X \) is recognized in the recognition mode specified by \( \text{RECOG} \) as an abbreviation for some file, returns the file's full name, otherwise \( \text{NIL} \). \( \text{RECOG} \) is one of the following:

- **OLD**: Chooses the newest existing version of the file. Returns \( \text{NIL} \) if no file named \( X \) exists.
- **OLDEST**: Chooses the oldest existing version of the file. Returns \( \text{NIL} \) if no file named \( X \) exists.
- **NEW**: Chooses a new version of the file. If versions of \( X \) already exist, then chooses a version number one higher than highest existing version; otherwise chooses version 1. For some file systems, \( \text{FULLNAME} \) returns \( \text{NIL} \) if you do not have the access rights necessary to create a new file named \( X \).
- **OLD/NEW**: Tries \( \text{OLD} \), then \( \text{NEW} \). Choose the newest existing version of the file, if any; otherwise chooses version 1. This usually only makes sense if you intend to open \( X \) for access BOTH.

\( \text{RECOG} = \text{NIL} \) defaults to \( \text{OLD} \). For all other values of \( \text{RECOG} \), generates an error \( \text{ILLEGAL ARG} \).

If \( X \) already contains a version number, the \( \text{RECOG} \) argument will never change it. In particular, \( \text{RECOG} = \text{NEW} \) does not require that the file actually be new. For example, \( \text{FULLNAME} \ '\text{FOO}.;2 \ '\text{NEW} \) may return \( \{\text{ERIS}\}<\text{LISP}>\text{FOO}.;2 \) if that file already exists, even though \( \text{FULLNAME} \ '\text{FOO} \ '\text{NEW} \) would default the version to a new number, perhaps returning \( \{\text{ERIS}\}<\text{LISP}>\text{FOO}.;5 \).

\( \text{INFILEP} \ \text{FILE} \) [Function]

Equivalent to \( \text{FULLNAME} \ \text{FILE} \ '\text{OLD} \). Returns the full file name of the newest version of \( \text{FILE} \) if \( \text{FILE} \) is the name of an existing file that can be opened for input, \( \text{NIL} \) otherwise.

\( \text{OUTFILEP} \ \text{FILE} \) [Function]

Equivalent to \( \text{FULLNAME} \ \text{FILE} \ '\text{NEW} \).

Note that \( \text{INFILEP} \), \( \text{OUTFILEP} \) and \( \text{FULLNAME} \) do not open any files; they are pure predicates. They are also only hints, as they do not imply that the caller has access rights to the file. For example, \( \text{INFILEP} \) might return non-\( \text{NIL} \), but \( \text{OPENSTREAM} \) might fail for the same file because you don’t have read access to it, or the file is open for output by another user. Similarly, \( \text{OUTFILEP} \) could return non-\( \text{NIL} \), but \( \text{OPENSTREAM} \) could fail with a \text{FILE SYSTEM RESOURCES EXCEEDED} error.

Note also that in a shared file system, such as a remote file server, intervening file operations by another user could contradict the information returned by recognition. For example, a file that was \( \text{INFILEP} \) might be deleted, or between an \( \text{OUTFILEP} \) and the subsequent \( \text{OPENSTREAM} \), another user might create a new version or delete the highest version, causing \( \text{OPENSTREAM} \) to open a different version of the file than the one returned by \( \text{OUTFILEP} \). In addition, some file servers do not support recognition of files in output context. Thus, the "truth" about a file can only be obtained by actually opening the file; creators of files should rely on the name of the stream opened by \( \text{OPENSTREAM} \), not...
the value returned from these recognition functions. In particular, programmers are discouraged from using OUTFILEP or (FULLNAME NAME 'NEW).

Using File Names Instead of Streams

In earlier implementations of Interlisp, from the days of Interlisp-10 onward, the "handle" used to refer to an open file was not a stream, but rather the file's full name, represented as a symbol. When the file name was passed to any I/O function, it was mapped to a stream by looking it up in a list of open files. This scheme was sometimes convenient for typing in file commands at the executive, but was poor for serious programming in two ways. First, mapping from file name to stream on every input/output operation is inefficient. Second, and more importantly, using the file name as the handle on an open stream means that it is not possible to have more than one stream open on a given file at once.

As of this writing, Medley is in a transition period, where it still supports the use of symbol file names as synonymous with open streams, but this use is not recommended. The remainder of this section discusses this usage of file names for the benefit of those reading older programs and wishing to convert them to work properly when this compatibility feature is removed.

File Name Efficiency Considerations

It is possible for a program to be seriously inefficient using a file name as a stream if the program is not using the name returned by OPENFILE (below). Any time that an input/output function is called with a file name other than the full file name, Interlisp must perform recognition on the partial file name to determine which open file is intended. Thus if repeated operations are to be performed, it is considerably more efficient to use the full file name returned from OPENFILE.

There is a more subtle problem with partial file names, in that recognition is performed on your entire directory, not just the open files. It is possible for a file name that previously denoted one file to suddenly denote a different file. For example, suppose a program performs (INFILE 'FOO), opening FOO.;1, and reads several expressions from FOO. Then you interrupt the program, create a FOO.;2 and resume the program (or a user at another workstation creates a FOO.;2). Now a call to READ giving it FOO as its FILE argument will generate a FILE NOT OPEN error, because FOO will be recognized as FOO.;2.

Obsolete File Opening Functions

The following functions are now obsolete, but are provided for backwards compatibility:

(OPENFILE FILE ACCESS RECOG PARAMETERS) [Function]

Opens FILE with access rights as specified by ACCESS, and recognition mode RECOG, and returns the full name of the resulting stream. Equivalent to (FULLNAME (OPENSTREAM FILE ACCESS RECOG PARAMETERS)).

(INFILE FILE) [Function]

Opens FILE for input, and sets it as the primary input stream. Equivalent to (INPUT (OPENSTREAM FILE 'INPUT 'OLD))
(OUTFILE FILE) [Function]  
Opens FILE for output, and sets it as the primary output stream. Equivalent to (OUTPUT
(OPENSTREAM FILE 'OUTPUT 'NEW)).

(IOFILE FILE) [Function]  
Opens FILE for both input and output. Equivalent to (OPENFILE FILE 'BOTH 'OLD).
Does not affect the primary input or output stream.

Converting Old Programs

At some point in the future, the Medley file system will change so that each call to OPENSTREAM
returns a distinct stream, even if a stream is already open to the specified file. This change is required
in order to deal with files in a multiprocessing environment.

This change will produce the following incompatibilities:

1. The functions OPENFILE, INPUT, and OUTPUT will return a stream, not a full file
   name. To make this less confusing in interactive situations, streams will have a print
   format that reveals the underlying file’s actual name.

2. Passing anything other than the object returned from OPENFILE to I/O operations
   will cause problems. Passing the file’s name will be significantly slower than passing
   the stream (even when passing the “full” file name), and in the case where there is more
   than one stream open on the file it might even act on the wrong one.

3. OPENP will return NIL when passed the name of a file rather than the value of
   OPENFILE or OPENSTREAM.

You should consider the following advice when writing new programs and editing existing programs,
so your programs will behave properly when the change occurs:

Because of the efficiency and ambiguity considerations described earlier, users have long been
encouraged to use only full file names as FILE arguments to I/O operations. The “proper” way to
have done this was to bind a variable to the value returned from OPENFILE and pass that variable to
all I/O operations; such code will continue to work. A less proper way to obtain the full file name,
but one which has to date not incurred any obvious penalty, is that which binds a variable to the
result of an INFILEP and passes that to OPENFILE and all I/O operations. This has worked because
INFILEP and OPENFILE both return a full file name, an invalid assumption in this future world.
Such code should be changed to pass around the value of the OPENFILE, not the INFILEP.

Code that calls OPENP to test whether a possibly incomplete file name is already open should be
recoded to pass to OPENP only the value returned from OPENFILE or OPENSTREAM.

Code that uses ordinary string functions to manipulate file names, and in particular the value
returned from OPENFILE, should be changed to use the the functions UNPACKFILENAME.STRING
and PACKFILENAME.STRING. Those functions work both on file names (strings) and streams
(coercing the stream to the name of its file).

Code that tests the value of OUTPUT for equality to some known file name or T should be examined
carefully and, if possible, recoded.
STREAMS & FILES

To see more directly the effects of passing around streams instead of file names, replace your calls to OPENFILE with calls to OPENSTREAM. OPENSTREAM is called in exactly the same way, but returns a STREAM. Streams can be passed to READ, PRINT, CLOSEF, etc just as the file’s full name can be currently, but using them is more efficient. The function FULLNAME, when applied to a stream, returns its full file name.

Using Files with Processes

Because Medley does not yet support multiple streams per file, problems can arise if different processes attempt to access the same file. You have to be careful not to have two processes manipulating the same file at the same time, since the two processes will be sharing a single input stream and file pointer. For example, you can’t have one process TCOMPL a file while another process is running LISTFILES on it.

File Attributes

Any file has a number of “file attributes”, such as the read date, protection, and bytesize. The exact attributes that a file can have is dependent on the file device. The functions GETFILEINFO and SETFILEINFO allow you to access file attributes:

\[
\text{GETFILEINFO} \quad \text{FILE ATTRIB} \quad \text{[Function]}
\]

Returns the current setting of the ATTRIB attribute of FILE.

\[
\text{SETFILEINFO} \quad \text{FILE ATTRIB VALUE} \quad \text{[Function]}
\]

Sets the attribute ATTRIB of FILE to be VALUE. SETFILEINFO returns T if it is able to change the attribute ATTRIB, and NIL if unsuccessful, either because the file device does not recognize ATTRIB or because the file device does not permit the attribute to be modified.

The FILE argument to GETFILEINFO and SETFILEINFO can be an open stream (or an argument designating an open stream, see Chapter 25), or the name of a closed file. SETFILEINFO in general requires write access to the file.

The attributes recognized by GETFILEINFO and SETFILEINFO fall into two categories: permanent attributes, which are properties of the file, and temporary attributes, which are properties only of an open stream to the file. The temporary attributes are only recognized when FILE designates an open stream; the permanent attributes are usually equally accessible for open and closed files. However, some devices are willing to change the value of certain attributes of an open stream only when specified in the PARAMETERS argument to OPENSTREAM (see above), not on a later call to SETFILEINFO.

The following are permanent attributes of a file:

- **BYTESIZE**  The byte size of the file. Medley currently only supports byte size 8.
- **LENGTH**  The number of bytes in the file. Alternatively, the byte position of the end-of-file. Like (GETEOFPTR FILE), but FILE does not have to be open.
SIZE   The size of FILE in pages.
CREATIONDATE The date and time, as a string, that the content of FILE was "created". The creation date changes whenever the content of the file is modified, but remains unchanged when a file is transported, unmodified, across file systems. Specifically, COPYFILE and RENAMEFILE (see below) preserve the file's creation date. Note that this is different from the concept of "creation date" used by some operating systems (e.g., Tops20).
WRITEDATE The date and time, as a string, that the content of FILE was last written to this particular file system. When a file is copied, its creation date does not change, but its write date becomes the time at which the copy is made.
READDATE The date and time, as a string, that FILE was last read, or NIL if it has never been read.
ICREATIONDATE IWRITEDATE IREADDATE The CREATIONDATE, WRITEDATE and READDATE, respectively, in integer form, as IDATE (Chapter 12) would return. This form is useful for comparing dates.
AUTHOR The name of the user who last wrote the file.
TYPE The "type" of the file, some indication of the nature of the file's content. The "types" of files allowed depends on the file device. Most devices recognize the symbol TEXT to mean that the file contains just characters, or BINARY to mean that the file contains arbitrary data.

Some devices support a wider range of file types that distinguish among the various sorts of files one might create whose content is "binary". All devices interpret any value of TYPE that they do not support to be BINARY. Thus, GETFILEINFO may return the more general value BINARY instead of the original type that was passed to SETFILEINFO or OPENSTREAM. Similarly, COPYFILE, while attempting to preserve the TYPE of the file it is copying, may turn, say, an INTERPRESS file into a mere BINARY file.

The way in which some file devices (e.g., Xerox file servers) support a wide range of file types is by representing the type as an integer, whose interpretation is known by the client. The variable FILING.TYPES is used to associate symbolic types with numbers for these devices. This list initially contains some of the well-known assignments of type name to number; you can add additional elements to handle any private file types. For example, suppose there existed an NS file type MAZEFILE with numeric value 5678. You could add the element (MAZEFILE 5678) to FILING.TYPES and then use MAZEFILE as a value for the TYPE attribute to SETFILEINFO or OPENSTREAM. Other devices are, of
course, free to store TYPE attributes in whatever manner they wish, be it numeric or symbolic. FILING.TYPES is merely considered the official registry for Xerox file types.

For most file devices, the TYPE of a newly created file, if not specified in the PARAMETERS argument to OPENSTREAM, defaults to the value of DEFAULTFILETYPE, initially TEXT.

The following are currently recognized as temporary attributes of an open stream:

**ACCESS**
The current access rights of the stream (see the beginning of this chapter). Can be one of INPUT, OUTPUT, BOTH, APPEND; or NIL if the stream is not open.

**ENDOFSTREAMOP**
The action to be taken when a stream is at "end of file" and an attempt is made to take input from it. The value of this attribute is a function of one argument, the stream. The function can examine the stream and its calling context and take any action it wishes. If the function returns normally, its should return either T, meaning to try the input operation again, or the byte that BIN would have returned had there been more bytes to read. Ordinarily, one should not let the ENDOFSTREAMOP function return unless one is only performing binary input from the file, since there is no way in general of knowing in what state the reader was at the time the end of file occurred, and hence how it will interpret a single byte returned to it.

The default ENDOFSTREAMOP is a system function that causes the error END OF FILE. The behavior of that error can be further modified for a particular stream by using the EOF option of WHENCLOSE (see below).

**EOL**
The end-of-line convention for the stream. This can be CR, LF, or CRLF, indicating with what byte or sequence of bytes the "End Of Line" character is represented on the stream. On input, that sequence of bytes on the stream is read as (CHARCODE EOL) by READCCODE or the string reader. On output, (TERPRI) and (PRINTCCODE (CHARCODE EOL)) cause that sequence of bytes to be placed on the stream.

The end of line convention is usually not apparent to you. The file system is usually aware of the convention used by a particular remote operating system, and sets this attribute accordingly. If you believe a file actually is stored with a different convention than the default, it is possible to modify the default behavior by including the EOL attribute in the PARAMETERS argument to OPENSTREAM.

**BUFFERS**
Value is the number of 512-byte buffers that the stream maintains at one time. This attribute is only used by certain random-access devices (currently, the local disk, floppy, and Leaf servers); all others ignore it.

Streams open to files generally maintain some portion of the file buffered in memory, so that each call to an I/O function does not
require accessing the actual file on disk or a file server. For files being
read or written sequentially, not much buffer space is needed, since
once a byte is read or written, it will never need to be seen again. In the
case of random access streams, buffering is more complicated, since a
program may jump around in the file, using SETFILEPTR (Chapter 25).
In this case, the more buffer space the stream has, the more likely it is
that after a SETFILEPTR to a place in the file that has already been
accessed, the stream still has that part of the file buffered and need not
go out to the device again. This benefit must, of course, be traded off
against the amount of memory consumed by the buffers.

NS servers implement the following additional attributes for GETFILEINFO (neither of these
attributes are settable with SETFILEINFO):

- **READER**: The name of the user who last read the file.
- **PROTECTION**: A list specifying the access rights to the file. Each element of the list is of
  the form (name nametype . rights). Name is the name of a user or group
  or a name pattern. Rights is one or more of the symbols ALL, READ,
  WRITE, DELETE, CREATE, or MODIFY. For servers running services 10.0
  or later, nametype is the symbol "-", in earlier releases it is one of the
  symbols INDIVIDUAL or GROUP.

### Closing and Reopening Files

The function WHENCLOSE permits you to associate certain operations with open streams that govern
how and when the stream will be closed. You can specify that certain functions will be executed
before CLOSEF closes the stream and/or after CLOSEF closes the stream. You can make a particular
stream be invisible to CLOSEALL, so that it will remain open across user invocations of CLOSEALL.

```
(WHENCLOSE FILE PROP₁ VAL₁ . . . PROPₙ VALₙ)
```

`FILE` must designate an open stream other than T (NIL defaults to the primary input
stream, if other than T, or primary output stream if other than T). The remaining
arguments specify properties to be associated with the full name of `FILE`. WHENCLOSE
returns the full name of `FILE` as its value.

WHENCLOSE recognizes the following property names:

- **BEFORE** `VAL` is a function that CLOSEF will apply to the stream just before it is
closed. This might be used, for example, to copy information about the
file from an in-core data structure to the file just before it is closed.

- **AFTER** `VAL` is a function that CLOSEF will apply to the stream just after it is
closed. This capability permits in-core data structures that know about
the stream to be cleaned up when the stream is closed.

- **CLOSEALL**: `VAL` is either YES or NO and determines whether `FILE` will be closed by
  CLOSEALL (YES) or whether CLOSEALL will ignore it (NO). CLOSEALL
uses CLOSEF, so that any AFTER functions will be executed if the stream is in fact closed. Files are initialized with CLOSEALL set to YES.

EOF VAL is a function that will be applied to the stream when an end-of-file error occurs, and the ERRORTYPELIST entry for that error, if any, returns NIL. The function can examine the context of the error, and can decide whether to close the stream, RETFROM some function, or perform some other computation. If the function supplied returns normally (i.e., does not RETFROM some function), the normal error machinery will be invoked.

The default EOF behavior, unless overridden by this WHENCLOSE option, is to call the value of DEFAULTEOFCLOSE (below).

For some applications, the ENDOFSTREAMOP attribute (see above) is a more useful way to intercept the end-of-file error. The ENDOFSTREAMOP attribute comes into effect before the error machinery is ever activated.

Multiple AFTER and BEFORE functions may be associated with a file; they are executed in sequence with the most recently associated function executed first. The CLOSEALL and EOF values, however, will override earlier values, so only the last value specified will have an effect.

DEFAULTEOFCLOSE [Variable]

Value is the name of a function that is called by default when an end of file error occurs and no EOF option has been specified for the stream by WHENCLOSE. The initial value of DEFAULTEOFCLOSE is NIL, meaning take no special action (go ahead and cause the error). Setting it to CLOSEF would cause the stream to be closed before the rest of the error machinery is invoked.

I/O Operations to and from Strings

It is possible to treat a string as if it were the contents of a file by using the following function:

(OPENSTRINGSTREAM STR ACCESS) [Function]

Returns a stream that can be used to access the characters of the string STR. ACCESS may be either INPUT, OUTPUT, or BOTH; NIL defaults to INPUT. The stream returned may be used exactly like a file opened with the same access, except that output operations may not extend past the end of the original string. Also, string streams do not appear in the value of (OPENP).

For example, after performing

(SBTQ STRM (OPENSTRINGSTREAM "THIS 2 (IS A LIST)"))

the following succession of reads could occur:
INTERLISP-D REFERENCE MANUAL

(READ STRM) => THIS
(RATOM STRM) => 2
(READ STRM) => (IS A LIST)
(EOPF STRM) => T

Compatibility Note: In Interlisp-10 it was possible to take input from a string simply by passing the string as the FILE argument to an input function. In order to maintain compatibility with this feature, Medley provides the same capability. This not terribly clean feature persists in the present implementation to give users time to convert old code. This means that strings are not equivalent to symbols when specifying a file name as a stream argument. In a future release, the old Interlisp-10 string-reading feature will be decommissioned, and OPENSTRINGSTREAM will be the only way to perform I/O on a string.

Temporary Files and the CORE Device

Many operating systems have a notion of “scratch file”, a file typically used as temporary storage for data most naturally maintained in the form of a file, rather than some other data structure. A scratch file can be used as a normal file in most respects, but is automatically deleted from the file system after its useful life is up, e.g., when the job terminates, or you log out. In normal operation, you need never explicitly delete such files, since they are guaranteed to disappear soon.

A similar functionality is provided in Medley by core-resident files. Core-resident files are on the device CORE. The directory structure for this device and all files on it are represented completely within your virtual memory. These files are treated as ordinary files by all file operations; their only distinguishing feature is that all trace of them disappears when the Medley image is abandoned.

Core files are opened and closed by name the same as any other file, e.g., (OPENSTREAM '{CORE}<FOO>FIE.DCOM 'OUTPUT). Directory names are completely optional, so files can also have names of the form (CORE)NAME.EXT. Core files can be enumerated by DIRECTORY (see below). While open, they are registered in (OPENP). They do consume virtual memory space, which is only reclaimed when the file is deleted. Some caution should thus be used when creating large CORE files. Since the virtual memory of an Medley workstation usually persists far longer than the typical process on a mainframe computer, it is still important to delete CORE files after they are no longer in use.

For many applications, the name of the scratch file is irrelevant, and there is no need for anyone to have access to the file independent of the program that created it. For such applications, NODIRCORE files are preferable. Files created on the device lisp NODIRCORE are core-resident files that have no name and are registered in no directory. These files “disappear”, and the resources they consume are reclaimed, when all pointers to the file are dropped. Hence, such files need never be explicitly deleted or, for that matter, closed. The “name” of such a file is simply the stream object returned from (OPENSTREAM '{NODIRCORE} OUTPUT), and it is this stream object that must be passed to all input/output operations, including CLOSEF and any calls to OPENSTREAM to reopen the file.

(COREDEVICE NAME NODIRFLG) [Function]

Creates a new device for core-resident files and assigns NAME as its device name. Thus, after performing (COREDEVICE 'FOO), one can execute (OPENSTREAM '{FOO}BAR 'OUTPUT) to open a file on that device. Medley is initialized with the single core-resident device named CORE, but COREDEVICE may be used to create any number of logically distinct core devices.
If \texttt{NODIRFLG} is non-NIL, a core device that acts like \texttt{\{NODIRCORE\}} is created.

Compatibility note: In Interlisp-10, it was possible to create scratch files by using file names with suffixes \\texttt{;S} or \\texttt{;T}. In Medley, these suffixes in file names are simply ignored when output is directed to a particular host or device. However, the function \texttt{PACKFILENAME.STRING} is defined to default the device name to \texttt{CORE} if the file has the \texttt{TEMPORARY} attribute and no explicit host is provided.

**NULL Device**

The \texttt{NULL} device provides a source of content-free ‘files’. \texttt{(OPENSTREAM \{NULL\} \{OUTPUT\})} creates a stream that discards all output directed at it. \texttt{(OPENSTREAM \{NULL\} \{INPUT\})} creates a stream that is perpetually at end-of-file (i.e., has no input).

**Deleting, Copying, and Renaming Files**

\texttt{(DELFILE FILE)} 

[Function]

Deletes \texttt{FILE} if possible. The file must be closed. Returns the full name of the file if deleted, else \texttt{NIL}. Recognition mode for \texttt{FILE} is \texttt{OLDEST}, i.e., if \texttt{FILE} does not have a version number specified, then \texttt{DELFILE} deletes the oldest version of the file.

\texttt{(COPYFILE FROMFILE TOFILE)} 

[Function]

Copies \texttt{FROMFILE} to a new file named \texttt{TOFILE}. The source and destination may be on any combination of hosts/devices. \texttt{COPYFILE} attempts to preserve the \texttt{TYPE} and \texttt{CREATIONDATE} where possible. If the original file’s file type is unknown, \texttt{COPYFILE} attempts to infer the type (file type is \texttt{BINARY} if any of its 8-bit bytes have their high bit on).

\texttt{COPYFILE} uses \texttt{COPYCHARS} (Chapter 25) if the source and destination hosts have different EOL conventions. Thus, it is possible for the source and destination files to be of different lengths.

\texttt{(RENAMEFILE OLDFILE NEWFILE)} 

[Function]

Renames \texttt{OLDFILE} to be \texttt{NEWFILE}. Causes an error, \texttt{FILE NOT FOUND} if \texttt{FILE} does not exist. Returns the full name of the new file, if successful, else \texttt{NIL} if the rename cannot be performed.

If \texttt{OLDFILE} and \texttt{NEWFILE} are on the same host/device, and the device implements a renaming primitive, \texttt{RENAMEFILE} can be very fast. However, if the device does not know how to rename files in place, or if \texttt{OLDFILE} and \texttt{NEWFILE} are on different devices, \texttt{RENAMEFILE} works by copying \texttt{OLDFILE} to \texttt{NEWFILE} and then deleting \texttt{OLDFILE}.
Searching File Directories

**DIRECTORIES** [Variable]

Global variable containing the list of directories searched (in order) by SPELLFILE and FINDFILE (below) when not given an explicit DIRLST argument. In this list, the atom NIL stands for the login directory (the value of LOGINHOST/DIR), and the atom T stands for the currently connected directory. Other elements should be *full* directory specifications, e.g., `{TWENTY} PS: <LISPUSERS>, not merely LISPUSERS.

**LISPUSERSDIRECTORIES** [Variable]

Global variable containing a list of directories to search for "library" package files. Used by the FILES file package command (Chapter 17).

**(SPELLFILE FILE NOPRINTFLG NSFLG DIRLST)** [Function]

Searches for the file name FILE, possibly performing spelling correction (see Chapter 20). Returns the corrected file name, if any, otherwise NIL.

If FILE has a directory field, SPELLFILE attempts spelling correction against the files in that particular directory. Otherwise, SPELLFILE searches for the file on the directory list DIRLST before attempting any spelling correction.

If NOPRINTFLG is NIL, SPELLFILE asks you to confirm any spelling correction done, and prints out any files found, even if spelling correction is not done. If NOPRINTFLG = T, SPELLFILE does not do any printing, nor ask for approval.

If NSFLG = T (or NOSPELLFLG = T, see Chapter 20), no spelling correction is attempted, though searching through DIRLST still occurs.

**DIRLST** is the list of directories searched if FILE does not have a directory field. If DIRLST is NIL, the value of the variable DIRECTORIES is used.

Note: If DIRLST is NIL, and FILE is not found by searching the directories on DIRECTORIES, but the root name of FILE has a FILEDATES property (Chapter 17) indicating that a file by that name has been loaded, then the directory indicated in the FILEDATES property is searched, too. This additional search is not done if DIRLST is non-NIL.

ERRORTYPELST (Chapter 14) initially contains the entry `((23 (SPELLFILE (CADR ERRORMESS) NIL NOFILESPELLFLG)) )`, which causes SPELLFILE to be called in case of a FILE NOT FOUND error. If the variable NOFILESPELLFLG is T (its initial value), then spelling correction is not done on the file name, but DIRECTORIES is still searched. If SPELLFILE is successful, the operation will be reexecuted with the new (corrected) file name.
STREAMS & FILES

(FINDFILE FILE NSFLG DRLST) [Function]

Uses SPELLFILE to search for a file named FILE. If it finds one, returns its full name, with no user interaction. Specifically, it calls (SPELLFILE FILE T NSFLG DRLST), after first performing two simple checks: If FILE has an explicit directory, it checks to see if a file so named exists, and if so returns that file. If DRLST is NIL, it looks for FILE on the connected directory before calling SPELLFILE.

Listing File Directories

The function DIRECTORY allows you to conveniently specify and/or program a variety of directory operations:

(DIRECTORY FILES COMMANDS DEFAULTTEXT DEFAULTVERS) [Function]

Returns, lists, or performs arbitrary operations on all files specified by the "file group" FILES. A file group has the form of a regular file name, except that the character * can be used to match any number of characters, including zero, in the file name. For example, the file group A*B matches all file names beginning with the character A and ending with the character B. The file group *.DCOM matches all files with an extension of DCOM.

If FILES does not contain an explicit extension, it is defaulted to DEFAULTTEXT; if FILES does not contain an explicit version, it is defaulted to DEFAULTVERS. DEFAULTTEXT and DEFAULTVERS themselves default to *. If the period or semicolon preceding the omitted extension or version, respectively, is present, the field is explicitly empty and no default is used. All other unspecified fields default to *. If FILES is NIL, it defaults to *.DCOM matches all files with an extension of DCOM.

If FILES does not contain an explicit extension, it is defaulted to DEFAULTTEXT; if FILES does not contain an explicit version, it is defaulted to DEFAULTVERS. DEFAULTTEXT and DEFAULTVERS themselves default to *. If the period or semicolon preceding the omitted extension or version, respectively, is present, the field is explicitly empty and no default is used. All other unspecified fields default to *. If FILES is NIL, it defaults to *.DCOM matches all files with an extension of DCOM.

Note: Some hosts/devices are not capable of supporting "highest version" in enumeration. Such hosts instead enumerate all versions.

For each file that matches the file group FILES, the "file commands" in COMMANDS are executed in order. Some of the file commands allow aborting the command processing for a given file, effectively filtering the list of files. The interpretation of the different file commands is described below. If COMMANDS is NIL, it defaults to (COLLECT), which collects the matching file names in a list and returns it as the value of DIRECTORY.

The "file commands" in COMMANDS are interpreted as follows:

P Prints the file's name. For readability, DIRECTORY strips the directory from the name, printing it once as a header in front of each set of consecutive files on the same directory.

PP Prints the file's name without a version number.

a string Prints the string.

READDATE, WRITEDATE
CREATIONDATE, SIZE
LENGTH, BYTESIZE
PROTECTION, AUTHOR

TYPE Prints the appropriate information returned by GETFILEINFO (see above).

COLLECT Adds the full name of this file to an accumulating list, which will be returned as the value of DIRECTORY.

COUNTSIZE Adds the size of this file to an accumulating sum, which will be returned as the value of DIRECTORY.

DELETE Deletes the file.

DELVER If this file is not the highest version of files by its name, delete it.

PAUSE Waits until you type any character before proceeding with the rest of the commands (good for display if you want to ponder).

The following commands are predicates to filter the list. If the predicate is not satisfied, then processing for this file is aborted and no further commands (such as those above) are executed for this file.

Note: if the \texttt{P} and \texttt{PP} commands appear in \texttt{COMMANDS} ahead of any of the filtering commands below except \texttt{PROMPT}, they are postponed until after the filters. Thus, assuming the caller has placed the attribute options after the filters as well, no printing occurs for a file that is filtered out. This is principally so that functions like \texttt{DIR} (below) can both request printing and pass arbitrary commands through to \texttt{DIRECTORY}, and have the printing happen in the appropriate place.

\texttt{PROMPT MESS} Prompts with the yes/no question \texttt{MESS}; if user responds with No, abort command processing for this file.

\texttt{OLDERTHAN} \textit{N} Continue command processing if the file hasn’t been referenced (read or written) in \textit{N} days. \textit{N} can also be a string naming an explicit date and time since which the file must not have been referenced.

\texttt{NEWERTHAN} \textit{N} Continue command processing if the file has been written within the last \textit{N} days. \textit{N} can also be a string naming an explicit date and time. Note that this is not quite the complement of \texttt{OLDERTHAN}, since it ignores the read date.

\texttt{BY USER} Continue command processing if the file was last written by the given user, i.e., its \texttt{AUTHOR} attribute matches (case insensitively) \texttt{USER}.

\texttt{@X} \textit{X} is either a function of one argument (\texttt{FILENAME}), or an arbitrary expression which uses the variable \texttt{FILENAME} freely. If \texttt{X} returns \texttt{NIL}, abort command processing for this file.

The following two commands apply not to any particular file, but globally to the manner in which directory information is printed.
STREAMS & FILES

OUT FILE  Directs output to FILE.

COLUMNS N  Attempts to format output in $N$ columns (rather than just 1).

DIRECTORY uses the variable DIRCOMMANDS as a spelling list to correct spelling and define abbreviations and synonyms (see Chapter 20). Currently the following abbreviations are recognized:

- $AU$ => AUTHOR
- $-$ => PAUSE
- $COLLECT?$ => PROMPT "$ ? " COLLECT
- $DA$
- $DATE$ => CREATIONDATE
- $TI$ => WRITEDATE
- $DEL$ => DELETE
- $DEL?$
- $DELETE?$ => PROMPT "$ delete? " DELETE
- $OLD$ => OLDERTHAN 90
- $PR$ => PROTECTION
- $SI$ => SIZE
- $VERBOSE$ => AUTHOR CREATIONDATE SIZE READDATE WRITEDATE

(FILDIR FILEGROUP)  [Function]

Obsolete synonym of (DIRECTORY FILEGROUP).

(DIR FILEGROUP COM1 ... COMN)  [NLambda NoSpread Function]

Convenient form of DIRECTORY for use in type-in at the executive. Performs (DIRECTORY 'FILEGROUP '(P COM1 ... COMN)).

(NDIR FILEGROUP COM1 ... COMN)  [NLambda NoSpread Function]

Version of DIR that lists the file names in a multi-column format. Also, by default only lists the most recent version of files (unless FILEGROUP contains an explicit version).
Medley can perform input/output operations on a large variety of physical devices, including local
disk drives, floppy disk drives, the keyboard and display screen, and remote file server computers
accessed over a network. While the low-level details of how all these devices perform input/output
vary considerably, the Interlisp-D language provides the programmer a small, common set of abstract
operations whose use is largely independent of the physical input/output medium involved—
operations such as read, print, change font, or go to a new line. By merely changing the targeted I/O
device, a single program can be used to produce output on the display, a file, or a printer.

The underlying data abstraction that permits this flexibility is the stream. A stream is a data object (an
instance of the data type STREAM) that encapsulates all of the information about an input/output
connection to a particular I/O device. Each of Medley’s general-purpose I/O functions takes a stream
as one of its arguments. The general-purpose function then performs action specific to the stream’s
device to carry out the requested operation. Not every device is capable of implementing every I/O
operation, while some devices offer additional functionality by way of special functions for that
device alone. Such restrictions and extensions are noted in the documentation of each device.

The vast majority of the streams commonly used in Medley fall into two interesting categories: the file
stream and the image stream.

A file is an ordered collection of data, usually a sequence of characters or bytes, stored on a file device
in a manner that allows the data to be retrieved at a later time. Floppy disks, hard disks, and remote
file servers are among the devices used to store files. Files are identified by a "file name", which
specifies the device on which the file resides and a name unique to a specific file on that device. Input
or output to a file is performed by obtaining a stream to the file, using OPENSTREAM (see below). In
addition, there are functions that manipulate the files themselves, rather than their data content.

An image stream is an output stream to a display device, such as the display screen or a printer. In
addition to the standard output operations, such as print, an image stream implements a variety of
graphics operations, such as drawing lines and displaying characters in multiple fonts. Unlike a file,
the "content" of an image stream cannot be retrieved. Image streams are described in Chapter 26.

The creation of other kinds of streams, such as network byte-stream connections, is described in the
chapters peculiar to those kinds of streams. The operations common to streams in general are
described in Chapter 24. This chapter describes operations specific to file devices: how to name files,
how to open streams to files, and how to manipulate files on their devices.

### Opening and Closing File Streams

In order to perform input from or output to a file, it is necessary to create a stream to the file, using
OPENSTREAM:
(OPENSTREAM FILE ACCESS RECOG PARAMETERS —) [Function]

Opens and returns a stream for the file specified by FILE, a file name. FILE can be either a string or a symbol. The syntax and manipulation of file names is described at length in the FILENAMES section below. Incomplete file names are interpreted with respect to the connected directory (below).

RECOG specifies the recognition mode of FILE, as described in a later section of this chapter. If RECOG = NIL, it defaults according to the value of ACCESS.

ACCESS specifies the "access rights” to be used when opening the file, one of the following:

- **INPUT** Only input operations are permitted on the file. The file must already exist. Starts reading at the beginning of the file. RECOG defaults to OLD.

- **OUTPUT** Only output operations are permitted on the file. Starts writing at the beginning of the file, which is initially empty. While the file is open, other users or processes are unable to open the file for either input or output. RECOG defaults to NEW.

- **BOTH** Both input and output operations are permitted on the file. Starts reading or writing at the beginning of the file. RECOG defaults to OLD/NEW. ACCESS = BOTH implies random accessibility (Chapter 25), and thus may not be possible for files on some devices.

- **APPEND** Only sequential output operations are permitted on the file. Starts writing at the end of the file. RECOG defaults to OLD/NEW. ACCESS = APPEND may not be allowed for files on some devices.

**Note:** ACCESS = OUTPUT implies that one intends to write a new or different file, even if a version number was specified and the corresponding file already exists. Thus any previous contents of the file are discarded, and the file is empty immediately after the OPENSTREAM. If it is desired to write on an already existing file while preserving the old contents, the file must be opened for access BOTH or APPEND.

PARAMETERS is a list of pairs (ATTRIB VALUE), where ATTRIB is any file attribute that the file system is willing to allow you to set (see SETFILEINFO below). A non-list ATTRIB in PARAMETERS is treated as the pair (ATTRIB T). Generally speaking, attributes that belong to the permanent file (e.g., TYPE) can only be set when creating a new file, while attributes that belong only to a particular opening of a file (e.g., ENDOFSTREAMOP) can be set on any call to OPENSTREAM. Not all devices honor all attributes; those not recognized by a particular device are simply ignored.

In addition to the attributes permitted by SETFILEINFO, the following tokens are accepted by OPENSTREAM as values of ATTRIB in its PARAMETERS argument:
DON'T.CHANGE.DATE If VALUE is non-NIL, the file's creation date is not changed when the file is opened. This option is meaningful only for old files being opened for access BOTH. This should be used only for specialized applications in which the caller does not want the file system to believe the file's content has been changed.

SEQUENTIAL If VALUE is non-NIL, this opening of the file need support only sequential access; i.e., the caller intends never to use SETFILEPTR. For some devices, sequential access to files is much more efficient than random access. Note that the device may choose to ignore this attribute and still open the file in a manner that permits random access. Also note that this attribute does not make sense with ACCESS = BOTH.

If FILE is not recognized by the file system, OPENSTREAM causes the error FILE NOT FOUND. Ordinarily, this error is intercepted via an entry on ERRORTYPELST (Chapter 24), which causes SPELLFILE (see the Searching File Directories section of this chapter) to be called. SPELLFILE searches alternate directories and possibly attempts spelling correction on the file name. Only if SPELLFILE is unsuccessful will the FILE NOT FOUND error actually occur.

If FILE exists but cannot be opened, OPENSTREAM causes one of several other errors: FILE WON'T OPEN if the file is already opened for conflicting access by someone else; PROTECTION VIOLATION if the file is protected against the operation; FILE SYSTEM RESOURCES EXCEEDED if there is no more room in the file system.

(CLOSEF FILE) [Function]
Closes FILE, and returns its full file name. Generates an error, FILE NOT OPEN, if FILE does not designate an open stream. After closing a stream, no further input/output operations are permitted on it.

If FILE is NIL, it is defaulted to the primary input stream if that is not the terminal stream, or else the primary output stream if that is not the terminal stream. If both primary input and output streams are the terminal input/output streams, CLOSEF returns NIL. If CLOSEF closes either the primary input stream or the primary output stream (either explicitly or in the FILE = NIL case), it resets the primary stream for that direction to be the corresponding terminal stream. See Chapter 25 for information on the primary input/output streams.

WHENCLOSE (see below) allows you to "advise" CLOSEF to perform various operations when a file is closed.

Because of buffering, the contents of a file open for output are not guaranteed to be written to the actual physical file device until CLOSEF is called. Buffered data can be
forced out to a file without closing the file by using the function \texttt{FORCEROUTE} (Chapter 25).

Some network file devices perform their transactions in the background. As a result, it is possible for a file to be closed by \texttt{CLOSE} and yet not be "fully" closed for some small period of time afterward, during which time the file appears to still be busy, and cannot be opened for conflicting access by other users.

\[(\texttt{CLOSEP? \textit{FILE}})\] \hspace{1em} \textbf{[Function]}

Closes \textit{FILE} if it is open, returning the value of \texttt{CLOSE}; otherwise does nothing and returns \texttt{NIL}.

In the present implementation of Medley, all streams to files are kept, while open, in a registry of "open files". This registry does not include nameless streams, such as string streams (see below), display streams (Chapter 28), and the terminal input and output streams; nor streams explicitly hidden from you, such as dribble streams (Chapter 30). This registry may not persist in future implementations of Medley, but at the present time it is accessible by the following two functions:

\[(\texttt{OPENP \textit{FILE} ACCESS})\] \hspace{1em} \textbf{[Function]}

\textit{ACCESS} is an access mode for a stream opening (one of \texttt{INPUT}, \texttt{OUTPUT}, \texttt{BOTH}, or \texttt{APPEND}), or \texttt{NIL}, meaning any access.

If \textit{FILE} is a stream, returns its full name if it is open for the specified access, else \texttt{NIL}.

If \textit{FILE} is a file name (a symbol), \textit{FILE} is processed according to the rules of file recognition (see below). If a stream open to a file by that name is registered and open for the specified access, then the file's full name is returned. If the file name is not recognized, or no stream is open to the file with the specified access, \texttt{NIL} is returned.

If \textit{FILE} is \texttt{NIL}, returns a list of the full names of all registered streams that are open for the specified access.

\[(\texttt{CLOSEALL ALLFLG})\] \hspace{1em} \textbf{[Function]}

Closes all streams in the value of \texttt{(OPENP)}. Returns a list of the files closed.

\texttt{WHENCLOSE} (see below) allows certain files to be "protected" from \texttt{CLOSEALL}. If \texttt{ALLFLG} is \texttt{T}, all files, including those protected by \texttt{WHENCLOSE}, are closed.

\section*{File Names}

A file name in Medley is a string or symbol whose characters specify a "path" to the actual file: on what host or device the file resides, in which directory, and so forth. Because Medley supports a variety of non-local file devices, parts of the path could be very device-dependent. However, it is desirable for programs to be able to manipulate file names in a device-independent manner. To this end, Medley specifies a uniform file name syntax over all devices; the functions that perform the
actual file manipulation for a particular device are responsible for any translation to that device’s naming conventions.

A file name is composed of a collection of fields, some of which have specific semantic interpretations. The functions described below refer to each field by a field name, a literal atom from among the following: HOST, DEVICE, DIRECTORY, NAME, EXTENSION, and VERSION. The standard syntax for a file name that contains all of those fields is \{HOST\}DEVICE:<DIRECTORY>NAME.EXTENSION;VERSION. Some host’s file systems do not use all of those fields in their file names.

HOST Specifies the host whose file system contains the file. In the case of local file devices, the “host” is the name of the device, e.g., DSK or FLOPPY.

DEVICE Specifies, for those hosts that divide their file system’s name space among mutiple physical devices, the device or logical structure on which the file resides. This should not be confused with Medley’s abstract “file device”, which denotes either a host or a local physical device and is specified by the HOST field.

DIRECTORY Specifies the “directory” containing the file. A directory usually is a grouping of a possibly large set of loosely related files, e.g., the personal files of a particular user, or the files belonging to some project. The DIRECTORY field usually consists of a principal directory and zero or more subdirectories that together describe a path through a file system’s hierarchy. Each subdirectory name is set off from the previous directory or subdirectory by the character “>”; e.g., “LISP>LIBRARY>NEW”.

NAME This field carries no specific meaning, but generally names a set of files thought of as being different renditions of the “same” abstract file.

EXTENSION This field also carries no specific meaning, but generally distinguishes the form of files having the same name. Most files systems have some “conventional” extensions that denote something about the content of the file. For example, in Medley, the extension DCOM standardly denotes a file containing compiled function definitions.

VERSION A number used to distinguish the versions or “generations” of the files having a common name and extension. The version number is incremented each time a new file by the same name is created.

Most functions that take as input “a directory” accept either a directory name (the contents of the DIRECTORY field of a file name) or a “full” directory specification—a file name fragment consisting of
only the fields HOST, DEVICE, and DIRECTORY. In particular, the "connected directory" (see below) consists, in general, of all three fields.

For convenience in dealing with certain operating systems, Medley also recognizes [] and () as host delimiters (synonymous with {}), and / as a directory delimiter (synonymous with < at the beginning of a directory specification and > to terminate directory or subdirectory specification). For example, a file on a Unix file server UNIX with the name /usr/foo/bar/stuff.tedit, whose DIRECTORY field is thus usr/foo/bar, could be specified as {UNIX}/usr/foo/bar/stuff.tedit, or (UNIX)<usr/foo/bar>stuff.tedit, or several other variations. Note that when using [] or () as host delimiters, they usually must be escaped with the reader's % escape character if the file name is expressed as a symbol rather than a string.

Different hosts have different requirements regarding which characters are valid in file names. From Medley's point of view, any characters are valid. However, in order to be able to parse a file name into its component fields, it is necessary that those characters that are conventionally used as file name delimiters be quoted when they appear inside of fields where there could be ambiguity. The file name quoting character is "'" (single quote). Thus, the following characters must be quoted when not used as delimiters: :, >, ;, /, and ' itself. The character . (period) need only be quoted if it is to be considered a part of the EXTENSION field. The characters }, ], and ) need only be quoted in a file name when the host field of the name is introduced by {, [, and (, respectively. The characters {, [, (, and < need only be quoted if they appear as the first character of a file name fragment, where they would otherwise be assumed to introduce the HOST or DIRECTORY fields.

The following functions are the standard way to manipulate file names in Interlisp. Their operation is purely syntactic—they perform no file system operations themselves.

\[
\text{UNPACKFILENAME.STRING FILENAME}
\]

[Function]

Parses , returning a list in property list format of alternating field names and field contents. The field contents are returned as strings. If is a stream, its full name is used.

Only those fields actually present in are returned. A field is considered present if its delimiting punctuation (in the case of EXTENSION and VERSION, the preceding period or semicolon, respectively) is present, even if the field itself is empty. Empty fields are denoted by "" (the empty string).

Examples:

\[
\text{(UNPACKFILENAME.STRING "FOO.BAR") =>
(NAME "FOO" EXTENSION "BAR")
}\]

\[
\text{(UNPACKFILENAME.STRING "FOO.;2") =>
(NAME "FOO" EXTENSION "2")
}\]

\[
\text{(UNPACKFILENAME.STRING "FOO;") =>
(NAME "FOO" VERSION "")
}\]

\[
\text{(UNPACKFILENAME.STRING
"{ERIS}<LISP>CURRENT>IMTRAN.DCOM;21")
=> (HOST "ERIS" DIRECTORY "LISP>CURRENT" NAME "IMTRAN" EXTENSION "DCOM"
VERSION "21")
}\]
(UNPACKFILENAME FILE)  [Function]
Old version of UNPACKFILENAME.STRING that returns the field values as atoms, rather than as strings. UNPACKFILENAME.STRING is now considered the "correct" way of unpacking file names, because it does not lose information when the contents of a field are numeric. For example,

   (UNPACKFILENAME 'STUFF.TXT) =>
   (NAME STUFF EXTENSION TXT)

but

   (UNPACKFILENAME 'STUFF.029) =>
   (NAME STUFF EXTENSION 29)

Explicitly omitted fields are denoted by the atom NIL, rather than the empty string.

   Note: Both UNPACKFILENAME and UNPACKFILENAME.STRING leave the trailing colon on the device field, so that the Tenex device NIL: can be distinguished from the absence of a device. Although UNPACKFILENAME.STRING is capable of making the distinction, it retains this behavior for backward compatibility. Thus,

   (UNPACKFILENAME.STRING '{TOAST}DSK:FOO) =>
   (HOST "TOAST" DEVICE "DSK:" NAME "FOO")

(FILENAMEFIELD FILENAME FIELDNAME)  [Function]
Returns, as an atom, the contents of the FIELDNAME field of FILENAME. If FILENAME is a stream, its full name is used.

(PACKFILENAME.STRING FIELD1 CONTENTS1 ... FIELDN CONTENTSN)  [NoSpread Function]
Takes a sequence of alternating field names and field contents (atoms or strings), and returns the corresponding file name, as a string.

If PACKFILENAME.STRING is given a single argument, it is interpreted as a list of alternating field names and field contents. Thus PACKFILENAME.STRING and UNPACKFILENAME.STRING operate as inverses.

If the same field name is given twice, the first occurrence is used.

The contents of the field name DIRECTORY may be either a directory name or a full directory specification as described above.

PACKFILENAME.STRING also accepts the "field name" BODY to mean that its contents should itself be unpacked and spliced into the argument list at that point. This feature, in conjunction with the rule that fields early in the argument list override later duplicates, is useful for altering existing file names. For example, to provide a default field, place BODY first in the argument list, then the default fields. To override a field, place the new fields first and BODY last.

If the value of the BODY field is a stream, its full name is used.
Examples:

```lisp
(PACKFILENAME.STRING 'DIRECTORY "LISP"
 'NAME "NET")
=> "<LISP>NET"

(PACKFILENAME.STRING 'NAME "NET"
 'DIRECTORY "{DSK}<LISPFILES>"
=> "{DSK}<LISPFILES>NET"

(PACKFILENAME.STRING 'DIRECTORY "{DSK}" 
 'BODY "\{TOAST\}<FOO>BAR"
=> "{DSK}BAR"

(PACKFILENAME.STRING 'DIRECTORY "FRED" 
 'BODY "\{TOAST\}<FOO>BAR"
=> "{TOAST}<FRED>BAR"

(PACKFILENAME.STRING 'BODY "\{TOAST\}<FOO>BAR"
 'DIRECTORY "FRED"
=> "{TOAST}<FOO>BAR"

(PACKFILENAME.STRING 'BODY "\{TOAST\}<FOO>BAR.BAR" 
 'VERSION NIL
=> "{TOAST}<FOO>BAR.BAR"

(PACKFILENAME.STRING 'BODY "\{TOAST\}<FOO>BAR.BAR.DCOM" 
 'VERSION 1
=> "{TOAST}<FOO>BAR.BAR.DCOM;1"

(PACKFILENAME.STRING 'BODY "\{TOAST\}<FOO>BAR.BAR.DCOM;1"
 'EXTENSION "DCOM"
=> "BAR.DCOM;1"

(PACKFILENAME.STRING 'BODY "BAR;1"
 'EXTENSION "DCOM"
=> "BAR.DCOM;1"
```

In the last two examples, note that in one case the extension is explicitly present in the body (as indicated by the preceding period), while in the other there is no indication of an extension, so the default is used.

```
(PACKFILENAME FIELD1 CONTENTS1 ... FIELDN CONTENTSN) [NoSpread Function]
```

The same as PACKFILENAME.STRING, except that it returns the file name as a symbol, instead of a string.

Incomplete File Names

In general, it is not necessary to pass a complete file name (one containing all the fields listed above) to functions that take a file name as argument. Interlisp supplies suitable defaults for certain fields, as described below. Functions that return names of actual files, however, always return the fully specified name.
If the version field is omitted from a file name, Interlisp performs version recognition, as described below.

If the host, device and/or directory field are omitted from a file name, Interlisp defaults them with respect to the currently connected directory. The connected directory is changed by calling the function CNDIR or using the programmer's assistant command CONN.

Defaults are added to the partially specified name "left to right" until a host, device or directory field is encountered. Thus, if the connected directory is \{TWENTY\}PS:<FRED>, then

```
B AR.DCOM  means  
\{TWENTY\}PS:<FRED>B AR.DCOM
<GRANOLA>BAR.DCOM  means  
\{TWENTY\}PS:<GRANOLA>B AR.DCOM
MTAO:<GRANOLA>BAR.DCOM  means  
\{TWENTY\}MTAO:<GRANOLA>B AR.DCOM
{THIRTY}<GRANOLA>BAR.DCOM  means  
{THIRTY}<GRANOLA>B AR.DCOM
```

In addition, if the partially specified name contains a subdirectory, but no principal directory, then the subdirectory is appended to the connected directory. For example,

```
ISO>B AR.DCOM  means  
\{TWENTY\}PS:<FRED>ISO>B AR.DCOM
```

Or, if the connected directory is the Unix directory \{UNX\}/usr/fred/, then iso/bar.dcom means \{UNX\}/usr/fred/iso/bar.dcom, but /other/bar.dcom means \{UNX\}/other/bar.dcom.

(CNDIR HOST/DIR)  [Function]

Connects to the directory HOST/DIR, which can either be a directory name or a full directory specification including host and/or device. If the specification includes just a host, and the host supports directories, the directory is defaulted to the value of (USERNAME); if the host is omitted, connection is made to another directory on the same host as before. If HOST/DIR is NIL, connects to the value of LOGINHOST/DIR.

CNDIR returns the full name of the now-connected directory. Causes an error, Non-existent directory, if HOST/DIR is not recognized as a valid directory.

Note that CNDIR does not necessarily require or provide any directory access privileges. Access privileges are checked when a file is opened.

CONN HOST/DIR  [Prog. Asst. Command]

Convenient command form of CNDIR for use at the executive. Connects to HOST/DIR, or to the value of LOGINHOST/DIR if HOST/DIR is omitted. This command is undoable—undoing it causes the system to connect to the previously connected directory.
LOGINHOST/DIR

[Variable]

CONN with no argument connects to the value of the variable LOGINHOST/DIR, initially (DSK), but usually reset in your greeting file (Chapter 12).

(DIRECTORYNAME DIRNAME STRPTR)

[Function]

If DIRNAME is T, returns the full specification of the currently connected directory. If DIRNAME is NIL, returns the "login" directory specification (the value of LOGINHOST/DIR). For any other value of DIRNAME, returns a full directory specification if DIRNAME designates an existing directory (satisfies DIRECTORYNAMEP), otherwise NIL.

If STRPTR is T, the value is returned as an atom, otherwise it is returned as a string.

DIRECTORYNAMEP DIRNAME HOSTNAME

[Function]

Returns T if DIRNAME is recognized as a valid directory on host HOSTNAME, or on the host of the currently connected directory if HOSTNAME is NIL. DIRNAME may be either a directory name or a full directory specification containing host and/or device as well.

If DIRNAME includes subdirectories, this function may or may not pass judgment on their validity. Some hosts support "true" subdirectories, distinct entities manipulable by the file system, while others only provide them as a syntactic convenience.

HOSTNAMEP NAME

[Function]

Returns T if NAME is recognized as a valid host or file device name at the moment HOSTNAMEP is called.

Version Recognition

Most of the file devices in Interlisp support file version numbers. That is, it is possible to have several files of the exact same name, differing only in their VERSION field, which is incremented for each new "version" of the file that is created. When a file name lacking a version number is presented to the file system, it is necessary to determine which version number is intended. This process is known as version recognition.

When OPENSTREAM opens a file for input and no version number is given, the highest existing version number is used. Similarly, when a file is opened for output and no version number is given, a new file is created with a version number one higher than the highest one currently in use with that file name. The version number defaulting for OPENSTREAM can be changed by specifying a different value for its RECOG argument, as described under FULLNAME, below.

Other functions that accept file names as arguments generally perform the default version recognition, which is newest version for existing files, or a new version if using the file name to create a new file. The one exception is DELFILE, which defaults to the oldest existing version of the file.
